The cranial nerves most often injured with TBI are the olfactory, optic, oculomotor, and trochlear nerves; the first and second branches of the trigeminal nerve; and the facial and auditory nerves. Anosmia and an apparent loss of taste (actually a loss of perception of aromatic flavors, with retained elementary taste perception) occur in ~10% of persons with serious head injuries, particularly from falls on the back of the head. This is the result of displacement of the brain and shearing of the fine olfactory nerve filaments that course through the cribriform bone. At least partial recovery of olfactory and gustatory function is expected, but if bilateral anosmia persists for several months, the prognosis is poor. Partial optic nerve injuries from closed trauma result in blurring of vision, central or paracentral scotomas, or sector defects. Direct orbital injury may cause short-lived blurred vision for close objects due to reversible iridoplegia. Diplopia limited to downward gaze and corrected when the head is tilted away from the side of the affected eye indicates trochlear (fourth nerve) nerve damage. It occurs frequently as an isolated problem after minor head injury or may develop for unknown reasons after a delay of several days. Facial nerve injury caused by a basilar fracture is present immediately in up to 3% of severe injuries; it may also be delayed for 5–7 days. Fractures through the petrous bone, particularly the less common transverse type, are liable to produce facial palsy. Delayed facial palsy occurring up to a week after injury, the mechanism of which is unknown, has a good prognosis. Injury to the eighth cranial nerve from a fracture of the petrous bone causes loss of hearing, vertigo, and nystagmus immediately after injury. Deafness from eighth nerve injury is rare and must be distinguished from blood in the middle ear or disruption of the middle ear ossicles. Dizziness, tinnitus, and high-tone hearing loss occur from cochlear concussion.

SEIZURES

Convulsions are surprisingly uncommon immediately after TBI, but a brief period of tonic extensor posturing or a few clonic movements of the limbs just after the moment of impact can occur. However, the cortical scars that evolve from contusions are highly epileptogenic and may later manifest as seizures, even after many months or years **(Chap. 425)**. The severity of injury roughly determines the risk of future seizures. It has been estimated that 17% of individuals with brain contusion, subdural hematoma, or prolonged LOC will develop a seizure disorder and that this risk extends for an indefinite period of time, whereas the risk is ≤2% after mild injury. The majority of convulsions in the latter group occur within 5 years of injury but may be delayed for decades. Penetrating injuries have a much higher rate of subsequent epilepsy.

CLINICAL SYNDROMES AND TREATMENT OF HEAD INJURY

CONCUSSION/MILD TBI

The patient who has briefly lost consciousness or been stunned after a minor head injury usually becomes fully alert and attentive within minutes but may complain of headache, dizziness, faintness, nausea, a single episode of emesis, difficulty with concentration, a brief amnestic period, or slight blurring of vision. This typical concussion syndrome has a good prognosis with little risk of subsequent deterioration. Children are particularly prone to drowsiness, vomiting, and irritability, symptoms that are sometimes delayed for several hours after apparently minor injuries. Vasovagal syncope that follows injury may cause undue concern. Generalized or frontal headache is common in the following days. It may be migrainous (throbbing and hemicranial) in nature or aching and bilateral. After several hours of observation, patients with minor injury may be accompanied home and observed for a day by a family member or friend, with written instructions to return if symptoms worsen.

Persistent severe headache and repeated vomiting in the context of normal alertness and no focal neurologic signs is usually benign, but CT should be obtained and a longer period of observation is appropriate. The decision to perform imaging tests also depends on clinical signs that indicate that the impact was severe (e.g., persistent confusion, repeated vomiting, palpable skull fracture); the presence of other serious bodily injuries, an underlying coagulopathy, or age >65 years; and on the degree of surveillance that can be anticipated after discharge. Guidelines have also indicated that older age (>65 years), two or more episodes of vomiting, >30 min of retrograde or persistent anterograde amnesia, seizure, and concurrent drug or alcohol intoxication are sensitive (but not specific) indicators of intracranial hemorrhage that justify CT scanning.

Though not incorporated into conventional clinical practice guidelines, growing evidence suggests that MRI improves sensitivity for detection of small intracranial hemorrhages and other lesions in mild TBI patients, particular among those with negative findings on CT. Specifically, intracranial abnormalities are fairly common on MRI (27%) in CT-negative patients. Further, acute MRI findings have prognostic utility in predicting recovery and outcome after mTBI/concussion (e.g., risk of functional impairment, time to return to activity).

Blood-based (serum and plasma) biomarkers of astrocyte damage/astrogliosis (glial fibrillary acidic protein [GFAP]) and neuronal injury (ubiquitin carboxy-terminal hydrolase L1 [UCHL1]) also hold promise in improving detection and outcome prediction across the full spectrum of TBI. With development of new rapid assay systems, these can now be used for real-time point-of-care assessment; GFAP in particular has high discriminant ability to detect intracranial abnormalities, as well as potential to differentiate CT+, CT–/MRI+, and CT–/MRI– patients. Similar to MRI, emerging biomarkers appear to have not only diagnostic but also prognostic utility in predicting the trajectory of recovery and functional impairments weeks and months after TBI.

SPORT-RELATED CONCUSSION

Based on its reported prevalence, acute effects, and fears over potential long-term neurologic consequences, sport-related concussion has become the focus of increasing concern from clinicians, researchers, sporting organizations, and athletes themselves. Concussion is a frequent injury in contact and collision sports (e.g., football, hockey, wrestling) at all levels of participation, including youth sports. Head injury associated with sport and recreational activity accounts for 45% of TBI-related emergency department visits in children age 17 years and under. Between 1997 to 2007, emergency department visits for 8- to 13-year-old children affected by concussion in organized team sports doubled, and increased by >200% in the 14- to 19-year-old group. Over the last decade, data from the Centers for Disease Control and Prevention indicate that this trend has reversed, with a 27% decrease in emergency department visits for sport- and recreation-related TBI in the United States between 2012 and 2018. Given that national and state surveillance systems continue to report increased sport-related concussion rates over the same time period, it could be inferred that diagnosis and management of sport-related concussion outside of the emergency department has increased.

The natural history of clinical recovery following sport-related concussion has been a subject of substantial ongoing research. In general, the findings on acute recovery are favorable. A 2003 report was the first to chart the continuous time course of acute recovery within several

days after concussion, indicating that >90% of athletes reported symptom recovery within 1 week. Several other prospective studies have since demonstrated that the overwhelming majority of athletes achieve a complete recovery in symptoms, cognitive functioning, postural stability, and other functional impairments over a period of 1–3 weeks following concussion.

In recent years, a paradigm shift toward a more rapid return to activity and a focus on rehabilitation has occurred. Specifically, while experts agree that initial rest post-injury is beneficial for recovery, extended inactivity beyond 5 days can be detrimental and increase risk for protracted recovery. Rather, active rehabilitation involving supervised subthreshold exercise has been shown to improve duration of symptoms and decrease risk of protracted recovery.

There are many anecdotal reports, however, of athletes who remain symptomatic or impaired on functional testing well beyond the window of recovery commonly reported in group studies. The greatest challenge arguably still facing sport medicine clinicians and public health experts is how to most effectively manage and reduce risk in this subset of athletes who do not follow the "typical" course of recovery. The precise frequency of athletes who do not follow the typical course of rapid, spontaneous recovery and instead exhibit prolonged postconcussive symptoms or other functional impairments after concussion remains unclear. Postinjury symptom burden is the most robust predictor of recovery and risk of prolonged symptoms. Preinjury mental health diagnosis and history of prior concussion are two factors that have been consistently identified as being associated with potential for prolonged recovery as well.

Following acute concussion, multimodal advanced neuroimaging has demonstrated a variety of changes, including decreased cerebral blood flow, increased global and local functional connectivity, and alterations in white matter microstructure reflecting axonal organization. In general, these metrics correlate with measures of injury severity, and resolution of these changes tends to parallel clinical recovery. However, a number of studies have shown that slight changes on advanced multimodal imaging can persist even after symptoms have fully resolved, supporting the concept that the "tail" of neurobiologic recovery may extend beyond the time course of apparent clinical recovery.

In the current absence of adequate data, a commonsense approach to athletic concussion has been to remove the individual from play immediately and avoid contact sports for at least several days after a mild injury, and for a longer period if there are more severe injuries or if there are protracted neurologic symptoms such as headache and difficulty concentrating. No individual should return to play unless all concussion-related symptoms have resolved and an assessment has been made by a health care professional who has experience with treatment of concussion. Validated symptom inventories, such as the Rivermead Post-Concussion Symptom Questionnaire **(Table 443-2)**, have been developed to aid clinicians with recording and quantifying the diverse range of physical, cognitive, and behavioral symptoms that can occur following concussion. In addition to characterizing the constellation of acute symptoms and their severity, symptom inventories can be beneficial to track the course and resolution of symptoms through recovery. Differentiating concussion-related symptoms from factors that may be also influencing endorsement (e.g., preinjury mood difficulties) is an important component of managing recovery from sport-related concussion. Once cleared, the individual can then begin a graduated program of increasing activity. Younger athletes are particularly likely to experience protracted concussive symptoms, and a slower return to play in this age group may be reasonable. These guidelines are designed in part to avoid a perpetuation of symptoms but also to prevent the rare *second-impact syndrome*, in which diffuse and fatal cerebral swelling follows a second minor head injury.

POSTCONCUSSIVE STATES

The *postconcussion syndrome* (PCS) refers to a state following mild TBI consisting of combinations of fatigue, dizziness, headache, and difficulty in concentration. Management is difficult and generally requires the identification and management of the specific problem or problems that are most troubling to the individual. A clear explanation and education around the symptoms that may follow concussion has been shown to reduce subsequent complaints. Care is taken to avoid prolonged use of drugs that produce dependence. Headache may initially be treated with acetaminophen and small doses of amitriptyline. Vestibular exercises **(Chap. 22)** and small doses of vestibular suppressants such as promethazine (Phenergan) may be helpful when dizziness is the main problem. Patients, who after mild or moderate injury have difficulty with memory or with complex cognitive tasks at work, may be reassured to know that these problems usually improve over several months, and a reduced workload or other accommodations may be prescribed in the interim.

TABLE 443-2 Review of Concussion Symptoms

PHYSICAL	COGNITIVE	BEHAVIORAL
Headaches	Forgetfulness or poor memory	Being irritable, easily angered
Dizziness	Poor concentration	Feeling depressed or tearful
Nausea and/or vomiting	Taking longer to think	Feeling frustrated or impatient
Noise sensitivity		Restlessness
Sleep disturbance		
Fatigue		
Blurred vision		
Light sensitivity		
Double vision		

Note: Items were adapted from the Rivermead Post-Concussion Symptom Questionnaire. Each item is rated on a 5-point Likert scale (0–4), as follows: 0 = Not experienced at all; 1 = No more of a problem now than preinjury; 2 = A mild problem; 3 = A moderate problem; 4 = A severe problem. Total scores can range from 0–64.

For the vast majority of individuals with mTBI, the symptoms of PCS subside and resolve within a few weeks of injury. For a subset of individuals with mTBI, however, complaints of postconcussion symptoms persist beyond the expectation derived from TBI severity markers. The term *postconcussion disorders* (PCDs) has been proposed for diagnostic use and to improve characterization of specific symptoms or types of sequelae following mTBI. These include neurologic, cognitive, behavioral, or somatic complaints that continue beyond the acute and subacute periods, becoming chronic and often operationalized as persisting beyond 3 months. Although the overall risk of developing PCD following mTBI is low, the frequency of mTBI patients who meet criteria for a diagnosis of PCD and present in a clinical setting is believed to be higher.

mTBI patients with PCD frequently present to the outpatient clinics of primary care physicians, physiatrists, or neurologists seeking relief for lingering PCD-related symptoms. While some patients will have already received an initial medical workup to rule out a more serious brain injury during the acute phase, many patients will have had no prior contact with health care specialists. A medical workup ordered in the outpatient setting for PCD-related complaints is typically unremarkable for any identifiable neurologic cause to account for the persisting symptoms reported by the patient. The development of uniform decision trees or "standard of care" treatment regimens for PCD-related symptoms has been limited by the diversity of symptoms that patients experience, even within mTBI subgroups that have sustained very similar injury patterns. While some patients experience somatic symptoms, others complain of subjective cognitive or behavioral changes. Symptom inventories (Table 443-2) can be helpful in documenting the broad range of these symptoms and serve as a metric for improvement following symptom-based treatment.

Active rehabilitation for the treatment of PCD involving subthreshold exercise has increased in popularity over recent years and has gained empirical support for its effectiveness as a useful intervention for protracted recovery.

PCD is not a unidimensional condition but rather an outcome influenced by diverse cognitive, emotional, medical, psychosocial, and motivational factors. Because of this complexity, treatments targeting

persistent and refractory PCD-related symptoms should be tailored to the needs and expectations of the individual patient, with referrals to specialists as needed for assistance with management of headache, neck and back pain, dizziness and vertigo, and other symptoms reported within the context of PCD. A comprehensive review of concussion- and PCD-related symptoms presented in Table 443-2 allows for development of an individualized approach that leverages currently available treatment for those sequelae that are most bothersome to the patient (e.g., vestibular rehabilitation therapy for vertigo, melatonin for sleep disturbance). Patients are frequently referred to behavioral health providers such as neuropsychologists, rehabilitation psychologists, health psychologists, and/or psychiatrists for a variety of reasons, but particularly when they are experiencing cognitive, emotional, or behavioral changes that accompany PCD. Patients with mood disorders (e.g., depression), anxiety disorders (e.g., posttraumatic stress disorder), or adjustment reactions may benefit from psychiatric consultation for appropriate medication trials or from time-limited psychotherapy such as cognitive behavioral therapy.

Due to the complexity of presentation and varying diagnostic criteria, there are limited studies regarding overall prognosis of PCD. However, treatment of PCD-related symptoms targeted to the individual's specific difficulties can improve functional outcomes and patient-rated quality of life. Further, collaborative care has been shown to improve outcomes among patients experiencing persistent postconcussion symptoms. These improved outcomes are likely due to a multidisciplinary team's ability to simultaneously address the diverse set of symptoms that can occur with PCD.

INJURY OF INTERMEDIATE SEVERITY

Patients who are not fully alert or have persistent confusion, behavioral changes, extreme dizziness, or focal neurologic signs such as hemiparesis should be admitted to the hospital and undergo a cerebral imaging study. A cerebral contusion or hematoma will usually be found. Common syndromes include: (1) delirium with a disinclination to be examined or moved, expletive speech, and resistance if disturbed (anterior temporal lobe contusions); (2) a quiet, disinterested, slowed mental state (abulia) alternating with irascibility (inferior frontal and frontopolar contusions); (3) a focal deficit such as aphasia or mild hemiparesis (due to subdural hematoma or convexity contusion or, less often, carotid artery dissection); (4) confusion and inattention, poor performance on simple mental tasks, and fluctuating orientation (associated with several types of injuries, including those described above, and with medial frontal contusions and interhemispheric subdural hematoma); (5) repetitive vomiting, nystagmus, drowsiness, and unsteadiness (labyrinthine concussion, but occasionally due to a posterior fossa subdural hematoma or vertebral artery dissection); and (6) diabetes insipidus (damage to the median eminence or pituitary stalk). Injuries of this degree can be complicated by drug or alcohol intoxication, and clinically inapparent cervical spine injury may be present. Blast injuries are often accompanied by rupture of the tympanic membranes.

After surgical removal of hematomas, patients in this category improve over weeks to months. During the first week, the state of alertness, memory, and other cognitive functions often fluctuate, and agitation and somnolence are common. Behavioral changes tend to be worse at night, as with many other encephalopathies, and may be treated with small doses of antipsychotic medications. Subtle abnormalities of attention, intellect, spontaneity, and memory return toward normal weeks or months after the injury, sometimes abruptly. However, the full extent of recovery may not be realized for several years. Persistent cognitive problems are discussed below.

SEVERE INJURY

Patients who are comatose from the moment of injury require immediate neurologic attention and resuscitation. After intubation, with care taken to immobilize the cervical spine, the depth of coma, pupillary size and reactivity, limb movements, and Babinski responses are assessed. As soon as vital functions permit and cervical spine x-rays and a CT scan have been obtained, the patient should be transported to a critical care unit. Hypoxia should be reversed, and normal saline used as the resuscitation fluid in preference to albumin. The finding of an epidural or subdural hematoma or large intracerebral hemorrhage is usually an indication for prompt surgery and intracranial decompression in an otherwise salvageable patient. Measurement of ICP with a ventricular catheter or fiberoptic device in order to guide treatment has been favored by many units but has not improved outcome. Similarly, induced hypothermia has shown no benefit. Hyperosmolar intravenous solutions are used in various regimens to limit intracranial pressure. Prophylactic antiepileptic medications are recommended for 7 days and should be discontinued unless there are multiple seizures postinjury. Management of raised ICP, a frequent feature of severe head injury, is discussed in **Chap. 307**.

Despite the improvement in mortality for severe TBI over the past few decades, a great deal of therapeutic nihilism persists in TBI. The common use of a 6-month outcome for TBI clinical studies reinforces this misconception. The recovery from severe TBI can take years. Furthermore, the ability to predict long-term outcome is limited and frequently incorrect. Best-practice guidelines recommend, in the absence of brain death, that aggressive therapy be instituted for at least 72 h in the acute injury period.

LONG-TERM OUTCOMES IN TBI

TBI (aggregated mild to severe) is associated with a 63–96% increased risk of all-cause dementia. The degree of risk for dementia ranges along the gradient of TBI severity (i.e., greatest risk among severe injuries). To date, investigations have less reliably established mTBI as a robust risk factor for dementia, likely due to methodologic heterogeneity (e.g., use of different diagnostic criteria, exposure misclassification, self-report vs. physician diagnoses of TBI or dementia). Though an identified risk factor for all-cause dementia, pathophysiologic and epidemiologic factors that underlie the association between TBI with risk of specific neurodegenerative pathologies and dementia-subtypes are not well understood. As a result, associations between TBI with clinical syndromes (e.g., Alzheimer's disease, Parkinson's disease, amyotrophic lateral sclerosis) or distinct neuropathologies (e.g., beta-amyloid, Lewy bodies, transactive response DNA-binding protein 43) have been inconsistently reported in the literature. In a large study involving clinical and neuropathologic data from three pooled prospective studies of community-based cohorts, a significant relationship was found between TBI with LOC >1 h and subsequent Parkinson's disease diagnosis, progression rate of parkinsonism, and Lewy body accumulation at postmortem examination.

There is some evidence that repeated mTBI or sport-related concussions, particularly among boxing and professional American football athletes, are associated with delayed and potentially progressive neurobehavioral changes. The brains of these patients display a characteristic deposition of tau protein in neurons located in the superficial cortical layers and perivascular regions, and particularly in the depths of sulci. This pattern has been defined as the pathognomonic lesion of *chronic traumatic encephalopathy* (CTE). A variety of neurodegenerative pathologies are commonly found in the presence of CTE, adding to the complexity of diagnosis. While staging criteria for this neuropathologic entity have yet to be established, a consensus meeting to define the neuropathologic criteria for CTE proposed an algorithm assessing CTE as "low" or "high" in severity. Overall, its contribution, if any, to late-life dementia and parkinsonism in former athletes, soldiers, or others who have sustained repeated concussive injuries is unknown.

Research criteria for the clinical diagnosis of CTE have been proposed, and include a range of cognitive and/or behavioral symptoms, including executive dysfunction, depression, insomnia, and behavioral dyscontrol. Multiple studies have suggested that these proposed criteria lack specificity (i.e., they are frequent in other conditions and non-CTE cases). As such, CTE remains a postmortem diagnosis. Advances in positron emission tomography (PET) have allowed for in vivo investigation of tau deposition. Significant correlations between greater years of football participation and greater standardized uptake value ratio (SUVR) of ^{18}F-flortaucipir (purportedly representative of tau deposition) in the bilateral superior frontal, bilateral medial temporal, and left

parietal regions have been reported. However, increased SUVR in these regions was not significantly associated with neuropsychologic and neuropsychiatric function. Taken together, further study is required to better refine the clinical and postmortem diagnostic criteria of CTE, enhance clinicopathologic correlation, and ultimately improve patient care and management. **CTE is also discussed in Chap. 424.**

444 Multiple Sclerosis

Bruce A. C. Cree, Stephen L. Hauser

MULTIPLE SCLEROSIS

Multiple sclerosis (MS) is an autoimmune disease of the central nervous system (CNS) characterized by chronic inflammation, demyelination, gliosis (plaques or scarring), and neuronal loss; the course can be relapsing or progressive. MS plaques typically develop at different times and in different CNS locations (i.e., MS is said to be disseminated in time and space). More than 900,000 individuals in the United States and millions of individuals worldwide are affected. The clinical course is extremely variable, ranging from a relatively benign condition to a rapidly evolving and incapacitating disease requiring profound lifestyle adjustments.

CLINICAL MANIFESTATIONS

The onset of MS may be abrupt or insidious. Symptoms may be severe or seem so trivial that a patient may not seek medical attention for months or years. Indeed, at autopsy, ~0.1% of individuals who were asymptomatic during life will be found, unexpectedly, to have pathologic evidence of MS. Similarly, an MRI scan obtained for an unrelated reason may show evidence of asymptomatic MS. Symptoms of MS are extremely varied and depend on the location and severity of lesions within the CNS **(Table 444-1)**. Examination often reveals evidence of neurologic dysfunction, often in asymptomatic locations. For example, a patient may present with symptoms in one leg but signs in both.

Sensory symptoms are varied and include both paresthesias (e.g., tingling, prickling sensations, formications, "pins and needles," or painful burning) and hypesthesia (e.g., reduced sensation, numbness, or a "dead" feeling). Unpleasant sensations (e.g., feelings that body parts are swollen, wet, raw, or tightly wrapped) are also common. Sensory impairment of the trunk and legs below a horizontal line on the torso (a sensory level) indicates that the spinal cord is the origin of the sensory disturbance. It is often accompanied by a bandlike sensation of tightness around the torso. Pain is a common symptom of MS, experienced by >50% of patients. Pain can occur anywhere on the body and can change locations over time.

TABLE 444-1 Initial Symptoms of Multiple Sclerosis (MS)

SYMPTOM	PERCENTAGE OF CASES	SYMPTOM	PERCENTAGE OF CASES
Sensory loss	37	Lhermitte	3
Optic neuritis	36	Pain	3
Weakness	35	Dementia	2
Paresthesias	24	Visual loss	2
Diplopia	15	Facial palsy	1
Ataxia	11	Impotence	1
Vertigo	6	Myokymia	1
Paroxysmal attacks	4	Epilepsy	1
Bladder	4	Falling	1

Source: Data from RJ Swingler, DA Compston: The morbidity of multiple sclerosis. Q J Med 83:325, 1992.

Optic neuritis (ON) presents as diminished visual acuity, dimness, or decreased color perception (desaturation) in the central field of vision. These symptoms can be mild or may progress to severe visual loss. Rarely, there is complete loss of light perception. Visual symptoms are generally monocular but may be bilateral. Periorbital pain (aggravated by eye movement) often precedes or accompanies the visual loss. An afferent pupillary defect **(Chap. 32)** is usually present. Fundoscopic examination may be normal or reveal optic disc swelling (papillitis). Pallor of the optic disc (optic atrophy) commonly follows ON. Uveitis is uncommon and should raise the possibility of alternative diagnoses such as sarcoidosis or lymphoma.

Weakness of the limbs may manifest as loss of strength, speed, or dexterity; as fatigue; or as a disturbance of gait. Exercise-induced weakness is a characteristic symptom of MS. The weakness is of the upper motor neuron type **(Chap. 24)** and is usually accompanied by other pyramidal signs such as spasticity, hyperreflexia, and Babinski signs. Occasionally, a tendon reflex may be lost (simulating a lower motor neuron lesion) if an MS lesion disrupts the afferent reflex fibers in the spinal cord **(see Fig. 24-2)**.

Facial weakness due to a lesion in the pons may resemble idiopathic Bell's palsy **(Chap. 441)**. Unlike Bell's palsy, facial weakness in MS is usually not associated with ipsilateral loss of taste sensation or retroauricular pain.

Spasticity **(Chap. 24)** is commonly associated with spontaneous and movement-induced muscle spasms. More than 30% of MS patients have moderate to severe spasticity, especially in the legs. This is often accompanied by painful spasms interfering with ambulation, work, or self-care. Occasionally, spasticity provides support for the body weight during ambulation, and in these cases, treatment of spasticity may actually do more harm than good.

Visual blurring in MS may result from ON or diplopia (double vision); if the symptom resolves when either eye is covered, the cause is diplopia. *Diplopia* may be caused by internuclear ophthalmoplegia (INO) or palsy of the sixth cranial nerve (rarely the third or fourth). An INO consists of impaired adduction of one eye due to a lesion in the ipsilateral medial longitudinal fasciculus **(Chaps. 32 and V3)**. Prominent nystagmus is often observed in the abducting eye, along with a small skew deviation. A bilateral INO is particularly suggestive of MS. Other common gaze disturbances in MS include (1) a horizontal gaze palsy, (2) a "one and a half" syndrome (horizontal gaze palsy plus an INO), and (3) acquired pendular nystagmus.

Ataxia usually manifests as cerebellar tremors **(Chap. 439)**. Ataxia may also involve the head and trunk or the voice, producing a characteristic cerebellar dysarthria (scanning speech).

Vertigo may appear suddenly from a brainstem lesion, superficially resembling acute labyrinthitis **(Chap. 22)**. *Hearing loss* **(Chap. 34)** may also occur in MS but is uncommon.

ANCILLARY SYMPTOMS

Paroxysmal symptoms are distinguished by their brief duration (10 s to 2 min), high frequency (5–40 episodes per day), lack of any alteration of consciousness or change in background electroencephalogram during episodes, and a self-limited course (generally lasting weeks to months). They may be precipitated by hyperventilation or movement. These syndromes may include Lhermitte's symptom; tonic contractions of a limb, face, or trunk (tonic seizures); paroxysmal dysarthria and ataxia; paroxysmal sensory disturbances; and several other less well-characterized syndromes. Paroxysmal symptoms probably result from spontaneous discharges, arising at the edges of demyelinated plaques and spreading to adjacent white matter tracts.

Lhermitte's symptom is an electric shock–like sensation (typically induced by flexion or other movements of the neck) that radiates down the back into the legs. Rarely, it radiates into the arms. It is generally self-limited but may persist for years. Lhermitte's symptom can also occur with other disorders of the cervical spinal cord (e.g., cervical spondylosis).

Trigeminal neuralgia, hemifacial spasm, and glossopharyngeal neuralgia **(Chap. 441)** can occur when the demyelinating lesion involves the root entry (or exit) zone of the fifth, seventh, and ninth cranial nerve, respectively. Trigeminal neuralgia (tic douloureux) is a very brief lancinating facial pain often triggered by an afferent input from the face or teeth. Most cases of trigeminal neuralgia are not MS related; however, atypical features such as onset before age 50 years, bilateral symptoms, objective sensory loss, or nonparoxysmal pain should raise the possibility that MS could be responsible.

Facial myokymia consists of either persistent rapid flickering contractions of the facial musculature (especially the lower portion of the orbicularis oculus) or a contraction that slowly spreads across the face. It results from lesions of the corticobulbar tracts or brainstem course of the facial nerve.

Heat sensitivity refers to neurologic symptoms produced by an elevation of the body's core temperature. For example, unilateral visual blurring may occur during a hot shower or with physical exercise (*Uhthoff's symptom*). It is also common for MS symptoms to worsen transiently, sometimes dramatically, during febrile illnesses. Such heat-related symptoms probably result from transient conduction block.

Bladder dysfunction is present in >90% of MS patients, and in one-third of patients, dysfunction results in weekly or more frequent episodes of incontinence. During normal reflex voiding, relaxation of the bladder sphincter (α-adrenergic innervation) is coordinated with contraction of the detrusor muscle in the bladder wall (muscarinic cholinergic innervation). *Detrusor hyperreflexia*, due to impairment of suprasegmental inhibition, causes urinary frequency, urgency, nocturia, and uncontrolled bladder emptying. *Detrusor sphincter dyssynergia*, due to loss of synchronization between detrusor and sphincter muscles, causes difficulty in initiating and/or stopping the urinary stream, producing hesitancy, urinary retention, overflow incontinence, and recurrent infection.

Constipation occurs in >30% of patients. Fecal urgency or *bowel incontinence* is less common (<15%) but can be socially debilitating.

Sexual dysfunction may manifest as decreased libido, impaired genital sensation, impotence in men, and diminished vaginal lubrication or adductor spasms in women.

Cognitive dysfunction can include memory loss; impaired attention; difficulties in executive functioning, memory, and problem solving; slowed information processing; and problems shifting between cognitive tasks. Euphoria (elevated mood) was once thought to be characteristic of MS but is actually uncommon, occurring in <20% of patients. Cognitive dysfunction sufficient to impair activities of daily living is rare.

Depression, experienced by approximately half of patients, can be reactive, endogenous, or part of the illness itself and can contribute to fatigue.

Fatigue **(Chap. 23)** is experienced by 90% of patients; this symptom is the most common reason for work-related disability in MS. Fatigue can be exacerbated by elevated temperatures, depression, expending exceptional effort to accomplish basic activities of daily living, or sleep disturbances (e.g., from frequent nocturnal awakenings to urinate).

DISEASE COURSE

Three clinical types of MS exist **(Fig. 444-1)**:

1. *Relapsing or bout onset MS* (RMS) accounts for 90% of MS cases and is characterized by discrete attacks of neurologic dysfunction that generally evolve over days to weeks (rarely over hours). With initial attacks, there is often substantial or complete recovery over the ensuing weeks to months. However, as attacks continue, recovery may be less evident **(Fig. 444-1*A*)**. Between attacks, patients were traditionally thought to be neurologically stable; however it is now clear that many patients with RMS experience subtle "silent" progression even when relapse-free.
2. *Secondary progressive MS* (SPMS) always begins as RMS **(Fig. 444-1*B*)**. At some point, however, the clinical course changes so that the patient experiences progressive deterioration in function unassociated with acute attacks. SPMS produces a greater amount of fixed neurologic disability than RMS. For a patient with RMS, the risk of developing SPMS was approximately 3% each year in the pretreatment era, meaning that the great majority of RMS would ultimately evolve into SPMS. However, recent case series have indicated a much lower rate of evolution to SPMS, estimated at slightly >1% each year, likely due to widespread use of effective therapies for MS.
3. *Primary progressive MS* (PPMS) accounts for ~10% of cases. These patients do not experience attacks but rather steadily decline in function from disease onset **(Fig. 444-1*C*)**. Compared to RMS, the sex distribution is more even, the disease begins later in life (mean age ~40 years), and disability develops faster (relative to the onset of the first clinical symptom). Despite these differences, PPMS appears to represent the same underlying illness as RMS.

Progressive MS and Disease Activity Patients with SPMS or even PPMS will occasionally experience relapses, albeit less often than in RMS. Progressive MS patients experiencing relapses or who are found to have acute new lesions on MRI are considered to have "active" progressive MS.

EPIDEMIOLOGY

MS is approximately threefold more common in women than men. The age of onset is typically between 20 and 40 years (slightly later in men than in women), but the disease can present across the lifespan. Approximately 10% of cases begin before the age of 18 years, and a small percentage of cases begin before the age of 10 years.

Geographic gradients are observed in MS, with the highest known prevalence for MS (250 per 100,000) in the Orkney Islands, located north of Scotland. In other temperate zone areas (e.g., northern

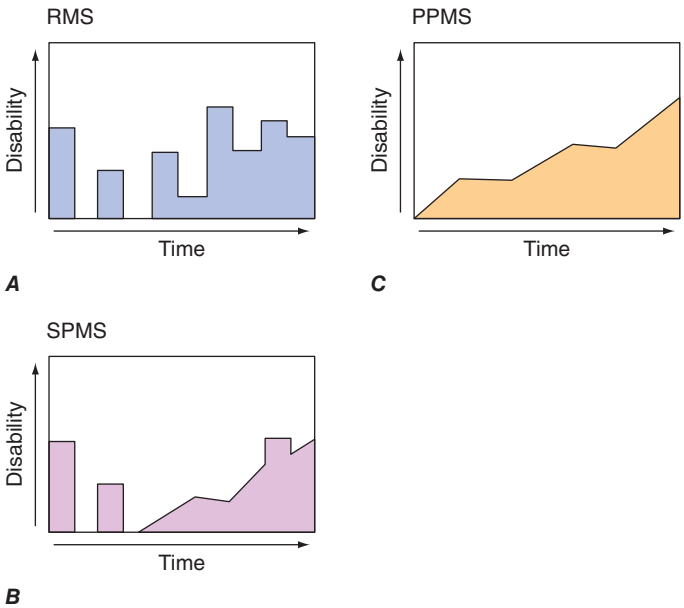

FIGURE 444-1 Clinical course of multiple sclerosis (MS). ***A.*** Relapsing MS (RMS). ***B.*** Secondary progressive MS (SPMS). ***C.*** Primary progressive MS (PPMS).

North America, northern Europe, southern Australia, and southern New Zealand), the prevalence of MS is 0.1–0.2%. By contrast, in the tropics (e.g., Asia, equatorial Africa, and the Middle East), the prevalence is often tenfold to twentyfold less.

The prevalence of MS has increased steadily (and dramatically) in several regions around the world over the past half-century, presumably reflecting the impact of some environmental shift. Moreover, the fact that this increase appears to have occurred primarily in women indicates that women are more responsive to this environmental change.

Well-established risk factors for MS include a genetic predisposition, vitamin D deficiency, Epstein-Barr virus (EBV) exposure after early childhood, and cigarette smoking.

Vitamin D deficiency is associated with an increase in MS risk, and data suggest that ongoing deficiency also increases disease activity after MS begins. Immunoregulatory effects of vitamin D could explain these apparent relationships. Exposure of the skin to ultraviolet-B (UVB) radiation from the sun is essential for the biosynthesis of vitamin D, and this endogenous production is the most important source of vitamin D in most individuals. A diet rich in fatty fish represents another source of vitamin D. At high latitudes, the amount of UVB radiation reaching the earth's surface is often insufficient, particularly during winter months, and consequently, low serum levels of vitamin D are common in temperate zones. The common practice to avoid direct sun exposure and the widespread use of sunblock would be expected to exacerbate any population-wide vitamin D deficiency (sun protection factor [SPF] 15 blocks 94% of incoming UVB radiation).

Evidence of a remote EBV infection playing some role in MS is supported by numerous epidemiologic and laboratory studies. A higher risk of infectious mononucleosis (associated with relatively late EBV infection) and higher antibody titers to latency-associated EBV nuclear antigen have been repeatedly associated with MS risk, although a causal role for EBV is not established.

A history of cigarette smoking also is associated with MS risk. Interestingly, in an animal model of MS, the lung was identified as a critical site for activation of pathogenic T lymphocytes responsible for autoimmune demyelination.

GENETIC CONSIDERATIONS

Whites are inherently at higher risk for MS than Africans or Asians, even when residing in a similar environment. Recent studies in the United States, however, have shown that MS risk in persons of African descent is as high, and possibly higher, than in whites. MS also aggregates within some families, and adoption, half-sibling, twin, and spousal studies indicate that familial aggregation is primarily due to genetic factors. Nonetheless, family studies also support a contribution of environment, as fraternal twins of MS patients are at higher risk than nontwin siblings **(Table 444-2)**.

Susceptibility to MS is polygenic, with each gene contributing a relatively small amount to the overall risk. The strongest susceptibility signal genome-wide maps to the human leukocyte antigen (HLA)-DRB1 gene in the class II region of the major histocompatibility complex (MHC) and specifically to HLA-DR15 (formerly designated DR2), and this association accounts for ~10% of the disease risk. This HLA association, first described in the early 1970s, suggests that MS, at its core, is an autoimmune disease. Whole-genome association studies have now identified ~230 other MS susceptibility variants, each of which individually has only a very small effect on MS risk. Many of these MS-associated genes have known roles in the adaptive and innate immune system, for example the genes for the interleukin (IL) 7 receptor (CD127), IL-2 receptor (CD25), and T-cell costimulatory molecule LFA-3 (CD58); some variants also influence susceptibility to other autoimmune diseases in addition to MS. The variants identified so far all lack specificity and sensitivity for MS; thus, at present, they are not useful for diagnosis or prediction of the future disease course.

TABLE 444-2 Risk of Developing Multiple Sclerosis (MS)

1 in 3	If an identical twin has MS
1 in 15	If a fraternal twin has MS
1 in 25	If a sibling has MS
1 in 50	If a parent or half-sibling has MS
1 in 100	If a first cousin has MS
1 in 1000	If a spouse has MS
1 in 1000	If no one in the family has MS

PATHOGENESIS

PATHOLOGY

Demyelination New MS lesions begin with perivenular cuffing by inflammatory mononuclear cells, predominantly T cells and macrophages, which also infiltrate the surrounding white matter. At sites of inflammation, the blood-brain barrier (BBB) is disrupted, but unlike in vasculitis, the vessel wall is preserved. At the leading edge of lesions, large numbers of cytotoxic CD8 cells are found. Involvement of the humoral immune system is also evident; small numbers of B lymphocytes infiltrate the nervous system, myelin-specific autoantibodies are present on degenerating myelin sheaths, and complement is activated.

Sharply demarcated areas of demyelination are the pathologic hallmark of MS lesions, and evidence of myelin degeneration is found at the earliest time points of tissue injury. Although relative sparing of axons is typical, partial or total axonal destruction can also occur, especially within highly inflammatory lesions. In some lesions, surviving oligodendrocytes or those that differentiate from precursor cells partially remyelinate the surviving axons, producing so-called *shadow plaques*. However, in many lesions oligodendrocyte precursor cells are present but they fail to differentiate into mature myelin-producing cells. Therefore, promoting remyelination to protect axons remains an important therapeutic goal. As lesions evolve, there is prominent astrocytic proliferation (gliosis) and the term *sclerosis* refers to these gliotic plaques that have a rubbery or hardened texture at autopsy.

Neurodegeneration Cumulative axonal and neuronal loss is the most important contributor to irreversible neurologic disability and progressive symptoms. With paraplegia due to MS, as many as 70% of axons are ultimately lost from the lateral corticospinal (e.g., motor) tracts. Demyelination can reduce trophic support for axons, redistribute ion channels, and destabilize action potential membrane potentials. Axons can adapt initially to these injuries, but over time distal and retrograde degeneration ("dying-back" axonopathy) occurs.

Multiple pathologies appear to contribute to progressive symptoms in longstanding MS. *Chronic active plaques* are preexisting white matter lesions that show evidence of persistent inflammation, progressive axonal loss, and gradual concentric expansion, with large numbers of microglial cells at the leading edge of enlarging lesions but without BBB disruption. Recent studies have also highlighted the importance of a primary injury to the cerebral cortex. Cortical plaques are frequent in MS but are generally not well visualized by MRI; these can extend upward from adjacent white matter lesions, or may be located within the cortex or underneath the pia. *Ectopic lymphoid follicles* are aggregates of B, T, and plasma cells located in the superficial meninges, especially overlying deep cortical sulci; similar clusters are also present in perivascular spaces. Ectopic lymphoid follicles are topographically associated with underlying demyelination and neuronal loss in the cerebral cortex, and diffusible factors from these lymphoid cells are believed to mediate subpial cortical demyelination and neurodegeneration. Neuronal and axonal death may result from glutamate-mediated excitotoxicity, oxidative injury, iron accumulation, and/or mitochondrial failure.

In relapsing MS, inflammation is associated with focal perivenular parenchymal infiltration of lymphocytes and monocytes associated with BBB disruption and active demyelination. By contrast, inflammation in progressive MS is more diffuse and is characterized by widespread microglial activation across large areas of white matter, associated with reduced myelin staining and axonal injury ("dirty white matter"). Activated astrocytes induced by microglia may also contribute to tissue damage **(Chap. 425)**. These observations imply

that ongoing inflammation occurs behind an intact BBB in many patients with progressive MS, and this feature could explain the failure of immunotherapies not capable of crossing the BBB to benefit patients with progressive MS.

PHYSIOLOGY

Nerve conduction in myelinated axons occurs in a saltatory manner, with the nerve impulse jumping from one node of Ranvier to the next without depolarization of the axonal membrane underlying the myelin sheath between nodes (Fig. 444-2). This produces faster conduction velocities (~70 m/s) than the slow velocities (~1 m/s) produced by continuous propagation in unmyelinated nerves. Conduction block occurs when the nerve impulse is unable to traverse the demyelinated segment. This can happen when the resting axon membrane becomes hyperpolarized due to exposure of voltage-dependent potassium channels that are normally buried underneath the myelin sheath. A temporary conduction block often follows a demyelinating event before sodium channels (originally concentrated at the nodes) redistribute along the naked axon (Fig. 444-2). This redistribution ultimately allows continuous propagation of nerve action potentials through the demyelinated segment. Conduction block may be incomplete, affecting high- but not low-frequency volleys of impulses. Variable conduction block can occur with raised body temperature or metabolic alterations and may explain clinical fluctuations that vary from hour to hour or appear with fever or exercise. Conduction slowing occurs when the demyelinated segments of the axonal membrane are reorganized to support continuous (slow) nerve impulse propagation.

IMMUNOLOGY

A proinflammatory autoimmune response directed against a component of CNS myelin, and perhaps other neural elements as well, remains the cornerstone of current concepts of MS pathogenesis.

AUTOREACTIVE T LYMPHOCYTES

Myelin basic protein (MBP), an intracellular protein involved in myelin compaction, is an important T-cell antigen in experimental allergic encephalomyelitis (EAE), a laboratory model, and possibly also in human MS. Activated MBP-reactive T cells have been identified in the blood, in cerebrospinal fluid (CSF), and within MS lesions. The MS associated HLA-DR15 protein binds with high affinity to a fragment of MBP (spanning amino acids 89–96), potentially stimulating T-cell responses to this self-protein. Several different populations of proinflammatory T cells are likely to mediate autoimmunity in MS. T-helper type 1 (T_H1) cells producing interferon γ (IFN-γ) are one key effector population; T_H1 cytokines, including IL-2, tumor necrosis factor (TNF)-α, and IFN-γ, also play key roles in activating and maintaining autoimmune responses, and TNF-α and IFN-γ may directly injure oligodendrocytes or the myelin membrane. As noted above, CD8 cytotoxic T cells are present at the active edges of expanding MS lesions, and activated CD8 cells also appear to be enriched for reactivity against myelin antigens in MS patients.

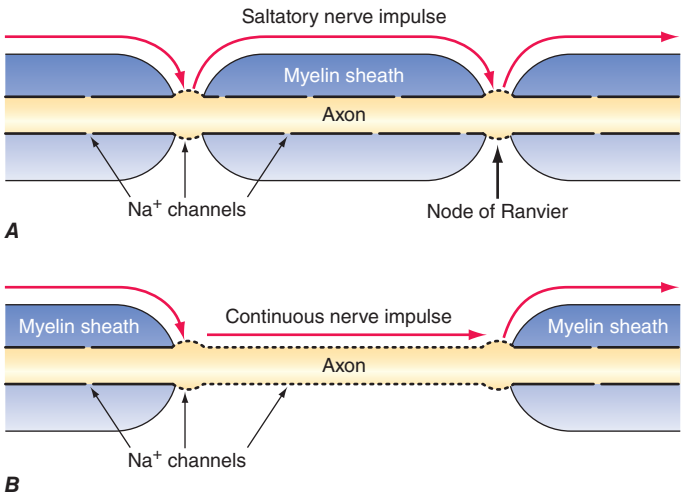

FIGURE 444-2 Nerve conduction in myelinated and demyelinated axons. ***A.*** Saltatory nerve conduction in myelinated axons occurs with the nerve impulse jumping from one node of Ranvier to the next. Sodium channels (*shown as breaks in the solid black line*) are concentrated at the nodes where axonal depolarization occurs. ***B.*** Following demyelination, additional sodium channels are redistributed along the axon itself, thereby allowing continuous propagation of the nerve action potential despite the absence of myelin.

HUMORAL AUTOIMMUNITY

B-cell activation and antibody responses are centrally involved in the development of demyelinating lesions, as evidenced by the efficacy of B cell–based treatments in all forms of MS (see "Treatment" below). Clonally restricted populations of activated, antigen-experienced, memory B cells and plasma cells are present in MS lesions, in meningeal lymphoid follicle-like structures overlying the cerebral cortex, and in the CSF. Similar populations are found in each compartment, indicating that a highly focused B-cell response occurs locally within the CNS. Myelin-specific autoantibodies, some directed against an extracellular myelin protein, myelin oligodendrocyte glycoprotein (MOG), have been detected bound to vesiculated myelin debris in MS plaques. In the CSF, elevated levels of locally synthesized immunoglobulins and oligoclonal antibodies, derived from clonally restricted CNS B cells and plasma cells, are also characteristic of MS. The pattern of oligoclonal banding is unique to each individual, and attempts to identify the targets of these antibodies have been largely unsuccessful; they appear to recognize a diverse array of antigens including intracellular ubiquitous proteins. Therefore, although intrathecal oligoclonal antibodies and elevated intrathecal synthesis of immunoglobulins are characteristic of MS, their role in disease pathogenesis remains uncertain.

Recent data suggest that the antigen presenting cell (APC) function of B cells may explain their role in MS pathogenesis. Remarkably, fragments of self-peptides derived from HLA-DR2 proteins themselves were found to bind intact DR2 molecules on B cells and serve as antigens for presentation to T cells. Memory CD4+ T cells derived from CSF responded to these self-peptides bound to DR2 molecules and, in some cases, these self-peptides were cross-reactive with myelin antigens, RAS guanyl-releasing protein 2 (RASGRP2) previously found to be a possible T-cell autoantigen in MS, EBV, and Akkermansia muciniphila, a commensal gut bacterium associated with dysbiosis in MS patients. Thus, the MS-associated HLA proteins contain fragments that might trigger autoimmunity through molecular mimicry with viral, bacterial, or cell-surface autoantigens.

DIAGNOSIS

There is no single diagnostic test for MS. Diagnostic criteria for clinically definite MS require documentation of two or more episodes of symptoms and two or more signs that reflect pathology in anatomically noncontiguous white matter tracts of the CNS (Table 444-3). Symptoms must last for >24 h and occur as distinct episodes that are separated by a month or more. In patients who have only one of the two required signs on neurologic examination, the second may be documented by abnormal tests such as MRI or evoked potentials (EPs). Similarly, in the most recent diagnostic scheme, the second clinical event (in time) may be supported solely by MRI findings, consisting of either the development of new focal white matter lesions on MRI or the simultaneous presence of both an enhancing lesion and a nonenhancing lesion in an asymptomatic location. In patients whose course is progressive from onset for ≥6 months without superimposed relapses, documentation of intrathecal IgG synthesis may be used to support a diagnosis of PPMS.

DIAGNOSTIC TESTS

MAGNETIC RESONANCE IMAGING

MRI has revolutionized the diagnosis and management of MS (Fig. 444-3); characteristic abnormalities are found in >95% of patients, although >90% of the lesions visualized by MRI are asymptomatic. An increase in vascular permeability from a breakdown of the BBB is detected by leakage of intravenous gadolinium (Gd) into

TABLE 444-3 Diagnostic Criteria for Multiple Sclerosis (MS)

CLINICAL PRESENTATION	ADDITIONAL DATA NEEDED FOR MS DIAGNOSIS
2 or more attacks; objective clinical evidence of 2 or more lesions or objective clinical evidence of 1 lesion with reasonable historical evidence of a prior attack	None
2 or more attacks; objective clinical evidence of 1 lesion	Dissemination in space, demonstrated by ≥1 T2 lesion on MRI in at least 2 out of 4 MS-typical regions of the CNS (periventricular, juxtacortical, infratentorial, or spinal cord) OR • Await a further clinical attack implicating a different CNS site
1 attack; objective clinical evidence of 2 or more lesions	Dissemination in time, demonstrated by • Simultaneous presence of asymptomatic gadolinium-enhancing and nonenhancing lesions at any time OR • A new T2 and/or gadolinium-enhancing lesion(s) on follow-up MRI, irrespective of its timing with reference to a baseline scan OR • Await a second clinical attack
1 attack; objective clinical evidence of 1 lesion (clinically isolated syndrome)	Dissemination in space and time, demonstrated by: For dissemination in space • ≥1 T2 lesion in at least 2 out of 4 MS-typical regions of the CNS (periventricular, juxtacortical, infratentorial, or spinal cord) OR • Await a second clinical attack implicating a different CNS site AND • For dissemination in time • Simultaneous presence of asymptomatic gadolinium-enhancing and nonenhancing lesions at any time OR • A new T2 and/or gadolinium-enhancing lesion(s) on follow-up MRI, irrespective of its timing with reference to a baseline scan OR • Await a second clinical attack
Insidious neurologic progression suggestive of MS (PPMS)	1 year of disease progression (retrospectively or prospectively determined) PLUS 2 out of the 3 following criteria: • Evidence for dissemination in space in the brain based on ≥1 T2+ lesions in the MS-characteristic periventricular, juxtacortical, or infratentorial regions • Evidence for dissemination in space in the spinal cord based on ≥2 T2+ lesions in the cord • Positive CSF (isoelectric focusing evidence of oligoclonal bands and/or elevated IgG index)

Abbreviations: CNS, central nervous system; CSF, cerebrospinal fluid; MRI, magnetic resonance imaging; PPMS, primary progressive multiple sclerosis.

the parenchyma. Such leakage occurs early in the development of an MS lesion and serves as a useful marker of inflammation. Gd enhancement typically persists for <1 month, and the residual MS plaque remains visible indefinitely as a focal area of hyperintensity (a lesion) on T2-weighted images. Lesions are frequently oriented perpendicular to the ventricular surface, corresponding to the pathologic pattern of perivenous demyelination (Dawson's fingers). Lesions are multifocal within the brain, brainstem, and spinal cord. Lesions >6 mm located in the corpus callosum, periventricular white matter, brainstem, cerebellum, or spinal cord are particularly helpful diagnostically. Current criteria for the use of MRI in the diagnosis of MS are shown in Table 444-3.

Serial MRI studies in early relapsing-remitting MS reveal that bursts of focal inflammatory disease activity occur far more frequently than would have been predicted by the frequency of relapses. Thus, early in MS, most disease activity is clinically silent.

The total volume of T2-weighted signal abnormality (the "burden of disease") shows a significant (albeit weak) correlation with clinical disability. Quantitative measures of brain and spinal cord atrophy are evidence of diffuse tissue injury and correlate more strongly with measures of disability or progressive MS. Serial MRI studies also indicate that progressive whole-brain atrophy occurs even in very early MS and continues throughout the disease course. Approximately one-third of T2-weighted lesions appear as hypointense lesions (black holes) on T1-weighted imaging. Black holes may be a marker of irreversible demyelination and axonal loss, although even this measure depends on the timing of the image acquisition (e.g., most acute Gd-enhancing T2 lesions are T1 dark).

EVOKED POTENTIALS

EP testing assesses function in afferent (visual, auditory, and somatosensory) or efferent (motor) CNS pathways. EPs use computer averaging to measure CNS electric potentials evoked by repetitive stimulation of selected peripheral nerves or of the brain. These tests provide the most information when the pathways studied are clinically uninvolved. For example, in a patient with a relapsing spinal cord syndrome with sensory deficits in the legs, an abnormal somatosensory EP following posterior tibial nerve stimulation provides little new information. By contrast, an abnormal visual EP in this circumstance would permit a diagnosis of clinically definite MS (Table 444-3). Abnormalities on one or more EP modalities occur in 80–90% of MS patients. EP abnormalities are not specific to MS, although a marked delay in the latency of a specific EP component (as opposed to a reduced amplitude or distorted wave-shape) is suggestive of demyelination.

CEREBROSPINAL FLUID

CSF abnormalities found in MS include a mononuclear cell pleocytosis and an increased level of intrathecally synthesized IgG. The total CSF protein is usually normal or mildly elevated. Various formulas distinguish intrathecally synthesized IgG from IgG that entered the CNS passively from the serum. The CSF IgG index expresses the ratio of IgG to albumin in the CSF divided by the same ratio in the serum. The IgG synthesis rate uses serum and CSF IgG and albumin measurements to calculate the rate of CNS IgG synthesis. The measurement of oligoclonal bands (OCBs) by agarose gel electrophoresis in the CSF also assesses intrathecal production of IgG. Two or more discrete OCBs, not present in a paired serum sample, are found in >90% of patients with MS. OCBs may be absent at the onset of MS, and in individual patients, the number of bands may increase with time.

A mild CSF pleocytosis (>5 cells/μL) is present in ~25% of cases, usually in young patients with RMS. A pleocytosis of >75 cells/μL, the presence of polymorphonuclear leukocytes, or a protein concentration >1 g/L (>100 mg/dL) in CSF should raise concern that the patient may not have MS.

DIFFERENTIAL DIAGNOSIS

The possibility of an alternative diagnosis should always be considered **(Table 444-4)**, particularly when (1) symptoms are localized exclusively to the posterior fossa, craniocervical junction, or spinal cord; (2) the patient is <15 or >60 years of age; (3) the clinical course is progressive from onset; (4) the patient has never experienced visual, sensory, or bladder symptoms; or (5) laboratory findings (e.g., MRI, CSF, or EPs) are atypical. Similarly, uncommon or rare symptoms in MS (e.g., aphasia, parkinsonism, chorea, isolated dementia, severe muscular atrophy, peripheral neuropathy, episodic loss of consciousness, fever, headache, seizures, or coma) should increase concern

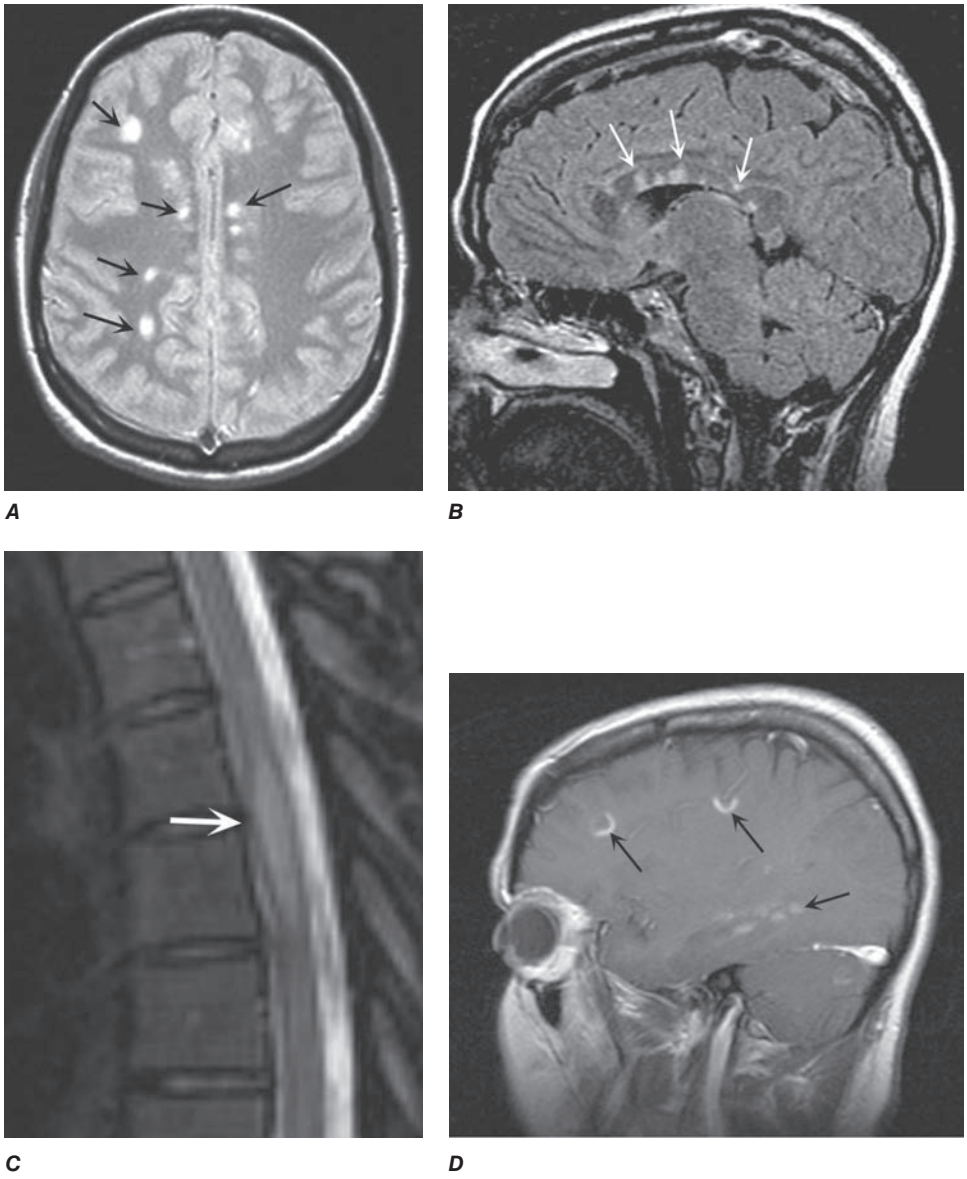

FIGURE 444-3 Magnetic resonance imaging findings in multiple sclerosis (MS). ***A.*** Axial first-echo image from T2-weighted sequence demonstrates multiple bright signal abnormalities in white matter, typical for MS. ***B.*** Sagittal T2-weighted fluid-attenuated inversion recovery (FLAIR) image in which the high signal of cerebrospinal fluid (CSF) has been suppressed. CSF appears dark, whereas areas of brain edema or demyelination appear high in signal, as shown here in the corpus callosum (*arrows*). Lesions in the anterior corpus callosum are frequent in MS and rare in vascular disease. ***C.*** Sagittal T2-weighted fast spin echo image of the thoracic spine demonstrates a fusiform high-signal-intensity lesion in the midthoracic spinal cord. ***D.*** Sagittal T1-weighted image obtained after the intravenous administration of gadolinium DTPA reveals focal areas of blood-brain barrier disruption, identified as high-signal-intensity regions (*arrows*).

about an alternative diagnosis. Diagnosis is also difficult in patients with a rapid or explosive (strokelike) onset or with mild symptoms and a normal neurologic examination. Rarely, intense inflammation and swelling may produce a mass lesion that mimics a primary or metastatic tumor. Disorders possibly mistaken for MS include: neuromyelitis optica **(Chap. 437)**, sarcoidosis, vascular disorders (antiphospholipid syndrome and vasculitis), rarely CNS lymphoma, and still more rarely infections such as syphilis or Lyme disease. The specific tests required to exclude alternative diagnoses will vary with each clinical situation; however, an erythrocyte sedimentation rate, serum B_{12} level, antinuclear antibodies, and treponemal antibody should probably be obtained in all patients with suspected MS.

PROGNOSIS

Historically, most patients with MS ultimately experienced progressive neurologic disability. In older studies conducted before disease-modifying therapies for MS were available, 15 years after onset, only 20% of patients had no functional limitation, and between one-third and one-half of RMS patients progressed to SPMS and required assistance with ambulation; furthermore, 25 years after onset, ~80% of MS patients reached this level of disability. The long-term prognosis for MS has improved substantially in recent years, and transition from RMS to SPMS now occurs at approximately a 1% annual rate compared with 2–3% in the pretreatment era. This improvement is almost certainly due, at least in part, to widespread use of disease-modifying therapies for RMS, and it is hoped that the prognosis will continue to improve as highly efficacious agents are increasingly employed early in the disease course.

Although the prognosis in an individual is difficult to establish, certain clinical features suggest a more favorable prognosis. These include ON or sensory symptoms at onset; fewer than two relapses in the first year of illness; and minimal impairment after 5 years. Predictors of an early aggressive course of the illness include older age at symptom onset and greater disability and the appearance of motor signs during the first year of the illness. By contrast, patients with truncal ataxia, action tremor, pyramidal symptoms, or a progressive disease course are more likely to become disabled. Patients with a long-term favorable course are likely to have developed fewer MRI lesions and have

TABLE 444-4 Disorders That Can Mimic Multiple Sclerosis (MS)

Acute disseminated encephalomyelitis (ADEM)
Antiphospholipid antibody syndrome
Behçet's disease
Cerebral autosomal-dominant arteriopathy, subcortical infarcts, and leukoencephalopathy (CADASIL)
Congenital leukodystrophies (e.g., adrenoleukodystrophy, metachromatic leukodystrophy)
Human immunodeficiency virus (HIV) infection
Ischemic optic neuropathy (arteritic and nonarteritic)
Lyme disease
Mitochondrial encephalopathy with lactic acidosis and stroke (MELAS)
Neoplasms (e.g., lymphoma, glioma, meningioma)
Neuromyelitis optica
Sarcoidosis
Sjögren's syndrome
Stroke and ischemic cerebrovascular disease
Syphilis
Systemic lupus erythematosus and related collagen vascular disorders
Tropical spastic paraparesis (HTLV-1/2 infection)
Vascular malformations (especially spinal dural AV fistulas)
Vasculitis (primary CNS or other)
Vitamin B_{12} deficiency

Abbreviations: AV, arteriovenous; CNS, central nervous system; HTLV, human T-cell lymphotropic virus.

less brain atrophy during the early years of disease, and vice versa. Importantly, some MS patients have a benign variant of MS and never develop neurologic disability even when untreated. The likelihood of having benign MS is thought to be <10%. Patients with benign MS 15 years after onset who have entirely normal neurologic examinations are likely to maintain their benign course.

In patients with their first demyelinating event (i.e., a clinically isolated syndrome), the brain MRI provides prognostic information. With three or more typical T2-weighted lesions, the risk of developing MS after 20 years is ~80%. Conversely, with a normal brain MRI, the likelihood of developing MS is <20%. Similarly, the presence of two or more Gd-enhancing lesions at baseline is highly predictive of future MS, as is the appearance of either new T2-weighted lesions or new Gd enhancement ≥3 months after the initial episode.

EFFECT OF PREGNANCY

Pregnant MS patients experience fewer attacks than expected during gestation (especially in the last trimester), but more attacks than expected in the first 3 months postpartum. When considering the pregnancy year as a whole (i.e., 9 months of pregnancy plus 3 months postpartum), the overall disease course is unaffected. Decisions about childbearing should thus be made based on (1) the mother's physical state, (2) her ability to care for the child, and (3) the availability of social support. Disease-modifying therapy is generally discontinued during pregnancy, although the actual risk from the interferons and glatiramer acetate (see below) appears to be low.

TREATMENT

Therapy for MS can be divided into several categories: (1) treatment of acute attacks, (2) treatment with disease-modifying agents that reduce the biologic activity of MS, and (3) symptomatic therapy. Treatments that promote remyelination or neural repair do not currently exist, but several promising approaches are being actively investigated.

The Expanded Disability Status Scale (EDSS) is a widely used measure of neurologic impairment in MS (**Table 444-5**). Most patients with EDSS scores <3.5 walk normally, and are generally not disabled; by contrast, patients with EDSS scores >4.0 have progressive MS (SPMS or PPMS), are gait-impaired, and often are occupationally disabled.

ACUTE ATTACKS OR INITIAL DEMYELINATING EPISODES

When patients experience acute deterioration, it is important to consider whether this change reflects new disease activity or a "pseudoexacerbation" resulting from an increase in ambient temperature, fever, or an infection. When the clinical change is thought to reflect a pseudoexacerbation, glucocorticoid treatment is inappropriate. Glucocorticoids are used to manage either first attacks or acute exacerbations. They provide short-term clinical benefit by reducing the severity and shortening the duration of attacks. Whether treatment provides any long-term benefit on the course of the illness is less clear. Therefore, mild attacks are often not treated. Physical and occupational therapy can help with mobility and manual dexterity.

Glucocorticoid treatment is usually administered as intravenous methylprednisolone, 500–1000 mg/d for 3–5 days, either without a taper or followed by a course of oral prednisone beginning at a dose of 60–80 mg/d and gradually tapered over 2 weeks. Orally administered methylprednisolone, prednisone, or dexamethasone (in equivalent dosages) can be substituted for the intravenous portion of the therapy. Outpatient treatment is almost always possible.

Side effects of short-term glucocorticoid therapy include fluid retention, potassium loss, weight gain, gastric disturbances, acne, and emotional lability. Concurrent use of a low-salt, potassium-rich diet and avoidance of potassium-wasting diuretics are advisable. Lithium carbonate (300 mg orally bid) may help manage emotional lability and insomnia associated with glucocorticoid therapy. Patients with a history of peptic ulcer disease may require cimetidine (400 mg bid) or ranitidine (150 mg bid). Proton pump inhibitors such as pantoprazole (40 mg orally bid) may reduce the likelihood of gastritis, especially when large doses are administered orally. Plasma exchange (five to seven exchanges: 40–60 mL/kg per exchange, every other day for 14 days) may benefit patients with fulminant attacks of demyelination that are unresponsive to glucocorticoids. However, the cost is high, and conclusive evidence of efficacy is lacking.

DISEASE-MODIFYING THERAPIES FOR RELAPSING FORMS OF MS (RMS, SPMS WITH EXACERBATIONS)

Regulatory bodies have approved more than a dozen immunomodulatory and immunosuppressive agents for treatment of RMS. In phase 3 clinical trials, each was shown to reduce the frequency of clinical relapses and evolution of new brain MRI lesions in relapsing forms of MS (**Table 444-6**). Each can also be used in SPMS patients who continue to experience attacks, both because SPMS can be difficult to distinguish from relapsing MS and because the available clinical trials, although not all definitive, suggest that such patients may sometimes derive therapeutic benefit. Moreover, regulators now consider patients with recent relapses to be a "relapsing form of MS" regardless of whether these patients previously had progressive disability independent from relapses. When considering the data in Table 444-6, however, it is important to note that the relative efficacy of the different agents has not been directly tested in head-to-head studies and that cross-trial comparisons are inaccurate. However, given the increasingly complex landscape of therapeutics for MS, for convenience the discussion of these agents has been divided into those used more and less frequently; and also by an estimate of their relative (high, moderate, or modest) perceived level of efficacy. These are meant to serve as rough guides only, and considerable variance exists in practice patterns, as well as availability of these agents, in different parts of the world.

FREQUENTLY USED AGENTS FOR RMS

ANTI-CD20 MONOCLONAL ANTIBODIES (HIGHLY EFFECTIVE)

Ocrelizumab is a humanized monoclonal antibody directed against the CD20 molecule present on the surface of mature B cells. CD20 is not expressed on early B-cell precursors or on antibody-producing plasma cells, thus treatment with ocrelizumab selectively depletes mature B cells while preserving preexisting humoral immunity and the capacity

TABLE 444-5 Scoring Systems for Multiple Sclerosis (MS)

Expanded Disability Status Scale (EDSS)

0.0 = Normal neurologic examination (all grade 0 in functional status [FS])
1.0 = No disability, minimal signs in one FS (i.e., grade 1)
1.5 = No disability, minimal signs in more than one FS (more than one grade 1)
2.0 = Minimal disability in one FS (one FS grade 2, others 0 or 1)
2.5 = Minimal disability in two FS (two FS grade 2, others 0 or 1)
3.0 = Moderate disability in one FS (one FS grade 3, others 0 or 1) or mild disability in three or four FS (three/four FS grade 2, others 0 or 1) although fully ambulatory
3.5 = Fully ambulatory but with moderate disability in one FS (one grade 3) and one or two FS grade 2; or two FS grade 3; or five FS grade 2 (others 0 or 1)
4.0 = Ambulatory without aid or rest for ~500 m
4.5 = Ambulatory without aid or rest for ~300 m
5.0 = Ambulatory without aid or rest for ~200 m
5.5 = Ambulatory without aid or rest for ~100 m
6.0 = Unilateral assistance required to walk about 100 m with or without resting
6.5 = Constant bilateral assistance required to walk about 20 m without resting
7.0 = Unable to walk beyond about 5 m even with aid; essentially restricted to wheelchair; wheels self and transfers alone
7.5 = Unable to take more than a few steps; restricted to wheelchair; may need aid to transfer
8.0 = Essentially restricted to bed or chair or perambulated in wheelchair, but out of bed most of day; retains many self-care functions; generally has effective use of arms
8.5 = Essentially restricted to bed much of the day; has some effective use of arm(s); retains some self-care functions
9.0 = Helpless bed patient; can communicate and eat
9.5 = Totally helpless bed patient; unable to communicate or eat
10.0 = Death due to MS

Functional Status (FS) Score

A. Pyramidal functions
0 = Normal
1 = Abnormal signs without disability
2 = Minimal disability
3 = Mild or moderate paraparesis or hemiparesis, or severe monoparesis
4 = Marked paraparesis or hemiparesis, moderate quadriparesis, or monoplegia
5 = Paraplegia, hemiplegia, or marked quadriparesis
6 = Quadriplegia

B. Cerebellar functions
0 = Normal
1 = Abnormal signs without disability
2 = Mild ataxia
3 = Moderate truncal or limb ataxia
4 = Severe ataxia all limbs
5 = Unable to perform coordinated movements due to ataxia

C. Brainstem functions
0 = Normal
1 = Signs only
2 = Moderate nystagmus or other mild disability
3 = Severe nystagmus, marked extraocular weakness, or moderate disability of other cranial nerves
4 = Marked dysarthria or other marked disability
5 = Inability to swallow or speak

D. Sensory functions
0 = Normal
1 = Vibration or figure-writing decrease only, in 1 or 2 limbs
2 = Mild decrease in touch or pain or position sense, and/or moderate decrease in vibration in 1 or 2 limbs, or vibratory decrease alone in 3 or 4 limbs
3 = Moderate decrease in touch or pain or position sense, and/or essentially lost vibration in 1 or 2 limbs, or mild decrease in touch or pain, and/or moderate decrease in all proprioceptive tests in 3 or 4 limbs
4 = Marked decrease in touch or pain or loss of proprioception, alone or combined, in 1 or 2 limbs or moderate decrease in touch or pain and/or severe proprioceptive decrease in >2 limbs
5 = Loss (essentially) of sensation in 1 or 2 limbs or moderate decrease in touch or pain and/or loss of proprioception for most of the body below the head
6 = Sensation essentially lost below the head

E. Bowel and bladder functions
0 = Normal
1 = Mild urinary hesitancy, urgency, or retention
2 = Moderate hesitancy, urgency, retention of bowel or bladder, or rare urinary incontinence
3 = Frequent urinary incontinence
4 = In need of almost constant catheterization
5 = Loss of bladder function
6 = Loss of bowel and bladder function

F. Visual (or optic) functions
0 = Normal
1 = Scotoma with visual acuity (corrected) better than 20/30
2 = Worse eye with scotoma with maximal visual acuity (corrected) of 20/30 to 20/59
3 = Worse eye with large scotoma, or moderate decrease in fields, but with maximal visual acuity (corrected) of 20/60 to 20/99
4 = Worse eye with marked decrease of fields and maximal acuity (corrected) of 20/100 to 20/200; grade 3 plus maximal acuity of better eye of 20/60 or less
5 = Worse eye with maximal visual acuity (corrected) <20/200; grade 4 plus maximal acuity of better eye of ≤20/60
6 = Grade 5 plus maximal visual acuity of better eye of ≤20/60

G. Cerebral (or mental) functions
0 = Normal
1 = Mood alteration only (does not affect EDSS score)
2 = Mild decrease in mentation
3 = Moderate decrease in mentation
4 = Marked decrease in mentation
5 = Chronic brain syndrome—severe or incompetent

for B-cell reconstitution by lymphoid stem cells. Ocrelizumab rapidly depletes circulating B cells through antibody-dependent cellular toxicity and complement-dependent cytotoxicity. The beneficial effects of B-cell depletion in MS may involve interruption in trafficking of B cells from the periphery to the CNS and reduction in antigen presentation and/or modulation of cytokine secretion by B cells (see "Immunology", above). In two phase 3 trials, ocrelizumab demonstrated a high degree of efficacy against RMS, reducing annualized relapse rates by 47%, reducing new MRI lesions by 95%, and improving other measures of inflammatory and degenerative disease activity, compared with three times per week interferon β-1a (Rebif). Ocrelizumab 600 mg is administered by intravenous infusion every 24 weeks (administered as two 300-mg infusions spaced 2 weeks apart for the first dose, and as a single 600-mg infusion thereafter); intravenous methylprednisolone

[1]Variable duration study with median time in randomized controlled period of 20 months.

[2]$p = 0.002$

[a]Percentage reductions (or increases) have been calculated by dividing the reported rates in the treated group by the comparable rates in the placebo group, except for magnetic resonance imaging (MRI) disease burden, which was calculated as the difference in the median percent change between the treated and placebo groups. [b]Severity = 1 point Expanded Disability Status Scale score progression, sustained for 3 months (in the IFN-β-1a 30 μg qw trial, this change was sustained for 6 months; in the IFN-β-1b trial, this was over 3 years). [c]Different studies measured these MRI measures differently, making comparisons difficult (numbers for new T2 represent the best-case scenario for each trial). [d]New lesions seen on T2-weighted MRI. [e]$p = .001$. [f]$p = .01$. [g]$p = .05$. [h]Pooled analysis from OPERA 1 and 2 studies. [i]Variable duration study with median time in randomized controlled period of 18 months.

Abbreviations: ALEM, alemtuzumab; CLAD, cladribine; DMF, dimethyl fumarate; FDA, food and drug administration; FNG, fingolimod; GA, glatiramer acetate; IFN-β, interferon β; IM, intramuscular; IV, intravenous; MTX, mitoxantrone; NR, not reported; NS, not significant; NTZ, natalizumab; OFA, ofatumumab; OFR, ocrelizumab; OZN, ozanimod; PNS, ponesimod; PO, oral; q3mo, once every 3 months; qd, daily; qmo, once per month; qod, every other day; qw, once per week; qyr, once per year; SC, subcutaneous; SIP, siponimod; TF, teriflunomide; tiw, three times per week.

100 mg is given prior to each infusion and optional prophylaxis with analgesics/antipyretics and antihistamines is recommended, along with adjustment of the infusion rate to manage infusion-related reactions. Ocrelizumab is generally well tolerated with infusion-related reactions occurring in a minority of patients; these are most often observed with the first infusion and are usually mild in degree. Vaccination responses may be blunted in patients receiving ocrelizumab or other anti-CD20 based therapies; whenever possible, immunizations should be administered prior to initiating treatment, and live vaccines should not be given in actively treated patients.

Ofatumumab is a fully human anti-CD20 monoclonal antibody that can be self-administered at home by monthly 20 mg subcutaneous injection, after initial 20-mg loading doses on days 1, 7, and 14. Two pivotal phase 3 trials demonstrated superiority of ofatumumab tested against teriflunomide with an efficacy profile against relapses similar to ocrelizumab, reduction of new MRI lesions by 95%, reduction of disability, and lowering of serum neurofilament light chain levels, a biomarker of neuronal damage. A high degree of safety was also observed in the trials.

Rituximab, another anti-CD20 antibody, was tested against MS in preliminary trials, and appears also to be highly effective based on numerous reports of real-world experience with this agent; rituximab (1g IV Q6 mo) is used in some settings despite lack of pivotal trial data. Rituximab is associated with a very small risk (estimated at <1:25,000/year) of progressive multifocal leukoencephalopathy (PML), a life-threatening condition resulting from infection by the John Cunningham (JC) virus, thus it is possible that ocrelizumab and ofatumumab will also carry a nonzero risk.

NATALIZUMAB (HIGHLY EFFECTIVE)

Natalizumab is a humanized monoclonal antibody directed against the α4 subunit of α4β1 integrin, a cellular adhesion molecule expressed on the surface of lymphocytes. It prevents lymphocytes from binding to endothelial cells, thereby preventing lymphocytes from penetrating the BBB and entering the CNS. Natalizumab is highly effective in reducing the attack rate and significantly improves all measures of disease severity in MS (both clinical and MRI). Moreover, it is well tolerated, and the dosing schedule of monthly intravenous infusions makes it convenient for patients. Natalizumab, 300 mg, is administered by IV infusion each month. Treatment is, in general, well tolerated. A small percentage (<10%) of patients experience hypersensitivity reactions (including anaphylaxis), and ~6% develop neutralizing antibodies to the molecule (only half of which persist).

The major concern is risk for PML, occurring in ~0.4% of patients treated with natalizumab. The incidence of PML is very low in the first year of treatment but then rises in subsequent years of treatment to

reach a level of about 2 cases per 1000 patients per year. Nevertheless, the measurement of antibodies against the JC virus in the serum can be used to stratify this risk. Approximately half of the adult population is JC antibody positive, indicating that they experienced an asymptomatic infection with the JC virus at some time in the past. Thus, in patients who do not have these antibodies, the risk of PML is minimal (<1:10,000 as long as they remain JC antibody free). Conversely, in patients who have these antibodies (especially those who have them in high titer), the risk may be as high as ≥1.1%. Up to 2% of seronegative MS patients undergoing treatment with natalizumab seroconvert annually; thus, it is recommended that JC antibody status be assessed at 6-month intervals in all patients receiving natalizumab. In antibody-positive patients, a change to another disease-modifying therapy should be strongly considered. The risk of PML is also high in patients who previously received immunosuppressive therapy. Natalizumab is generally recommended only for JC antibody-negative patients, unless they have failed alternative therapies or if they have a particularly aggressive disease course.

S1P RECEPTOR MODULATORS (MODERATELY EFFECTIVE)

Fingolimod is a sphingosine-1-phosphate (S1P) modulator that prevents the egress of lymphocytes from secondary lymphoid organs such as the lymph nodes and spleen. Fingolimod binds to S1P1, S1P3, S1P4, and S1P5 receptors. Its mechanism of action is probably due to sequestration of lymphocytes in the periphery, thereby inhibiting their trafficking to the CNS. Fingolimod reduces the attack rate and significantly improves all measures of disease severity in MS. It is well tolerated, and the daily oral dosing schedule makes it convenient for patients. A head-to-head phase 3 randomized study demonstrated the superiority of fingolimod over low-dose (weekly) IFN-β-1a. Fingolimod, 0.5 mg, is administered orally each day. Mild abnormalities on routine laboratory evaluation (e.g., elevated liver function tests or lymphopenia) are more common than in controls, sometimes requiring discontinuation of the medication. First- and second-degree heart block and bradycardia can also occur when fingolimod therapy is initiated. A 6-h period of observation (including electrocardiogram monitoring) is recommended for all patients receiving their first dose. Other side effects include macular edema and, rarely, disseminated varicella-zoster virus (VZV) and cryptococcal infections; prior to initiating therapy with fingolimod, an ophthalmic examination and VZV vaccination for seronegative individuals are indicated. Fingolimod can also cause QT prolongation with the potential for drug–drug interactions with other medications that also prolong the QT interval.

Ozanimod is a S1P1- and S1P5-selective S1P inhibitor that, like fingolimod, prevents the egress of lymphocytes from secondary lymphoid organs. Ozanimod was shown to be superior to low-dose (weekly) IFN-β-1a in preventing relapses and new lesion formation on brain MRI. Because ozanimod binds only weakly to S1P3 receptors, cardiac conduction-related side effects, such as QT prolongation and secondary-degree heart block that are associated with modulation of myocardial S1P3 receptors, are not associated with ozanimod. An up-titration scheme is used when starting this medication to reduce the risk of transient decreases in heart rate and atrioventricular conduction delays that may occur after the first dose. In contrast to fingolimod, cardiovascular monitoring is not required during first-dose administration in most patients. Ozanimod was not studied in patients with severe untreated sleep apnea, class III/IV heart failure, significant cardiac conduction disorders, or in those who experienced thromboembolic events in the last 6 months, and is relatively contraindicated in these patients. Patients starting ozanimod should undergo a CBC, LFTs, ECG, and eye examination before starting therapy. Infections and hypertension should be monitored for during treatment. Live vaccines should be avoided during treatment and for 3 months after discontinuation.

Ponesimod is a S1P1-selective modulator. Ponesimod was shown to be superior to teriflunomide in preventing relapses and new MRI lesion formation. An up-titration scheme is used when starting this medication to reduce the risk of transient decreases in heart rate and atrioventricular conduction delays that may occur after the first dose. A 4-h first-dose observation period with cardiovascular monitoring is necessary in patients whose resting heart rate is <55 beats/min. Ponesimod is contraindicated in patients who have in the prior 6 months experienced stroke, heart attack, unstable angina, class III or IV decompensated heart failure or have a Mobitz type II or greater degree of heart block without a pacemaker. Patients should undergo a CBC, LFTs, ECG, and eye examination before starting therapy, and be monitored for infections and hypertension during treatment. Live vaccines should be avoided during treatment.

DIMETHYL FUMARATE (MODERATELY EFFECTIVE)

Dimethyl fumarate (DMF) is a small-molecule and a Krebs cycle metabolite with anti-inflammatory effects. DMF is metabolized to the active compound monomethyl fumarate. Although the precise mechanisms of action are not fully understood, it seems to modulate the expression of proinflammatory and anti-inflammatory cytokines. Also, DMF inhibits the ubiquitylation and degradation of nuclear factor E2-related factor 2 (Nrf2)—a transcription factor that binds antioxidant response elements (AREs) located on DNA and induces transcription of several antioxidant proteins. DMF reduces the attack rate and significantly improves all measures of disease severity in MS patients. However, its twice-daily oral dosing schedule makes it somewhat less convenient for patients than daily oral therapies. In addition, compliance is likely to be less with a twice-daily dosing regimen—a factor that could be of concern given the observation (in a small clinical trial) that once-daily DMF lacks efficacy. A head-to-head trial provided evidence that DMF was superior to glatiramer acetate on some outcome measures. DMF, 240 mg, is administered orally twice each day. Gastrointestinal side effects (abdominal discomfort, nausea, vomiting, flushing, and diarrhea) are common at the start of therapy but generally subside with continued administration. Other adverse events include flushing, mild decreases in neutrophil and lymphocyte counts, and elevations in liver enzymes. Nevertheless, in general, treatment with DMF is well tolerated after an initial period of adjustment. Following the release of DMF, several cases of PML were reported in patients receiving products that contained DMF. Most of these patients were lymphopenic and monitoring for lymphopenia every 6 months is recommended. Patients who are persistently lymphopenic (lymphocyte count <500 cells/mL) are recommended to consider alternate treatments due to the PML risk. Clinically significant liver injury has been reported with DMF treatment. Liver function tests should be assessed before treatment and when clinically indicated. Elevations in liver function tests resolve following treatment discontinuation.

Diroximel fumarate is, like DMF, metabolized to monomethyl fumarate. The efficacy of diroximel fumarate is based upon bioavailability studies in patients with RMS and healthy subjects. The adverse event profile and monitoring requirements are the same as with DMF.

GLATIRAMER ACETATE (MODESTLY EFFECTIVE)

Glatiramer acetate is a synthetic, random polypeptide composed of four amino acids (l-glutamic acid, l-lysine, l-alanine, and l-tyrosine). Its mechanism of action may include (1) induction of antigen-specific suppressor T cells; (2) binding to MHC molecules, thereby displacing bound MBP; or (3) altering the balance between proinflammatory and regulatory cytokines. Glatiramer acetate reduces the attack rate (whether measured clinically or by MRI) in RRMS. Glatiramer acetate also benefits disease-severity measures, although, for clinical disability, this is less well established than for IFN-β. Nevertheless, two head-to-head trials demonstrated that the impact of glatiramer acetate on clinical relapse rates and disability was comparable to high-dose, high-frequency IFN-β. Therefore, glatiramer acetate should be considered as an equally effective alternative to IFN-β in RRMS patients. Its usefulness in progressive disease is unknown. Glatiramer acetate is administered by subcutaneous injection of either 20 mg every day or 40 mg thrice weekly. Injection-site reactions can occur. In addition, ~15% of patients experience one or more episodes of flushing, chest tightness, dyspnea, palpitations, and anxiety after injection. This systemic reaction is unpredictable, brief (duration <1 h), and tends not to recur. Finally, some

patients experience lipoatrophy, which, on occasion, can be disfiguring and require cessation of treatment. Recently, glatiramer acetate was U.S. Food and Drug Administration (FDA) approved as a biosimilar medication (Glatopa) and is dosed at 20 mg every day. Although clinical trials were not performed with biosimilar glatiramer acetate, the efficacy and safety are presumed to be similar to the branded product.

INTERFERON β (MODESTLY EFFECTIVE)

Interferon β (IFN-β) is a class I interferon originally identified by its antiviral properties. Efficacy in MS probably results from immunomodulatory properties including: (1) downregulating expression of MHC molecules on antigen-presenting cells, (2) reducing proinflammatory and increasing regulatory cytokine levels, (3) inhibiting T-cell proliferation, and (4) limiting the trafficking of inflammatory cells in the CNS. IFN-β reduces the attack rate, and slows accumulation of disability and MRI-documented disease burden. IFN-β should be considered in patients with either relapsing forms of MS (either RRMS or SPMS with superimposed relapses). Head-to-head trials suggest that dosing IFN-β more frequently and at higher doses has better efficacy but is also more likely to induce neutralizing antibodies (see below). IFN-β-1a (Avonex), 30 μg, is administered by intramuscular injection once every week. IFN-β-1a (Rebif), 44 μg, is administered by subcutaneous injection three times per week. IFN-β-1b (Betaseron or Extavia), 250 μg, is administered by subcutaneous injection every other day. Pegylated IFN-β-1a (Plegridy), 125 μg, is administered by subcutaneous injection once every 14 days. Pegylated IFN-β-1a is an interferon to which a single, linear 20,000 dalton methoxy poly(ethyleneglycol)-O-2-methylproprionaldehyde molecule is covalently attached; the pegylated molecule contributes to reduced in vivo clearance allowing less frequent administration. Common side effects of IFN-β therapy include flulike symptoms (e.g., fevers, chills, and myalgias) and mild abnormalities on routine laboratory evaluation (e.g., elevated liver function tests or lymphopenia). Rarely, more severe hepatotoxicity may occur. Subcutaneous IFN-β also causes reactions at the injection site (e.g., pain, redness, induration, or, rarely, skin necrosis). Side effects can usually be managed with concomitant nonsteroidal anti-inflammatory medications. Depression, increased spasticity, and cognitive changes have been reported, although these symptoms can also be due to the underlying disease. Side effects due to IFN-β therapy usually subside over time. Rates of serious infection are lower with IFN-β therapy than many other disease-modifying medications.

Approximately 2–10% of IFN-β-1a (Avonex) recipients, 15–25% of IFN-β-1a (Rebif) recipients, and 30–40% of IFN-β-1b (Betaseron/Extavia) recipients develop neutralizing antibodies to IFN-β, which may disappear over time. Less than 1% of patients treated with pegylated IFN-β-1a develop neutralizing antibodies. For a patient doing well on therapy, the presence of antibodies should not affect treatment. Conversely, for a patient doing poorly on therapy, alternative treatment should be considered, even if there are no detectable antibodies.

LESS COMMONLY USED AGENTS FOR RMS

TERIFLUNOMIDE (MODESTLY EFFECTIVE)

Teriflunomide inhibits the mitochondrial enzyme dihydro-orotate dehydrogenase, which is a key part of the pathway for de novo pyrimidine biosynthesis from carbamoyl phosphate and aspartate. It is the active metabolite of the drug leflunomide (FDA-approved for rheumatoid arthritis), and it exerts its anti-inflammatory effects by limiting the proliferation of rapidly dividing T and B cells. This enzyme is not involved in the so-called salvage pathway, by which existing pyrimidine pools are recycled for DNA and RNA synthesis in resting and homeostatically proliferating cells. Consequently, teriflunomide is considered to be cytostatic rather than cytotoxic. Teriflunomide reduces the attack rate and significantly improves all measures of disease severity in MS patients. It is well tolerated, and its daily oral dosing schedule makes it very convenient for patients. A head-to-head trial suggested the equivalence, but not superiority, of teriflunomide and thrice-weekly IFN-β-1a. Teriflunomide, either 7 or 14 mg, is administered orally each day. In the pivotal clinical trials, mild hair thinning and gastrointestinal symptoms (nausea and diarrhea) were more common than in controls, but in general, treatment with teriflunomide was well tolerated. Teriflunomide rarely causes toxic epidermal necrolysis or Stevens-Johnson syndrome. A major limitation, especially in women of childbearing age, is its possible teratogenicity (pregnancy category X); teriflunomide can remain in the bloodstream for 2 years due to hepatobiliary reabsorption. Therefore, it is recommended that exposed men and women who wish to conceive receive cholestyramine or activated charcoal to eliminate residual drug.

CLADRIBINE (MODERATELY EFFECTIVE)

Cladribine is a prodrug that when phosphorylated by deoxycytidine kinase to its metabolite 2-chlorodeoxyadenosine becomes active and is incorporated into nuclear and mitochondrial DNA causing apoptosis. Because deoxycytidine kinase is expressed at high levels in lymphocytes, cladribine can be administered as a relatively specific lymphotoxic therapy. In intravenous or subcutaneously administered forms, cladribine is indicated for treatment of hairy cell leukemia. Cladribine's oral formulation is indicated for treatment of relapsing forms of MS including active SPMS. Cladribine reduces the attack rate and disability measures in RMS patients. It is well tolerated, and is dosed based on body weight (3.5 mg/kg divided into 2 yearly treatment courses). Patients are treated with 1 or 2 doses of cladribine daily for 4 or 5 consecutive days, receive a second similar cycle of treatment 23 to 27 days after the first cycle, and then are retreated after 1 year. Cladribine has beneficial effects in MS that are sustained beyond the 2-year course of administration. The basis for these benefits is poorly understood but is presumably related to immune reconstitution by nonpathogenic lymphocytes. Cladribine is associated with malignancy, including in the MS clinical trials, and for this reason is not recommended in treatment-naïve patients. Cladribine is also contraindicated in pregnant women because it is a known teratogen in animals and can cause embryolethality. Despite cladribine's relatively short terminal half-life of 1 day, women and men treated with cladribine are recommended to not plan conception for 6 months after the last dose. Prior to treatment, patients should undergo a complete blood count including lymphocyte count and liver function tests; be screened for HIV, tuberculosis, and hepatitis B and C; be vaccinated for varicella zoster virus; and undergo a brain MRI within 3 months of treatment because of a presumed risk of treatment-emergent PML.

ALEMTUZUMAB (HIGHLY EFFECTIVE)

Alemtuzumab is a humanized monoclonal antibody directed against the CD52 antigen that is expressed on both monocytes and lymphocytes. It causes lymphocyte depletion (of both B and T cells) and a change in the composition of lymphocyte subsets. Both of these changes, particularly the impact on lymphocyte subsets, are long lasting. In two phase 3 trials, which used the active comparator of thrice-weekly, high-dose IFN-β-1a, alemtuzumab markedly reduced the attack rate and significantly improved measures of disease severity in MS patients although its impact on clinical disability was found in only one of the two trials. The European and Canadian drug agencies were the first to approve this agent for use in RRMS; the FDA has also approved alemtuzumab, but only after an appeal following initial disapproval. The reasons for initial disapproval were based on a perceived lack of a convincing disability effect and concerns over potential toxicity. The toxicities of concern were the occurrence of (1) autoimmune diseases including thyroiditis, Graves' disease, thrombocytopenia, hemolytic anemia, pancytopenia, antiglomerular basement membrane disease, and membranous glomerulonephritis; (2) malignancies including thyroid cancer, melanoma, breast cancer, human papillomavirus (HPV)-related cancers, and lymphoproliferative disorders including lymphoma; (3) serious infections; and (4) infusion reactions. Because of its toxicity profile, alemtuzumab is indicated by the U.S. FDA only in patients who have tried and failed at least two other DMTs.

MITOXANTRONE HYDROCHLORIDE (HIGHLY EFFECTIVE)

Mitoxantrone, an anthracenedione, exerts its antineoplastic action by (1) intercalating into DNA and producing both strand breaks

and interstrand cross-links, (2) interfering with RNA synthesis, and (3) inhibiting topoisomerase II (involved in DNA repair). The FDA approved mitoxantrone on the basis of a single phase 3 clinical trial in Europe, in addition to even smaller phase 2 studies. Mitoxantrone is indicated for use in patients with rapidly worsening MS (defined as patients whose neurologic status remains significantly abnormal between MS attacks). Despite this broad indication, however, data supporting its efficacy are less robust compared to other approved therapies. Mitoxantrone is cardiotoxic (e.g., cardiomyopathy, reduced left ventricular ejection fraction, and irreversible congestive heart failure). As a result, a cumulative dose >140 mg/m^2 is not recommended. At currently approved doses (12 mg/m^2 every 3 months), the maximum duration of therapy can be only 2–3 years. Furthermore, >40% of women will experience amenorrhea, which may be permanent. Finally, there is risk of acute leukemia from mitoxantrone, estimated as at least a 1.4% lifetime risk. Because of these risks, and the availability of alternative therapies, mitoxantrone is now rarely used for MS.

DECISION-MAKING FOR TREATMENT OF RMS

First-line therapy should be initiated in patients with a clinically isolated syndrome at high risk for MS or in patients diagnosed with RMS (according to 2017 McDonald criteria).

We favor use of the most highly effective DMTs as first-line options for most patients with active MS, rather than the more traditional "treat to target" approach in which a treatment of modest or moderate effectiveness is first used, and therapy advanced to a more effective agent when breakthrough disease (evident clinically or by MRI) occurs. As noted above, observational studies suggest that early use of high-efficacy therapy could improve long-term outcomes. For many patients, we begin with an anti-CD20 agent, either ocrelizumab or ofatumumab, or with natalizumab in JCV-negative patients. Anti-CD20 agents are attractive given their high level of efficacy, relative ease of use, favorable safety profile, and absence of rebound following discontinuation. For patients who prefer oral treatment, either an S1P modulator or fumarate is also reasonable for first-line therapy.

Switching DMTs may be required in the following situations: suboptimal response, experiencing more than one relapse with active MRI scans while on treatment, and safety issues including development of persistent high-titer neutralizing antibodies in patients receiving IFN-β. Discontinuation of DMTs is required in cases of serious adverse events that may be drug-related and for many DMTs in women who become pregnant while on treatment. Exceptions to this practice include glatiramer acetate that can be continued during pregnancy, and in some cases prior use of ocrelizumab, alemtuzumab, and cladribine that have prolonged pharmacodynamic effects that persist after the drug has been eliminated.

For patients who present with a mild initial course—e.g., normal examination or minimal impairment (EDSS ≤2.5) and low disease activity by MRI—either an oral (fumarates, S1P modulators, teriflunomide) or injectable (IFN-β or glatiramer acetate) agent can be considered. The injectable agents (IFN-β and glatiramer acetate) have a superb long-term track record for safety but have a high nuisance factor due to the need for frequent injections, as well as bothersome side effects that contribute to noncompliance.

The safety and value of combination therapy is also largely unknown and is generally not recommended. One clinical trial demonstrated no added benefit to the combination of glatiramer acetate with once-weekly IFN-β-1a. The optimal duration of therapy is also unknown.

The long-term impact of these treatments on the disease course remains controversial, although as noted above ("Prognosis") several observational studies showed that these agents improve the long-term outcome of MS including a prolongation of the time to reach certain disability outcomes (e.g., SPMS and requiring assistance to ambulate) and reduction in MS-related mortality. These benefits seem most conspicuous when treatment begins early in the relapsing stage of the illness. It may be reasonable to delay initiating treatment in patients with (1) normal neurologic examinations, (2) a single attack or a low attack frequency, and (3) a low burden of disease as assessed by brain MRI. Untreated patients, however, should be followed closely with periodic brain MRI scans; the need for therapy is reassessed if scans reveal evidence of ongoing, subclinical disease. Finally, vitamin D deficiency should be corrected in all patients with MS, and generally this requires oral supplementation with vitamin D3, 4000 IU daily. Several clinical trials showed that supplementation with vitamin D in relapsing MS patients reduces MRI measures of disease activity and may also reduce the relapse frequency in patients actively treated with either interferon or glatiramer acetate.

DISEASE-MODIFYING THERAPIES FOR PROGRESSIVE MS

SPMS

Siponimod is a selective S1P1 S1P5 receptor modulator (see S1P receptor modulators above) that was shown in a single phase 3 study to be superior to placebo in reducing the risk of progression in SPMS patients. Siponimod also reduced the risk of relapse and MRI measures of the burden of disease. Subgroup analysis showed that patients with a relapse in the 2 years prior to treatment and those with contrast-enhancing lesions on brain MRI received the most therapeutic benefit. Siponimod was subsequently approved for patients with SPMS who had active disease. Siponimod is dosed based on CYP2C9 genotype. For patients with CYP2C9 **1**/*3 or **2**/*3, siponimod is administered as 1 mg daily. Siponimod dosage is reduced in patients with the CYP2C9 *__3__/*3 genotype (<0.5% of the population) due to substantially elevated drug levels. Prior to treatment patients should undergo a complete blood count, ophthalmic evaluation, electrocardiogram, liver function tests, and vaccination for varicella zoster virus. Unlike fingolimod, first-dose monitoring is required only in patients with sinus bradycardia, first- or second-degree heart block, or a history of myocardial infarction or heart failure.

Ocrelizumab, cladribine, and ponesimod are also indicated in active SPMS although none of these therapies were specifically studied in this patient population. High-dose IFN-β probably has a modest beneficial effect in patients with SPMS with active disease (see above). IFN-β is probably ineffective in patients with SPMS who do not have active disease. Although mitoxantrone was approved for patients with rapidly progressive MS, this is not the population studied in the pivotal trial; therefore, no evidence-based recommendation can be made with regard to its use in this setting.

PPMS

Ocrelizumab (see above) was shown in a phase 3 trial to reduce progression of clinical disability in PPMS by 24%, and also to improve other clinical and MRI markers of inflammatory and degenerative disease activity. Ocrelizumab represents the first agent to convincingly modify the course of PPMS. The dosing of ocrelizumab for PPMS is identical as for RMS (above).

OFF-LABEL TREATMENT OPTIONS FOR RMS AND SPMS

Azathioprine (2–3 mg/kg per day) has been used primarily in relapsing MS. Meta-analysis of published trials suggests that azathioprine is marginally effective at lowering relapse rates, although a benefit on disability progression has not been demonstrated.

Methotrexate (7.5–20 mg/week) was shown in one study to slow the progression of upper-extremity dysfunction in SPMS. Because of the possibility of developing irreversible liver damage, some experts recommend a blind liver biopsy after 2 years of therapy.

Cyclophosphamide (700 mg/m2, every other month) may be helpful for treatment-refractory patients who are (1) otherwise in good health, (2) ambulatory, and (3) <40 years of age. Because cyclophosphamide can be used for periods in excess of 3 years, it may be preferable to mitoxantrone in these circumstances.

Intravenous immunoglobulin (IVIg), administered in monthly pulses (up to 1 g/kg) for up to 2 years, appears to reduce annual exacerbation rates. However, its use is limited because of its high cost, questions about optimal dose, and uncertainty about its having any impact on long-term disability.

Methylprednisolone in one study, administered as monthly high-dose intravenous pulses, reduced disability progression (see above).

Autologous hematopoietic stem cell transplantation appears to be highly effective in reducing the occurrence of relapses and may improve disability in relapsing MS. It appears to be ineffective for patients with progressive MS. Stem cell transplantation also carries significant risk, and randomized trials with appropriate comparators are needed in order to position this procedure with respect to available pharmacologic interventions.

PROMISING EXPERIMENTAL THERAPIES

Numerous clinical trials of promising experimental therapies are currently underway. These include studies of molecules to promote remyelination; autologous hematopoietic stem cell transplantation; higher doses of ocrelizumab; and selective kinase inhibitors including Bruton's tyrosine kinase (BTK).

OTHER THERAPEUTIC CLAIMS

Many purported treatments for MS have never been subjected to scientific scrutiny. These include dietary therapies (e.g., the Swank diet, the Paleo diet, the Wahls diet), megadose vitamins, calcium orotate, bee stings, cow colostrum, hyperbaric oxygen, procarin (a combination of histamine and caffeine), chelation, acupuncture, acupressure, various Chinese herbal remedies, and removal of mercury-amalgam tooth fillings, among many others. Patients should avoid costly or potentially hazardous unproven treatments. Many such treatments lack biologic plausibility. No reliable case of mercury poisoning resembling typical MS has ever been described, therefore challenging the notion that removal of mercury-amalgam tooth fillings would be beneficial. Although potential roles for EBV, human herpesvirus (HHV) 6, or chlamydia have been suggested for MS, treatment with antiviral agents or antibiotics is not recommended. A chronic cerebrospinal insufficiency (CCSVI) was proposed as a cause of MS with vascular-surgical intervention recommended. However, multiple independent studies have failed to even approximate the initial claims, and patients should be strongly advised to avoid diagnostic procedures and potentially dangerous surgery for this condition. A double-blind trial of high-dose biotin to improve disability in progressive forms of MS found no benefit.

SYMPTOMATIC THERAPY

For all patients, it is important to encourage attention to a healthy lifestyle, including maintaining an optimistic outlook, a healthy diet, and regular exercise as tolerated (swimming is often well-tolerated because of the cooling effect of cold water). It is reasonable also to correct vitamin D deficiency with oral vitamin D.

Ataxia/tremor is often intractable. Clonazepam, 1.5–20 mg/d; primidone, 50–250 mg/d; propranolol, 40–200 mg/d; or ondansetron, 8–16 mg/d, may help. Wrist weights occasionally reduce tremor in the arm or hand. Thalamotomy and deep-brain stimulation have been tried with mixed success.

Spasticity and *spasms* may improve with physical therapy, regular exercise, and stretching. Avoidance of triggers (e.g., infections, fecal impactions, bed sores) is extremely important. Effective medications include baclofen (20–120 mg/d), diazepam (2–40 mg/d), tizanidine (8–32 mg/d), dantrolene (25–400 mg/d), and cyclobenzaprine hydrochloride (10–60 mg/d). For severe spasticity, a baclofen pump (delivering medication directly into the CSF) can provide substantial relief.

Weakness can sometimes be improved with the use of potassium channel blockers such as 4-aminopyridine (20 mg/d) and 3,4-di-aminopyridine (40–80 mg/d), particularly in the setting where lower-extremity weakness interferes with the patient's ability to ambulate. The FDA approved extended-release 4-aminopyridine (at 10 mg twice daily), and this can be obtained either as dalfampridine (Ampyra) or through a compounding pharmacy. The principal concern with the use of these agents is the possibility of inducing seizures at high doses.

Pain is treated with anticonvulsants (carbamazepine, 100–1000 mg/d; phenytoin, 300–600 mg/d; gabapentin, 300–3600 mg/d; or pregabalin, 50–300 mg/d), antidepressants (amitriptyline, 25–150 mg/d; nortriptyline, 25–150 mg/d; desipramine, 100–300 mg/d; or venlafaxine, 75–225 mg/d), or antiarrhythmics (mexiletine, 300–900 mg/d). If these approaches fail, patients should be referred to a comprehensive pain-management program.

Bladder dysfunction management is best guided by urodynamic testing. Evening fluid restriction or frequent voluntary voiding may help *detrusor hyperreflexia*. If these methods fail, propantheline bromide (10–15 mg/d), oxybutynin (5–15 mg/d), hyoscyamine sulfate (0.5–0.75 mg/d), tolterodine tartrate (2–4 mg/d), or solifenacin (5–10 mg/d) may help. Coadministration of pseudoephedrine (30–60 mg) is sometimes beneficial.

Detrusor/sphincter dyssynergia may respond to phenoxybenzamine (10–20 mg/d) or terazosin hydrochloride (1–20 mg/d). Loss of reflex bladder wall contraction may respond to bethanechol (30–150 mg/d). However, both conditions often require catheterization.

Urinary tract infections should be treated promptly. Patients with postvoid residual urine volumes >200 mL are predisposed to infections. Prevention by urine acidification (with cranberry juice or vitamin C) inhibits some bacteria. Prophylactic administration of antibiotics is sometimes necessary but may lead to colonization by resistant organisms. Intermittent catheterization may help to prevent recurrent infections and reduce overflow incontinence.

Treatment of *constipation* includes high-fiber diets and fluids. Natural or other laxatives may help. *Fecal incontinence* may respond to a reduction in dietary fiber.

Depression should be treated. Useful drugs include the selective serotonin reuptake inhibitors (fluoxetine, 20–80 mg/d, or sertraline, 50–200 mg/d), the tricyclic antidepressants (amitriptyline, 25–150 mg/d; nortriptyline, 25–150 mg/d; or desipramine, 100–300 mg/d), and the nontricyclic antidepressants (venlafaxine, 75–225 mg/d).

Fatigue may improve with assistive devices, help in the home, or successful management of spasticity. Patients with frequent nocturia may benefit from anticholinergic medication at bedtime. Excessive daytime somnolence caused by MS may respond to amantadine (200 mg/d), methylphenidate (5–25 mg/d), modafinil (100–400 mg/d), or armodafinil (150–250 mg/d).

Cognitive problems may respond marginally to lisdexamfetamine (40 mg/d).

Paroxysmal symptoms respond dramatically to low-dose anticonvulsants (acetazolamide, 200–600 mg/d; carbamazepine, 50–400 mg/d; phenytoin, 50–300 mg/d; or gabapentin, 600–1800 mg/d).

Heat sensitivity may respond to heat avoidance, air-conditioning, or cooling garments.

Sexual dysfunction may be helped by lubricants to aid in genital stimulation and sexual arousal. Management of pain, spasticity, fatigue, and bladder/bowel dysfunction may also help. Sildenafil (50–100 mg), tadalafil (5–20 mg), or vardenafil (5–20 mg), taken 1–2 h before sex, are standard treatments for erectile dysfunction.

CLINICAL VARIANTS OF MS

Acute MS (*Marburg's variant*) is a fulminant demyelinating process that in some cases progresses inexorably to death within 1–2 years. Typically, there are no remissions. Marburg's variant does not seem to follow infection or vaccination, and it is unclear whether this syndrome represents an extreme form of MS or another disease altogether. When an acute demyelinating syndrome presents as a solitary expansile lesion, a brain tumor is often suspected **(Fig. 444-4)**. Such cases are designated tumefactive MS, and a brain biopsy may be required to establish the diagnosis.

Balo's concentric sclerosis is another fulminant demyelinating syndrome characterized by concentric brain or spinal cord lesions with alternating spheres of demyelination and remyelination (Fig. 444-4). For these fulminant demyelinating states, no controlled trials of therapy exist; high-dose glucocorticoids, plasma exchange, and cyclophosphamide have been tried, with uncertain benefit.

ACUTE DISSEMINATED ENCEPHALOMYELITIS (ADEM)

ADEM has a monophasic course and is most frequently associated with an antecedent infection (postinfectious encephalomyelitis); ~5% of ADEM cases follow immunization (postvaccinal encephalomyelitis). ADEM is far more common in children than adults, and many adult cases initially thought to represent ADEM subsequently experience

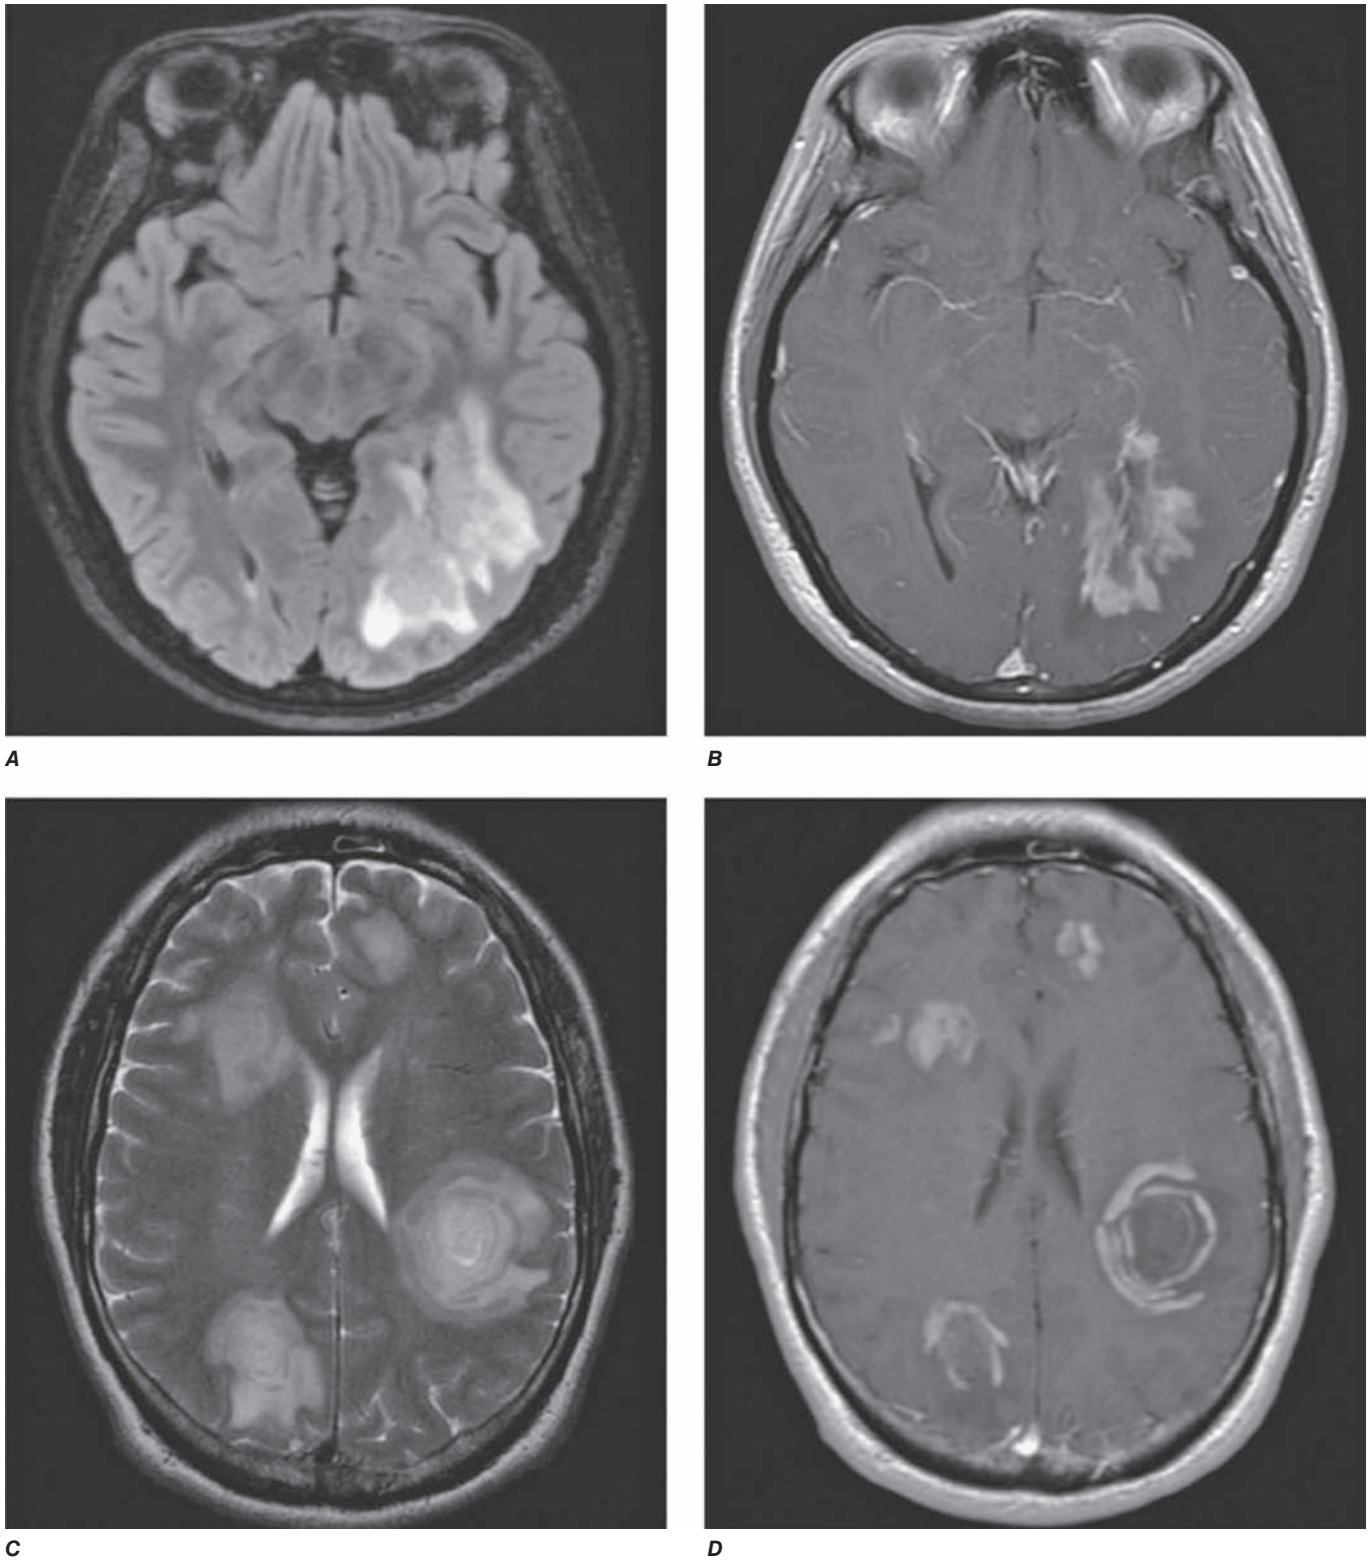

FIGURE 444-4 Magnetic resonance imaging findings in variants of MS. ***A*** and ***B***. Acute tumefactive MS. In ***A***, a sagittal T2-weighted fluid-attenuated inversion recovery (FLAIR) image of a large solitary right parieto-occipital white matter lesion is shown, with effacement of overlying cortical sulci consistent with mass effect. In ***B***, T1-weighted image obtained after the intravenous administration of gadolinium DTPA reveals a large serpiginous area of blood-brain barrier disruption consistent with acute inflammation. ***C*** and ***D***. Balo's concentric sclerosis. In ***C***, an axial T2-weighted sequence shows multiple areas of abnormal ovoid bright signal in the supratentorial white matter bilaterally; some lesions reveal concentric layers, typical of Balo's concentric sclerosis. In ***D***, T1-weighted MR images postgadolinium demonstrate abnormal enhancement of all lesions with some lesions demonstrating concentric ring enhancement.

late relapses qualifying as either MS or another chronic inflammatory disorder such as vasculitis, sarcoidosis, or lymphoma. The hallmark of ADEM is the presence of widely scattered foci of perivenular inflammation and demyelination that can involve both white matter and grey matter structures, in contrast to larger confluent white matter lesions typical of MS. In the most explosive form of ADEM, acute hemorrhagic leukoencephalitis, the lesions are vasculitic and hemorrhagic, and the clinical course is devastating.

Postinfectious encephalomyelitis is most frequently associated with the viral exanthems of childhood. Infection with measles virus is the most common antecedent (1 in 1000 cases). Worldwide, measles encephalomyelitis is still common, although use of the live measles

vaccine has dramatically reduced its incidence in developed countries. An ADEM-like illness rarely follows vaccination with live measles vaccine (1–2 in 10^6 immunizations). ADEM is now most frequently associated with varicella (chickenpox) infections (1 in 4000–10,000 cases). It may also follow infection with rubella, mumps, influenza, parainfluenza, EBV, HHV-6, HIV, dengue, Zika, other viruses, and *Mycoplasma pneumoniae*. Recently, cases have been described in association with COVID-19 infection. Some patients may have a nonspecific upper respiratory infection or no known antecedent illness. In addition to measles, postvaccinal encephalomyelitis may also follow the administration of vaccines for smallpox (5 cases per million), the Semple rabies, and Japanese encephalitis. Modern vaccines that do not require viral culture in CNS tissue have reduced the ADEM risk.

All forms of ADEM presumably result from a cross-reactive immune response to the infectious agent or vaccine that then triggers an inflammatory demyelinating response. Autoantibodies to MBP and to other myelin antigens have been detected in the CSF from some patients with ADEM, and approximately half of children with ADEM have circulating and CSF antibodies against MOG **(Chap. 445)**. Attempts to demonstrate direct viral invasion of the CNS have been unsuccessful.

CLINICAL MANIFESTATIONS

In severe cases, onset is abrupt and progression rapid (hours to days). In postinfectious ADEM, the neurologic syndrome generally begins late in the course of the viral illness as the exanthem is fading. Fever reappears, and headache, meningismus, and lethargy progressing to coma may develop. Seizures are common. Signs of disseminated neurologic disease are consistently present (e.g., hemiparesis or quadriparesis, extensor plantar responses, lost or hyperactive tendon reflexes, sensory loss, and brainstem involvement). In ADEM due to chickenpox, cerebellar involvement is often conspicuous. CSF protein is modestly elevated (0.5–1.5 g/L [50–150 mg/dL]). Lymphocytic pleocytosis, generally ≥200 cells/μL, occurs in 80% of patients. Occasional patients have higher counts or a mixed polymorphonuclear-lymphocytic pattern during the initial days of the illness. Transient CSF oligoclonal banding has been reported. MRI usually reveals extensive changes in the brain and spinal cord, consisting of white matter hyperintensities on T2 and fluid-attenuated inversion recovery (FLAIR) sequences with Gd enhancement on T1-weighted sequences.

DIAGNOSIS

The diagnosis is most reliably established when there is a history of recent vaccination or viral exanthematous illness. In severe cases with predominantly cerebral involvement, acute encephalitis due to infection with herpes simplex or other viruses including HIV may be difficult to exclude; other considerations include hypercoagulable states including the antiphospholipid antibody syndrome, autoimmune (paraneoplastic) limbic encephalitis, vasculitis, neurosarcoid, primary CNS lymphoma, or metastatic cancer. An explosive presentation of MS can mimic ADEM, and, especially in adults, it may not be possible to distinguish these conditions at onset. The simultaneous onset of disseminated symptoms and signs is common in ADEM and rare in MS. Similarly, meningismus, drowsiness, coma, and seizures suggest ADEM rather than MS. Unlike MS, in ADEM, optic nerve involvement is generally bilateral and transverse myelopathy complete. MRI findings that favor ADEM include extensive and relatively symmetric white matter abnormalities, basal ganglia or cortical gray matter lesions, and Gd enhancement of all abnormal areas. By contrast, OCBs in the CSF are more common in MS. In one study of adult patients initially thought to have ADEM, 30% experienced additional relapses over a follow-up period of 3 years, and they were reclassified as having MS. Other patients initially classified as ADEM are subsequently found to have neuromyelitis optica spectrum disorder **(Chap. 445)**. Occasional patients with "recurrent ADEM" have also been reported, especially children; however, it is not possible to distinguish this entity from atypical MS. Because of the clinical overlap at presentation between ADEM and MS, it is crucial that routine surveillance imaging be performed following recovery from ADEM so that subclinical disease activity due to MS can be recognized and treatment for MS initiated.

TREATMENT

■ ACUTE DISSEMINATED ENCEPHALOMYELITIS

Initial treatment is with high-dose glucocorticoids; depending on the response, treatment may need to be continued for 8 weeks. Patients who fail to respond within a few days may benefit from a course of plasma exchange or intravenous immunoglobulin. The prognosis reflects the severity of the underlying acute illness. In recent case series of presumptive ADEM in adults, mortality rates of 5–20% are reported, and many survivors have permanent neurologic sequelae.

GLIAL FIBRILLARY ACIDIC PROTEIN (GFAP) AUTOIMMUNITY

Autoimmunity against the astrocyte protein GFAP presents with a range of symptoms referable to meningismus, encephalitis, myelitis, and optic neuritis. MRI shows characteristic patterns of gadolinium enhancement localized to GFAP-enriched CNS regions including venous structures in a periventricular radial orientation, the leptomeninges, the peri-ependymal spinal cord, and a striking serpiginous pattern involving brain parenchyma. These enhancement patterns share some similarities with patterns that can be observed in neurosarcoidosis. The presence of these patterns should prompt consideration for either condition. A lymphocytic pleocytosis is commonly present in the CSF. Antibodies against GFAP can be measured in the CSF or serum. GFAP autoimmunity is found as a paraneoplastic syndrome in 25% of cases, most commonly associated with ovarian teratoma, and can coexist with anti-*N*-methyl-D-aspartate receptor (NMDAR) encephalitis or neuromyelitis optica spectrum disorder (NMOSD). T cells are implicated in pathophysiology based on histopathology and association with checkpoint inhibitor treatment for cancer or in the setting of HIV. GFAP autoimmunity is generally glucocorticoid responsive. Early recognition with prompt intervention is associated with more favorable outcomes. Relapses occur in approximately 20% of patients and require use of immune suppression therapy.

445 Neuromyelitis Optica

Bruce A. C. Cree, Stephen L. Hauser

INTRODUCTION

Neuromyelitis optica (NMO; Devic's disease) is an aggressive inflammatory disorder characterized by recurrent attacks of optic neuritis (ON) and myelitis; the more inclusive term *NMO spectrum disorder* (NMOSD) was proposed to include individuals with partial forms, and also those with involvement of additional regions in the central nervous system **(Table 445-1)**. NMO is more frequent in women than men (9:1), and typically begins in adulthood, with a mean age of onset of 40 years, but can arise at any age. An important consideration, especially early in its presentation, is distinguishing NMO from multiple sclerosis (MS; **Chap. 444**). In patients with NMO, attacks of ON can be bilateral and produce severe visual loss (uncommon in MS); myelitis can be severe and transverse (rare in MS) and is typically longitudinally extensive **(Fig. 445-1)**, involving three or more contiguous vertebral segments. In contrast to MS, progressive symptoms typically do not occur in NMO. The brain MRI was earlier thought to be normal in NMO, but it is now recognized that in many cases brain lesions are present, including areas of nonspecific signal change as well as lesions associated with specific syndromes such as the hypothalamus causing an endocrinopathy; the area postrema in the lower medulla presenting as intractable hiccups or vomiting; or the cerebral hemispheres producing focal symptoms, encephalopathy, or seizures. Large MRI lesions in the cerebral hemispheres can be asymptomatic, sometimes have a "cloudlike" appearance and, unlike MS lesions, are often not destructive and can resolve completely. Spinal cord MRI lesions typically consist of focal enhancing areas of swelling and tissue destruction, extending over three or more spinal cord segments, and on axial sequences, these are centered on the grey matter of the cord. Cerebrospinal fluid (CSF) findings include pleocytosis greater than that observed in MS, with neutrophils and eosinophils present in many acute cases; oligoclonal bands (OCBs) are uncommon, occurring in <20% of NMO patients. The pathology of NMO is a distinctive astrocytopathy with inflammation, loss of astrocytes, and an absence of staining of the water channel protein AQP4 by immunohistochemistry, plus thickened blood vessel walls, demyelination, and deposition of antibody and complement.

TABLE 445-1 Diagnostic Criteria for Neuromyelitis Optica Spectrum Disorder

Diagnostic Criteria for NMOSD with AQP4-IgG

1. At least 1 core clinical characteristic
2. Positive test for AQP4-IgG using best-available detection method (cell-based assay strongly recommended)
3. Exclusion of alternative diagnoses

Diagnostic Criteria for NMOSD Without AQP4-IgG or NMOSD with Unknown AQP4-IgG Status

1. At least 2 core clinical characteristics occurring as a result of one or more clinical attacks and meeting all of the following requirements:
   a. At least 1 core clinical characteristic must be optic neuritis, acute myelitis with LETM, or area postrema syndrome
   b. Dissemination in space (2 or more different clinical characteristics)
   c. Fulfillment of additional MRI requirements, as applicable
2. Negative test for AQP4-IgG using best-available detection method or testing unavailable
3. Exclusion of alternative diagnoses

Core Clinical Characteristics

1. Optic neuritis
2. Acute myelitis
3. Area postrema syndrome: episode of otherwise unexplained hiccups or nausea or vomiting
4. Acute brainstem syndrome
5. Symptomatic narcolepsy or acute diencephalic clinical syndrome with NMOSD-typical diencephalic MRI lesions
6. Symptomatic cerebral syndrome with NMOSD-typical brain lesions

Additional MRI Requirements for NMOSD Without AQP4-IgG and NMOSD with Unknown AQP4-IgG Status

1. Acute optic neuritis: requires brain MRI showing (a) normal findings or only nonspecific white matter lesions, OR (b) optic nerve MRI with T2-hyperintense lesion of T1-weighted gadolinium-enhancing lesion extending over >1/2 optic nerve length or involving optic chiasm
2. Acute myelitis: requires associated intramedullary MRI lesion extending ≥3 contiguous segments (LETM) OR ≥3 contiguous segments of focal spinal cord atrophy in patients with history compatible with acute myelitis
3. Area postrema syndrome requires associated dorsal medulla/area postrema lesions
4. Acute brainstem syndrome requires periependymal brainstem lesions

IMMUNOLOGY

NMO is an autoimmune disease associated with a highly specific autoantibody directed against aquaporin-4 (AQP-4) that is present in the sera of ~90% of patients with a clinical diagnosis of NMO. AQP-4 is localized to the foot processes of astrocytes in close apposition to endothelial surfaces, as well as at paranodal regions near nodes of Ranvier. It is likely that AQP-4 antibodies are pathogenic because their passive transfer into laboratory animals can reproduce histologic features of the disease. Antibody-mediated complement fixation is thought to represent the primary mechanism of astrocyte injury in NMO. During acute attacks of myelitis, CSF levels of interleukin-6 (IL-6; a proinflammatory cytokine) and astrocyte-specific glial fibrillary acidic protein (GFAP) levels are markedly elevated, consistent with active inflammation and astrocyte injury. Proinflammatory T-lymphocytes of the Th17 type recognize an immunodominant epitope of AQP4 and may also contribute to pathogenesis. Because of the high specificity of the antibody, its presence is considered to be diagnostic when found in conjunction with a typical clinical presentation. Anti-AQP4 seropositive patients have a high risk for future relapses; more than half of untreated patients will relapse within 1 year.

CLINICAL COURSE

NMO is typically a recurrent disease; the course is monophasic in <10% of patients. Individuals who test negative for AQP4 antibodies are somewhat more likely to have a monophasic course. Untreated NMO is usually quite disabling over time; in one series, respiratory failure from cervical myelitis was present in one-third of patients, and 8 years after onset, 60% of patients were blind and more than half had permanent paralysis of one or more limbs. The long-term course of NMO appears to have been substantially improved with the development of therapies to treat acute attacks and prevent relapses. Estimates of the 5-year survival rate increased from 68–75% in 1999 to 91–98% in 2017, a change likely due to improved diagnosis and widespread use of immunosuppressant drugs.

GLOBAL CONSIDERATIONS

The incidence and prevalence of NMO show considerable variation between populations and geographic regions, with prevalence estimates that range from <1 to > 4 per 100,000. Although NMO can occur in people of any ethnic background, individuals of Asian and African origin are disproportionately affected. The highest reported prevalence is from Martinique. Among white populations, MS **(Chap. 444)** is far more common than NMO.

Interestingly, when MS affects individuals of African or Asian ancestry, there is a propensity for demyelinating lesions to involve predominantly the optic nerve and spinal cord, an MS subtype termed *opticospinal MS*. Some individuals with opticospinal MS are seropositive for AQP4 antibodies, indicating that such cases represent NMOSD.

ASSOCIATED CONDITIONS

Up to 40% of NMO patients have a systemic autoimmune disorder, such as systemic lupus erythematosus, Sjögren's syndrome, perinuclear antineutrophil cytoplasmic antibody (p-ANCA)–associated vasculitis, myasthenia

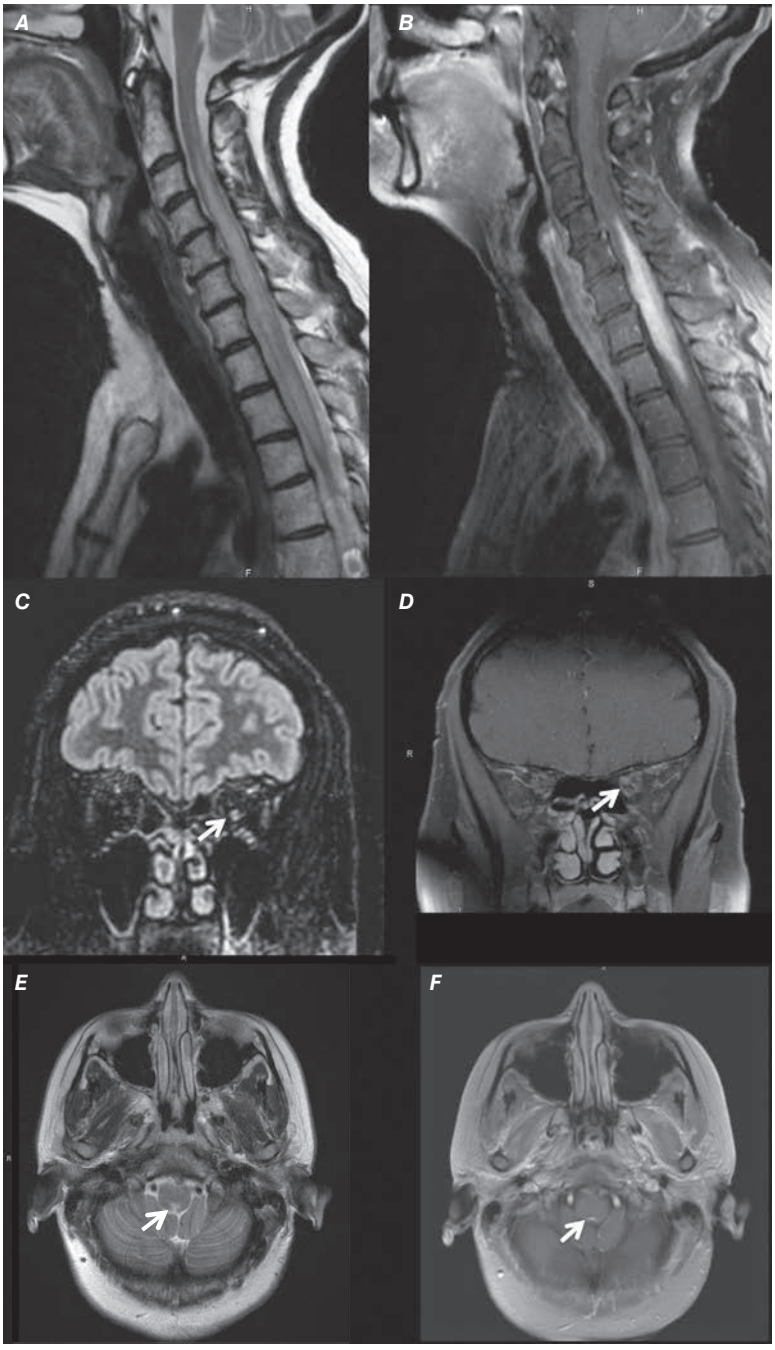

FIGURE 445-1 Imaging findings in neuromyelitis optica: longitudinally extensive transverse myelitis, optic neuritis, and brainstem involvement. ***A.*** Sagittal fluid attenuation inversion recovery (FLAIR) cervical-spine MRI showing an area of increased signal change on T2-weighted imaging spanning >3 vertebral segments in length. ***B.*** Sagittal T1-weighted cervical-spine MRI following gadolinium-diethylene triamine pentaacetic acid (DPTA) infusion showing enhancement. ***C.*** Coronal brain MRI shows hyperintense signal on FLAIR imaging within the left optic nerve. ***D.*** Coronal T1-weighted brain MRI following gadolinium-DPTA infusion shows enhancement of the left optic nerve. ***E.*** Axial brain MRI shows an area of hyperintense signal on T2-weighted imaging within the area postrema (*arrow*). ***F.*** Axial T1-weighted brain MRI following gadolinium-DPTA infusion shows punctate enhancement of the area postrema (*arrow*).

gravis, Hashimoto's thyroiditis, or mixed connective tissue disease. This is another feature distinct from MS; MS patients rarely have other comorbid autoimmune diseases with the exception of hypothyroidism. In some NMO cases, onset may be associated with acute infection with varicella zoster virus, Epstein-Barr virus, HIV, or tuberculosis. Rare cases appear to be paraneoplastic and associated with breast, lung, or other cancers.

TREATMENT

Neuromyelitis Optica

Until recently, disease-modifying therapies were not rigorously studied in NMO. Acute attacks are usually treated with high-dose glucocorticoids (e.g., methylprednisolone 1 g/d for 5–10 days followed by a prednisone taper). Plasma exchange (typically 5–7 exchanges of 1.5 plasma volumes/exchange) is used empirically for acute episodes that do not respond to glucocorticoids. Given the unfavorable natural history of untreated NMO, prophylaxis against relapses is recommended for most patients and several empiric regimens have been commonly used including: mycophenolate mofetil (1000 mg bid); the B-cell depleting anti-CD20 monoclonal antibody rituximab (2 g IV Q 6 months); or a combination of glucocorticoids (500 mg IV methylprednisolone daily for 5 days; then oral prednisone 1 mg/kg per day for 2 months, followed by slow taper) plus azathioprine (2 mg/kg per day started on week 3). Importantly, some therapies with efficacy in MS do not appear to be useful for NMO. Available evidence suggests that interferon beta is ineffective and paradoxically may increase the

TABLE 445-2 Therapeutic Trials for NMO

	RISK REDUCTION IN AQP4-SEROPOSITIVE PATIENTS
Eculizumab (add-on to immune suppression)	94%, P<0.001
Inolimomab (monotherapy)	78%, P=0.01
Satralizumab (add-on to immune suppression)	74%, P=0.001
Satralizumab (monotherapy)	77%, P<0.001

risk of NMO relapses, and based on limited data glatiramer acetate, fingolimod, natalizumab, and alemtuzumab also appear to be ineffective. These differences highlight the importance of distinguishing NMO from MS.

Three monoclonal antibody therapies have now received regulatory approval for attack prevention in NMO: eculizumab, a terminal complement inhibitor; inebilizumab, a B-cell depleter; and satralizumab, an IL-6 receptor blocker **(Table 445-2)**.

Eculizumab is a monoclonal antibody that binds to the complement protein C5, inhibiting its cleavage into C5a and C5b and preventing generation of the terminal complement attack complex C5b-9. Investigated as add-on therapy in AQP4 seropositive NMO, eculizumab lengthened the time to first attack by 94%, reduced the attack rate by 96%, and reduced rates of hospitalization, glucocorticoid, and plasma exchange use. Eculizumab is dosed as follows: 900 mg weekly for the first 4 weeks, followed by 1200 mg for the fifth dose 1 week later, then 1200 mg every 2 weeks thereafter.

Eculizumab is available only through a restricted program under a Risk Evaluation and Mitigation Strategy (REMS). Life-threatening and fatal meningococcal infections have occurred in eculizumab-treated patients (Boxed Warning). Eculizumab-treated patients should be immunized with meningococcal vaccines at least 2 weeks prior to administering the first dose unless the risk of delaying eculizumab therapy outweigh the risk of developing a meningococcal infection. Vaccination reduces, but does not eliminate, the risk of meningococcal infections. All eculizumab-treated patients must be monitored for early signs of meningococcal infections and evaluated immediately if infection is suspected.

Inebilizumab is a humanized monoclonal antibody that binds to the B-cell-specific surface antigen CD19 and depletes a wide range of B cells including some plasmablasts as well as a proportion of plasma cells in secondary lymphoid organs and bone marrow. Inebilizumab used as monotherapy reduced time to the first NMO attack by 77% compared to placebo, and also reduced hospitalizations by 78%, disability worsening by 63%, and new MRI lesions by 43%. Inebilizumab is dosed as follows: 300 mg IV infusion followed 2 weeks later by a second 300 mg IV infusion with subsequent doses of 300 mg infusions every 6 months thereafter.

Inebilizumab is associated with a dose-dependent decline in serum IgG levels and with neutropenia in some patients.

Satralizumab is a monoclonal antibody that binds to the interleukin-6 receptor, blocking engagement of IL-6. Satralizumab was investigated in NMOSD in two trials: one as monotherapy and the other as add-on therapy. Both AQP4 seropositive and AQP4 seronegative participants were enrolled. In both studies, the time to first attack was longer with satralizumab treatment compared with placebo. The risk of attack was reduced by 74% in the monotherapy study, and in the add-on study by 78%, with satralizumab. Although both studies recruited substantial numbers of AQP4 seronegative participants, there was no clinically meaningful impact of satralizumab in the seronegative participants. Satralizumab is administered as follows: a loading dosage of 120 mg by subcutaneous injection at weeks 0, 2, and 4, followed by a maintenance dosage of 120 mg every 4 weeks.

Screening for hepatitis B virus, tuberculosis, and liver transaminase elevations is required before starting satralizumab. Hepatic transaminases should be monitored during treatment for transaminase elevation, and CBC should be monitored during treatment for neutropenia. Satralizumab is also associated with weight gain.

MYELIN OLIGODENDROCYTE GLYCOPROTEIN-ANTIBODY-ASSOCIATED DISEASE (MOGAD)

Although long considered to be a likely target for antibody-mediated demyelination, anti-MOG antibodies detected by a cell-based assay that enables recognition of myelin oligodendrocyte glycoprotein (MOG) epitopes in a lipid bilayer were recently found to be associated with cases of acute disseminated encephalomyelitis (ADEM) **(Chap. 444)** in children, and then with cases of AQP4 seronegative NMO. Further studies showed that patients who are seropositive for anti-MOG antibodies are at risk for bilateral, synchronous optic neuritis and myelitis. A clinical feature that can help distinguish ON associated with MOGAD from NMO or MS is the presence of papillitis seen by funduscopy or orbital MRI. ON associated with MOGAD is typically longitudinally extensive on MRI, and brain MRI can be normal or show fluffy areas of increased signal change in white or grey matter structures, similar to NMO. MRI lesions that are typical for MS, including finger-like lesions oriented perpendicular to the ventricular surface (Dawson fingers) and T1-hypointense lesions, are uncommon. Spinal cord lesions can be longitudinally extensive or short and sometimes involve the conus medullaris. Demyelination associated with MOGAD is sometimes monophasic, as in ADEM, but can also be recurrent. The CSF may show a pleocytosis with occasional neutrophils. Elevated intrathecal synthesis of gammaglobulins is atypical: oligoclonal bands are present in ~6–13% of cases and intrathecal synthesis of anti-MOG antibodies does not occur. The mechanism of CNS injury in MOGAD is not established. Studies in MOG-induced experimental autoimmune encephalomyelitis suggest that anti-MOG antibodies may opsonize traces of MOG protein in secondary lymphoid tissues, triggering an encephalitogenic peripheral immune response.

Acute episodes are managed with high-dose glucocorticoids followed by a prednisone taper and sometimes by plasmapheresis, as with NMO. Brain lesions associated with MOGAD often respond rapidly to treatment with glucocorticoids and may resolve entirely. Some patients experience disease recurrence following discontinuation of prednisone and can become glucocorticoid dependent. Clinical trials have not been undertaken and there is limited data on other immune-suppressing medications typically used in NMO. Off-label empiric treatments include daily prednisone, IVIg, rituximab, and mycophenolate mofetil. Anti-MOG antibody titers appear to decline either spontaneously or in the setting of treatment.

Rare cases of relapsing optic nerve and spinal cord disease resembling NMOSD have recently been recognized in patients with autoantibodies against glial fibrillary acidic protein (GFAP), an astrocyte-specific protein, although more commonly the disorder presents as a meningoencephalitis resembling acute disseminated encephalomyelitis. **GFAP astrocytopathy is discussed in Chap. 444.**

Section 3 Nerve and Muscle Disorders

446 Peripheral Neuropathy

Anthony A. Amato, Richard J. Barohn

Peripheral nerves are composed of sensory, motor, and autonomic elements. Diseases can affect the cell body of a neuron or its peripheral processes, namely the axons or the encasing myelin sheaths. Most peripheral nerves are mixed and contain sensory and motor as well as autonomic fibers. Nerves can be subdivided into three major classes: large myelinated, small myelinated, and small unmyelinated. Motor axons are usually large myelinated fibers that conduct rapidly (~50 m/s). Sensory fibers may be any of the three types. Large-diameter sensory fibers conduct proprioception and vibratory sensation to the brain, while the smaller-diameter myelinated and unmyelinated fibers transmit pain and temperature sensation. Autonomic nerves are also small in diameter. Thus, peripheral neuropathies can impair sensory, motor, or autonomic function, either singly or in combination. Peripheral neuropathies are further classified into those that primarily affect the cell body (e.g., neuronopathy or ganglionopathy), myelin (myelinopathy), and the axon (axonopathy). These different classes of peripheral neuropathies have distinct clinical and electrophysiologic features. This chapter discusses the clinical approach to a patient suspected of having a peripheral neuropathy, as well as specific neuropathies, including hereditary and acquired neuropathies. **The inflammatory neuropathies are discussed in Chap. 447.**

GENERAL APPROACH

In approaching a patient with a neuropathy, the clinician has three main goals: (1) identify where the lesion is, (2) identify the cause, and (3) determine the proper treatment. The first goal is accomplished by obtaining a thorough history, neurologic examination, and electrodiagnostic and other laboratory studies **(Fig. 446-1)**. While gathering this information, seven key questions are asked **(Table 446-1)**, the answers to which help identify the pattern of involvement and the cause of the neuropathy **(Table 446-2)**. Despite an extensive evaluation, in approximately half of patients, no etiology is ever found; these patients typically have a predominately sensory polyneuropathy and have been labeled as having idiopathic or cryptogenic sensory and sensorimotor polyneuropathy (CSPN).

INFORMATION FROM THE HISTORY AND PHYSICAL EXAMINATION: SEVEN KEY QUESTIONS (TABLE 446-1)

1. What Systems Are Involved? It is important to determine if the patient's symptoms and signs are motor, sensory, autonomic, or a combination of these. If the patient has only weakness without any evidence of sensory or autonomic dysfunction, a motor neuropathy, neuromuscular junction abnormality, or myopathy should be considered. Some peripheral neuropathies are associated with significant autonomic nervous system dysfunction. Symptoms of autonomic involvement include fainting spells or orthostatic lightheadedness; heat intolerance; or any bowel, bladder, or sexual dysfunction **(Chap. 440)**. There will typically be an orthostatic fall in blood pressure without an appropriate increase in heart rate. Autonomic dysfunction in the absence of diabetes should alert the clinician to the possibility of amyloid polyneuropathy. Rarely, a pandysautonomic syndrome can be the only manifestation of a peripheral neuropathy without other motor or sensory findings. The majority of neuropathies are predominantly sensory in nature.

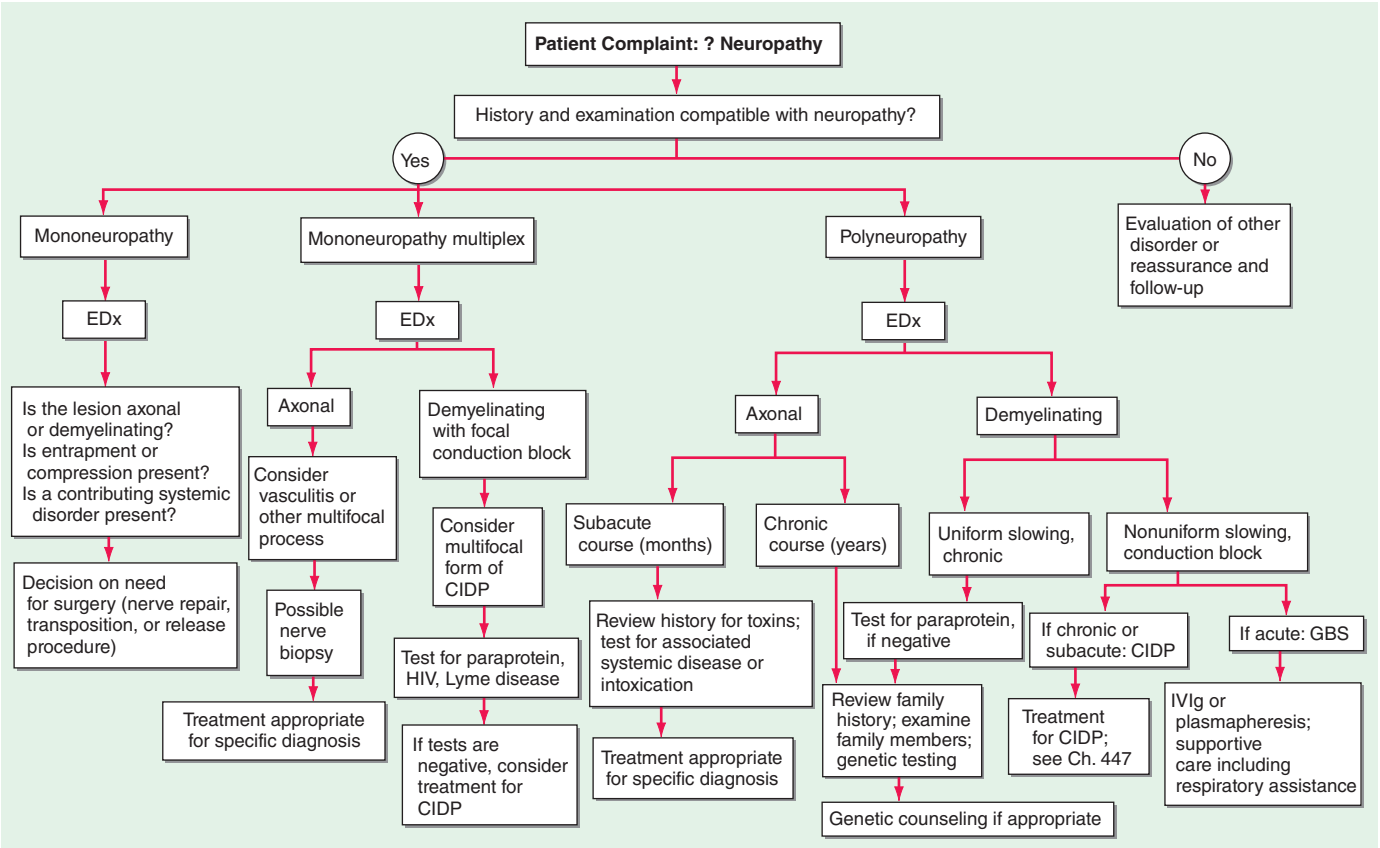

FIGURE 446-1 Approach to the evaluation of peripheral neuropathies. CIDP, chronic inflammatory demyelinating polyradiculoneuropathy; EDx, electrodiagnostic; GBS, Guillain-Barré syndrome; IVIg, intravenous immunoglobulin.

TABLE 446-1 Approach to Neuropathic Disorders: Seven Key Questions

1. **What systems are involved?**
   - Motor, sensory, autonomic, or combinations
2. **What is the distribution of weakness?**
   - Only distal versus proximal and distal
   - Focal/asymmetric versus symmetric
3. **What is the nature of the sensory involvement?**
   - Temperature loss or burning or stabbing pain (e.g., small fiber)
   - Vibratory or proprioceptive loss (e.g., large fiber)
4. **Is there evidence of upper motor neuron involvement?**
   - Without sensory loss
   - With sensory loss
5. **What is the temporal evolution?**
   - Acute (days to 4 weeks)
   - Subacute (4–8 weeks)
   - Chronic (>8 weeks)
   - Monophasic, progressive, or relapsing-remitting
6. **Is there evidence for a hereditary neuropathy?**
   - Family history of neuropathy
   - Lack of sensory symptoms despite sensory signs
7. **Are there any associated medical conditions?**
   - Cancer, diabetes mellitus, connective tissue disease or other autoimmune diseases, infection (e.g., HIV, Lyme disease, leprosy)
   - Medications including over-the-counter drugs that may cause a toxic neuropathy
   - Preceding events, drugs, toxins

2. What Is the Distribution of Weakness? Delineating the pattern of weakness, if present, is essential for diagnosis, and in this regard, two additional questions should be answered: (1) Does the weakness only involve the distal extremity, or is it both proximal and distal? and (2) Is the weakness focal and asymmetric, or is it symmetric? Symmetric proximal and distal weakness is the hallmark of acquired immune demyelinating polyneuropathies, both the acute form (Guillain-Barré syndrome [GBS]) and the chronic form (chronic inflammatory demyelinating polyneuropathy [CIDP]) **(Chap. 447)**. The importance of finding symmetric proximal and distal weakness in a patient who presents with both motor and sensory symptoms cannot be overemphasized because this identifies the important subset of patients who may have a treatable acquired demyelinating neuropathic disorder (i.e., GBS or CIDP).

Findings of an asymmetric or multifocal pattern of weakness narrow the differential diagnosis. Some neuropathic disorders may present with unilateral extremity weakness. In the absence of sensory symptoms and signs, such weakness evolving over weeks or months would be worrisome for motor neuron disease (e.g., amyotrophic lateral sclerosis [ALS]), but it would be important to exclude multifocal motor neuropathy that may be treatable **(Chap. 447)**. In a patient presenting with asymmetric subacute or acute sensory and motor symptoms and signs, radiculopathies, plexopathies, compressive mononeuropathies, or multiple mononeuropathies (e.g., mononeuropathy multiplex) must be considered.

ALS can produce prominent neck extensor weakness (head drop), tongue and pharyngeal weakness (dysarthria and dysphagia), or shortness of breath. These focal symmetric weakness patterns can also be seen in neuromuscular junction disorders (myasthenia gravis, Lambert-Eaton myasthenic syndrome [LEMS] **[Chap. 448]**) and some myopathies, particularly isolated neck extensor myopathy **(Chap. 449)**.

3. What Is the Nature of the Sensory Involvement? The patient may have loss of sensation (numbness), altered sensation to touch (hyperpathia or allodynia), or uncomfortable spontaneous sensations (tingling, burning, or aching) **(Chap. 25)**. Neuropathic pain can be burning, dull, and poorly localized (protopathic pain), presumably transmitted by polymodal C nociceptor fibers, or sharp and lancinating

TABLE 446-2 Patterns of Neuropathic Disorders

Pattern 1: Symmetric proximal and distal weakness with sensory loss
- Consider: inflammatory demyelinating polyneuropathy (GBS and CIDP)

Pattern 2: Symmetric distal sensory loss with or without distal weakness
- Consider: cryptogenic or idiopathic sensory polyneuropathy (CSPN), diabetes mellitus and other metabolic disorders, drugs, toxins, familial (HSAN), CMT, amyloidosis, and others

Pattern 3: Asymmetric distal weakness with sensory loss
- With involvement of multiple nerves
  - Consider: multifocal CIDP, vasculitis, cryoglobulinemia, amyloidosis, sarcoid, infectious (leprosy, Lyme, hepatitis B, C, or E, HIV, CMV), HNPP, tumor infiltration
- With involvement of single nerves/regions
  - Consider: may be any of the above but also could be compressive mononeuropathy, plexopathy, or radiculopathy

Pattern 4: Asymmetric proximal and distal weakness with sensory loss
- Consider: polyradiculopathy or plexopathy due to diabetes mellitus, meningeal carcinomatosis or lymphomatosis, sarcoid, amyloid, hereditary plexopathy (HNPP, HNA), idiopathic

Pattern 5: Asymmetric distal weakness without sensory loss
- With upper motor neuron findings
  - Consider: motor neuron disease
- Without upper motor neuron findings
  - Consider: progressive muscular atrophy, juvenile monomelic amyotrophy (Hirayama's disease), multifocal motor neuropathy, multifocal acquired motor axonopathy

Pattern 6: Symmetric sensory loss and distal areflexia with upper motor neuron findings
- Consider: vitamin B_{12}, vitamin E, and copper deficiency with combined system degeneration with peripheral neuropathy, chronic liver disease, hereditary leukodystrophies (e.g., adrenomyeloneuropathy) HSP-plus

Pattern 7: Symmetric weakness without sensory loss
- With proximal and distal weakness
  - Consider: SMA
- With distal weakness
  - Consider: hereditary motor neuropathy ("distal" SMA) or atypical CMT

Pattern 8: Focal midline proximal symmetric weakness
- Neck extensor weakness
  - Consider: ALS
- Bulbar weakness
  - Consider: ALS/PLS, isolated bulbar ALS (IBALS), Kennedy's syndrome (X-linked, bulbospinal SMA), bulbar presentation GBS
- Diaphragm weakness (SOB)
  - Consider: ALS

Pattern 9: Asymmetric proprioceptive sensory loss without weakness
- Consider causes of a sensory neuronopathy (ganglionopathy):
- Cancer (paraneoplastic)
- Sjögren's syndrome
- Idiopathic sensory neuronopathy (possible GBS variant)
- Cisplatin and other chemotherapeutic agents
- Vitamin B_6 toxicity
- HIV-related sensory neuronopathy

Pattern 10: Autonomic symptoms and signs
- Consider neuropathies associated with prominent autonomic dysfunction:
- Hereditary sensory and autonomic neuropathy
- Amyloidosis (familial and acquired)
- Diabetes mellitus
- GBS
- Idiopathic pandysautonomia (may be a variant of GBS)
- Porphyria
- HIV-related autonomic neuropathy
- Vincristine and other chemotherapeutic agents

Abbreviations: ALS, amyotrophic lateral sclerosis; CIDP, chronic inflammatory demyelinating polyneuropathy; CMT, Charcot-Marie-Tooth disease; CMV, cytomegalovirus; GBS, Guillain-Barré syndrome; HIV, human immunodeficiency virus; HNA, hereditary neuralgic amyotrophy; HNPP, hereditary neuropathy with liability to pressure palsies; HSAN, hereditary sensory and autonomic neuropathy; HSP-plus, hereditary spastic paraplegia plus neuropathy; PLS, primary lateral sclerosis; SMA, spinal muscular atrophy; SOB, shortness of breath.

(epicritic pain), relayed by A-delta fibers. If pain and temperature perception are lost, while vibratory and position sense are preserved along with muscle strength, deep tendon reflexes, and normal nerve conduction studies (NCS), a small-fiber neuropathy is likely. The most likely causes of small-fiber neuropathies, when one is identified, are diabetes mellitus (DM) or glucose intolerance. Amyloid neuropathy should be considered as well in such cases, but most of these small-fiber neuropathies remain idiopathic despite extensive evaluation.

Severe proprioceptive loss also narrows the differential diagnosis. Affected patients will note imbalance, especially in the dark. A neurologic examination revealing a dramatic loss of proprioception with vibration loss and normal strength should alert the clinician to consider a sensory neuronopathy/ganglionopathy (Pattern 9, Table 446-2). In particular, if this loss is asymmetric or affects the arms more than the legs, this pattern suggests a non-length-dependent process as seen in sensory neuronopathies.

4. Is There Evidence of Upper Motor Neuron Involvement? If the patient presents with symmetric distal sensory symptoms and signs suggestive of a distal sensory neuropathy, but there is additional evidence of symmetric upper motor neuron involvement **(Chap. 24)**, the physician should consider a combined system degeneration with neuropathy. The most common cause for this pattern is vitamin B_{12} deficiency, but other etiologies should also be considered (e.g., copper deficiency, human immunodeficiency virus [HIV] infection, severe hepatic disease, adrenomyeloneuropathy [AMN]), and hereditary spastic paraplegia plus a neuropathy.

5. What Is the Temporal Evolution? It is important to determine the onset, duration, and evolution of symptoms and signs. Does the disease have an acute (days to 4 weeks), subacute (4–8 weeks), or chronic (>8 weeks) course? Is the course monophasic, progressive, or relapsing? Most neuropathies are insidious and slowly progressive in nature. Neuropathies with acute and subacute presentations include GBS, vasculitis, and radiculopathies related to diabetes or Lyme disease. A relapsing course can be present in CIDP and porphyria.

6. Is There Evidence for a Hereditary Neuropathy? In patients with slowly progressive distal weakness over many years with few sensory symptoms yet significant sensory deficits on clinical examination, the clinician should consider a hereditary neuropathy (e.g., Charcot-Marie-Tooth disease [CMT]). On examination, the feet may show high or flat arches or hammer toes, and scoliosis may be present. In suspected cases, it may be necessary to perform neurologic and electrophysiologic studies on family members in addition to the patient.

7. Does the Patient Have Any Other Medical Conditions? It is important to inquire about associated medical conditions (e.g., DM, systemic lupus erythematosus [SLE]); preceding or concurrent infections (e.g. diarrheal illness preceding GBS); surgeries (e.g., gastric bypass and nutritional neuropathies); medications (toxic neuropathy), including over-the-counter vitamin preparations (B_6); alcohol; dietary habits; and use of dentures (e.g., fixatives contain zinc that can lead to copper deficiency).

PATTERN RECOGNITION APPROACH TO NEUROPATHIC DISORDERS

Based on the answers to the seven key questions, neuropathic disorders can be classified into several patterns based on the distribution or pattern of sensory, motor, and autonomic involvement (Table 446-2). Each pattern has a limited differential diagnosis, and information from laboratory studies usually permits a final diagnosis to be established.

ELECTRODIAGNOSTIC STUDIES

The electrodiagnostic (EDx) evaluation of patients with a suspected peripheral neuropathy consists of NCS and needle electromyography (EMG). In addition, studies of autonomic function can be valuable. The electrophysiologic data can confirm whether the neuropathic disorder is a mononeuropathy, multiple mononeuropathy (mononeuropathy multiplex), radiculopathy, plexopathy, or generalized polyneuropathy.

TABLE 446-3 Electrophysiologic Features: Axonal Degeneration versus Segmental Demyelination

	AXONAL DEGENERATION	SEGMENTAL DEMYELINATION
Motor Nerve Conduction Studies		
CMAP amplitude	Decreased	Normal (except with CB or distal dispersion)
Distal latency	Normal	Prolonged
Conduction velocity	Normal	Slow
Conduction block	Absent	Present
Temporal dispersion	Absent	Present
F wave	Normal or absent	Prolonged or absent
H reflex	Normal or absent	Prolonged or absent
Sensory Nerve Conduction Studies		
SNAP amplitude	Decreased	Normal or decreased
Distal latency	Normal	Prolonged
Conduction velocity	Normal	Slow
Needle EMG		
Spontaneous activity		
Fibrillations	Present	Absent
Fasciculations	Present	Absent
Motor unit potentials		
Recruitment	Decreased	Decreased
Morphology	Long duration, large amplitude, polyphasic (if there is reinnervation)	Normal

Abbreviations: CB, conduction block; CMAP, compound motor action potential; EMG, electromyography; SNAP, sensory nerve action potential.

Similarly, EDx evaluation can ascertain whether the process involves only sensory fibers, motor fibers, autonomic fibers, or a combination of these. Finally, the electrophysiologic data can help distinguish axonopathies from myelinopathies as well as axonal degeneration secondary to ganglionopathies from the more common length-dependent axonopathies.

NCS are most helpful in classifying a neuropathy as due to axonal degeneration or segmental demyelination **(Table 446-3)**. In general, low-amplitude potentials with relatively preserved distal latencies, conduction velocities, and late potentials, along with fibrillations on needle EMG, suggest an axonal neuropathy. On the other hand, slow conduction velocities, prolonged distal latencies and late potentials, relatively preserved amplitudes, and the absence of fibrillations on needle EMG imply a primary demyelinating neuropathy. The presence of nonuniform slowing of conduction velocity, conduction block, or temporal dispersion further suggests an acquired demyelinating neuropathy (e.g., GBS or CIDP) as opposed to a hereditary demyelinating neuropathy (e.g., CMT type 1).

Autonomic studies are used to assess small myelinated (A-delta) or unmyelinated (C) nerve fiber involvement. Such testing includes heart rate response to deep breathing, heart rate, and blood pressure response to both the Valsalva maneuver and tilt-table testing and quantitative sudomotor axon reflex testing **(Chap. 440)**. These studies are particularly useful in patients who have pure small-fiber neuropathy or autonomic neuropathy in which routine NCS are normal.

OTHER IMPORTANT LABORATORY INFORMATION

In patients with generalized symmetric peripheral neuropathy, a standard laboratory evaluation should include a complete blood count, basic chemistries including serum electrolytes and tests of renal and hepatic function, fasting blood glucose (FBS), hemoglobin (Hb) A_{1c}, urinalysis, thyroid function tests, B_{12}, folate, erythrocyte sedimentation rate (ESR), rheumatoid factor, antinuclear antibodies (ANA), serum protein electrophoresis (SPEP) and immunoelectrophoresis or immunofixation, and urine for Bence Jones protein. Quantification of the

concentration of serum-free light chains and the kappa/lambda ratio is more sensitive than SPEP, immunoelectrophoresis, or immunofixation to detect a monoclonal gammopathy and therefore should be done if amyloidosis is suspected. A skeletal survey should be performed in patients with acquired demyelinating neuropathies and M-spikes to look for osteosclerotic or lytic lesions. Patients with monoclonal gammopathy should also be referred to a hematologist for consideration of a bone marrow biopsy. An oral glucose tolerance test is indicated in patients with painful sensory neuropathies even if FBS and HbA_{1c} are normal, as the test is abnormal in about one-third of such patients. In addition to the above tests, patients with a mononeuropathy multiplex pattern of involvement should have a vasculitis workup, including antineutrophil cytoplasmic antibodies (ANCAs), cryoglobulins, hepatitis serology, Western blot for Lyme disease, HIV, and occasionally a cytomegalovirus (CMV) titer.

There are many autoantibody panels (various antiganglioside antibodies) marketed for screening routine neuropathy patients for a treatable condition. These autoantibodies have no proven clinical utility or added benefit beyond the information obtained from a complete clinical examination and detailed EDx. A heavy metal screen is also not necessary as a screening procedure, unless there is a history of possible exposure or suggestive features on examination (e.g., severe painful sensorimotor and autonomic neuropathy and alopecia—thallium; severe painful sensorimotor neuropathy with or without gastrointestinal [GI] disturbance and Mee's lines—arsenic; wrist or finger extensor weakness and anemia with basophilic stippling of red blood cells—lead).

In patients with suspected GBS or CIDP, a lumbar puncture is indicated to look for an elevated cerebrospinal fluid (CSF) protein. In idiopathic cases of GBS and CIDP, CSF pleocytosis is usually absent. If cells are present, one should consider HIV infection, Lyme disease, sarcoidosis, or lymphomatous or leukemic infiltration of nerve roots. Recently, serum IgG4 antibodies to neurofascin and contactin-2 have been discovered in CIDP with severe sensory ataxia, tremor, and distal weakness **(Chap. 447)**. These cases are difficult to treat with standard immunotherapies but may respond to rituximab. Some patients with GBS and CIDP have abnormal liver function tests. In these cases, it is important to also check for hepatitis B and C, HIV, CMV, and Epstein-Barr virus (EBV) infection. In patients with an axonal GBS (by EMG/NCS) or those with a suspicious coinciding history (e.g., unexplained abdominal pain, psychiatric illness, significant autonomic dysfunction), it is reasonable to screen for porphyria.

In patients with a severe sensory ataxia, a sensory ganglionopathy or neuronopathy should be considered. The most common causes of sensory ganglionopathies are Sjögren's syndrome **(Chap. 361)** and a paraneoplastic neuropathy **(Chap. 94)**. Neuropathy can be the initial manifestation of Sjögren's syndrome. Thus, one should always inquire about dry eyes and mouth in patients with sensory signs and symptoms. Further, some patients can manifest sicca complex without other manifestations of Sjögren's syndrome. Thus, patients with sensory ataxia should be tested for antibodies to SS-A/Ro and SS-B/La, in addition to the routine ANA. To evaluate a possible paraneoplastic sensory ganglionopathy, antineuronal nuclear antibodies (e.g., anti-Hu antibodies) should be obtained. These antibodies are most commonly seen in patients with small-cell carcinoma of the lung but are also present with breast, ovarian, lymphoma, and other cancers. Importantly, the paraneoplastic neuropathy can precede the detection of the cancer, and detection of these autoantibodies should lead to a search for malignancy.

NERVE BIOPSIES

Nerve biopsies are now rarely performed in the evaluation of neuropathies. The primary indication for nerve biopsy is suspicion for amyloid neuropathy or vasculitis. In most instances, the abnormalities present on biopsies do not help distinguish one form of peripheral neuropathy from another (beyond what is already apparent by clinical examination and the NCS). Nerve biopsies should only be performed when the NCS are abnormal. The sural nerve is most commonly biopsied because it is a pure sensory nerve and biopsy will not result in loss of motor function. In suspected vasculitis, a combination biopsy of a superficial peroneal nerve (pure sensory) and the underlying peroneus brevis muscle obtained from a single small incision increases the diagnostic yield. Tissue can be analyzed to assess for evidence of inflammation, vasculitis, or amyloid deposition. Semithin plastic sections, teased fiber preparations, and electron microscopy are used to assess the morphology of the nerve fibers and to distinguish axonopathies from myelinopathies.

SKIN BIOPSIES

Skin biopsies are sometimes used to diagnose a small-fiber neuropathy. Following a punch biopsy of the skin in the distal lower extremity, immunologic staining can be used to measure the density of small unmyelinated fibers. The density of these nerve fibers is reduced in patients with small-fiber neuropathies in whom NCS and routine nerve biopsies are often normal. This technique may allow for an objective measurement in patients with mainly subjective symptoms. However, it often adds little to what one already knows from the clinical examination and EDx.

SPECIFIC DISORDERS

HEREDITARY NEUROPATHIES

CMT disease is the most common type of hereditary neuropathy (Pattern 2, Table 446-2). Rather than one disease, CMT is a syndrome of many genetically distinct disorders **(Table 446-4)**. The various subtypes of CMT are classified according to the nerve conduction velocities (NCVs) and predominant pathology (e.g., demyelination or axonal degeneration), inheritance pattern (autosomal dominant, recessive, or X-linked), and the specific mutated genes. Type 1 CMT (or CMT1) refers to inherited demyelinating sensorimotor neuropathies, whereas the axonal sensory neuropathies are classified as CMT2. By definition, motor conduction velocities in the arms are slowed to <38 m/s in CMT1 and are >38 m/s in CMT2. However, most cases of CMT1 actually have motor NCVs between 20 and 25 m/s. CMT1 and CMT2 usually begin in childhood or early adult life; however, onset later in life can occur, particularly in CMT2. Both are inherited in an autosomal dominant fashion, with a few exceptions. CMT3 is an autosomal dominant neuropathy that appears in infancy and is associated with severe demyelination or hypomyelination. CMT4 is an autosomal recessive neuropathy that typically begins in childhood or early adult life. There are no medical therapies for any of the CMTs, but physical and occupational therapy can be beneficial, as can bracing (e.g., ankle-foot orthotics for foot drop) and other orthotic devices.

CMT1

CMT1 is the most common form of hereditary neuropathy. Affected individuals usually present in the first to third decade of life with distal leg weakness (e.g., foot drop), although patients may remain asymptomatic even late in life. People with CMT generally do not complain of numbness or tingling, which can be helpful in distinguishing CMT from acquired forms of neuropathy in which sensory symptoms usually predominate. Although usually asymptomatic, reduced sensation to all modalities is apparent on examination. Muscle stretch reflexes are unobtainable or reduced throughout. There is often atrophy of the muscles below the knee (particularly the anterior compartment), leading to so-called inverted champagne bottle legs.

Motor NCVs are generally in the 20–25 m/s range. Nerve biopsies usually are not performed on patients suspected of having CMT1, because the diagnosis usually can be made by less invasive testing (e.g., NCS and genetic studies). However, when done, the biopsies reveal reduced numbers of myelinated nerve fibers with a predilection for loss of large-diameter fibers and Schwann cell proliferation around thinly or demyelinated fibers, forming so-called onion bulbs.

CMT1A is the most common subtype of CMT1, representing 70% of cases, and is caused by a 1.5-megabase (Mb) duplication within chromosome 17p11.2-12 encoding the gene for peripheral myelin protein-22 (PMP-22). This results in patients having three copies of the PMP-22 gene rather than two. This protein accounts for 2–5% of myelin protein and is expressed in compact regions of the peripheral myelin sheath. Approximately 20% of patients with CMT1 have CMT1B,

TABLE 446-4 Classification of Charcot-Marie-Tooth Disease and Related Neuropathies

NAME	INHERITANCE	GENE LOCATION	GENE PRODUCT
CMT1			
CMT1A	AD	17p11.2	PMP-22 (usually duplication of gene)
CMT1B	AD	1q21-23	MPZ
CMT1C	AD	16p13.1-p12.3	LITAF
CMT1D	AD	10q21.1-22.1	ERG2
CMT1E (with deafness)	AD	17p11.2	Point mutations in *PMP-22* gene
CMT1F	AD	8p13-21	Neurofilament light chain
CMT1G	AD	8q21	PMP2

caused by mutations in the myelin protein zero (MPZ). CMT1B is for the most part clinically, electrophysiologically, and histologically indistinguishable from CMT1A. MPZ is an integral myelin protein and accounts for more than half of the myelin protein in peripheral nerves. Other forms of CMT1 are much less common and also indistinguishable from one another clinically and electrophysiologically.

CMT2

CMT2 occurs approximately half as frequently as CMT1, and CMT2 tends to present later in life. Affected individuals usually become symptomatic in the second decade; some cases present earlier in childhood, whereas others remain asymptomatic into late adult life. Clinically, CMT2 is for the most part indistinguishable from CMT1. NCS are helpful in this regard; in contrast to CMT1, the velocities are normal or only slightly slowed. The most common cause of CMT2 is a mutation in the gene for mitofusin 2 (MFN2), which accounts for ~20–30% of CMT2 cases overall. MFN2 localizes to the outer mitochondrial membrane, where it regulates the mitochondrial network architecture by participating in mitochondrial fusion. The other genes associated with CMT2 are much less common.

CMTDI

In dominant-intermediate CMTs (CMTDIs), the NCVs are faster than usually seen in CMT1 (e.g., >38 m/s) but slower than in CMT2.

CMT3

CMT3 was originally described by Dejerine and Sottas as a hereditary demyelinating sensorimotor polyneuropathy presenting in infancy or early childhood. Affected children are severely weak. Motor NCVs are markedly slowed, typically ≤5–10 m/s. Most cases of CMT3 are caused by point mutations in the genes for PMP-22, MPZ, or ERG-2, which are also the genes responsible for CMT1.

CMT4

CMT4 is extremely rare and is characterized by a severe, childhood-onset sensorimotor polyneuropathy that is usually inherited in an autosomal recessive fashion. Electrophysiologic and histologic evaluations can show demyelinating or axonal features. CMT4 is genetically heterogeneous (Table 446-4).

CMT1X

CMT1X is an X-linked dominant disorder with clinical features similar to CMT1 and CMT2, except that the neuropathy is much more severe in males than in females. CMT1X accounts for ~10–15% of CMT overall. Males usually present in the first two decades of life with atrophy and weakness of the distal arms and legs, areflexia, pes cavus, and hammer toes. Obligate female carriers are frequently asymptomatic

but can develop signs and symptoms of CMT. Onset in females is usually after the second decade of life, and the neuropathy is milder in severity.

NCS reveal features of both demyelination and axonal degeneration. In males, motor NCVs in the arms and legs are moderately slowed (in the low to mid 30-m/s range). About 50% of males with CMT1X have motor NCVs between 15 and 35 m/s with ~80% of these falling between 25 and 35 m/s (intermediate slowing). In contrast, ~80% of females with CMT1X have NCVs in the normal range and 20% have NCVs in the intermediate range. CMT1X is caused by mutations in the connexin-32 gene. Connexins are gap junction structural proteins that are important in cell-to-cell communication.

Hereditary Neuropathy with Liability to Pressure Palsies (HNPP) HNPP is an autosomal dominant disorder related to CMT1A. While CMT1A is usually associated with a 1.5-Mb duplication in chromosome 17p11.2 that results in an extra copy of PMP-22 gene, HNPP is caused by inheritance of the chromosome with the corresponding 1.5-Mb deletion of this segment, and thus, affected individuals have only one copy of the PMP-22 gene. Patients usually manifest in the second or third decade of life with painless numbness and weakness in the distribution of single peripheral nerves, although multiple mononeuropathies can occur (Pattern 3, Table 446-2). Symptomatic mononeuropathy or multiple mononeuropathies are often precipitated by trivial compression of nerve(s) as can occur with wearing a backpack, leaning on the elbows, or crossing one's legs for even a short period of time. These pressure-related mononeuropathies may take weeks or months to resolve. In addition, some affected individuals manifest with a progressive or relapsing, generalized and symmetric, sensorimotor peripheral neuropathy that resembles CMT.

Hereditary Neuralgic Amyotrophy (HNA) HNA is an autosomal dominant disorder characterized by recurrent attacks of pain, weakness, and sensory loss in the distribution of the brachial plexus often beginning in childhood (Pattern 4, Table 446-2). These attacks are similar to those seen with idiopathic brachial plexitis (see below). Attacks may occur in the postpartum period, following surgery, or at other times of stress. Most patients recover over several weeks or months. Slightly dysmorphic features, including hypotelorism, epicanthal folds, cleft palate, syndactyly, micrognathia, and facial asymmetry, are evident in some individuals. EDx demonstrate an axonal process. HNA is genetically heterogeneous but can be caused by mutations in septin 9 (*SEPT9*). Septins may be important in formation of the neuronal cytoskeleton and have a role in cell division, but it is not known how mutations in *SEPT9* lead to HNA.

Hereditary Sensory and Autonomic Neuropathy (HSAN) The HSANs are a very rare group of hereditary neuropathies in which sensory and autonomic dysfunction predominates over muscle weakness, unlike CMT, in which motor findings are most prominent (Pattern 2, Table 446-2; Table 446-4). Nevertheless, affected individuals can develop motor weakness, and there can be overlap with CMT. There are no medical therapies available to treat these neuropathies, other than prevention and treatment of mutilating skin and bone lesions.

Of the HSANs, only HSAN1 typically presents in adults. HSAN1 is the most common of the HSANs and is inherited in an autosomal dominant fashion. Affected individuals usually manifest in the second through fourth decades of life. HSAN1 is associated with the degeneration of small myelinated and unmyelinated nerve fibers leading to severe loss of pain and temperature sensation, deep dermal ulcerations, recurrent osteomyelitis, Charcot joints, bone loss, gross foot and hand deformities, and amputated digits. Although most people with HSAN1 do not complain of numbness, they often describe burning, aching, or lancinating pains. Autonomic neuropathy is not a prominent feature, but bladder dysfunction and reduced sweating in the feet may occur. HSAN1A, which is most common, is caused by mutations in the serine palmitoyltransferase long-chain base 1 (*SPTLC1*) gene.

OTHER HEREDITARY NEUROPATHIES (TABLE 446-5)

FABRY'S DISEASE

Fabry's disease (angiokeratoma corporis diffusum) is an X-linked dominant disorder. Although men are more commonly and severely affected, women can also manifest symptoms and signs of the disease. Angiokeratomas are reddish-purple maculopapular lesions that are usually found around the umbilicus, scrotum, inguinal region, and perineum. Burning or lancinating pain in the hands and feet often develops in males in late childhood or early adult life (Pattern 2, Table 446-2). However, the neuropathy is usually overshadowed by complications arising from an associated premature atherosclerosis (e.g., hypertension, renal failure, cardiac disease, and stroke) that often lead to death by the fifth decade of life. Some patients also manifest primarily with a dilated cardiomyopathy.

Fabry's disease is caused by mutations in the α-galactosidase gene that leads to the accumulation of ceramide trihexoside in nerves and blood vessels. A decrease in α-galactosidase activity is evident in leukocytes and cultured fibroblasts. Glycolipid granules may be appreciated in ganglion cells of the peripheral and sympathetic nervous systems and in perineurial cells. Enzyme replacement therapy with α-galactosidase B can improve the neuropathy if patients are treated early, before irreversible nerve fiber loss develops.

ADRENOLEUKODYSTROPHY/ ADRENOMYELONEUROPATHY

Adrenoleukodystrophy (ALD) and AMN are allelic X-linked dominant disorders caused by mutations in the peroxisomal transmembrane adenosine triphosphate-binding cassette (ABC) transporter gene. Patients with ALD manifest with central nervous system (CNS) abnormalities. However, ~30% of patients with mutations in this gene present with the AMN phenotype that typically manifests in the third to fifth decade of life as mild to moderate peripheral neuropathy combined with

Source: Modified from AA Amato, J Russell: *Neuromuscular Disorders,* 2nd ed. New York, McGraw-Hill, 2016, Table 12-1, p. 299.

progressive spastic paraplegia (Pattern 6, Table 446-2) (Chap. 442). Rare patients present with an adult-onset spinocerebellar ataxia or only with adrenal insufficiency.

EDx is suggestive of a primary axonopathy with secondary demyelination. Nerve biopsies demonstrate a loss of myelinated and unmyelinated nerve fibers with lamellar inclusions in the cytoplasm of Schwann cells. Very-long-chain fatty acid (VLCFA) levels (C24, C25, and C26) are increased in the urine. Laboratory evidence of adrenal insufficiency is evident in approximately two-thirds of patients. The diagnosis can be confirmed by genetic testing.

Adrenal insufficiency is managed by replacement therapy; however, there is no proven effective therapy for the neurologic manifestations of ALD/AMN. Diets low in VLCFAs and supplemented with Lorenzo's oil (erucic and oleic acids) reduce the levels of VLCFAs and increase the levels of C22 in serum, fibroblasts, and liver; however, several large, open-label trials of Lorenzo's oil failed to demonstrate efficacy.

REFSUM'S DISEASE

Refsum's disease can manifest in infancy to early adulthood with the classic tetrad of (1) peripheral neuropathy, (2) retinitis pigmentosa, (3) cerebellar ataxia, and (4) elevated CSF protein concentration. Most affected individuals develop progressive distal sensory loss and weakness in the legs leading to foot drop by their twenties (Pattern 2, Table 446-2). Subsequently, the proximal leg and arm muscles may become weak. Patients may also develop sensorineural hearing loss, cardiac conduction abnormalities, ichthyosis, and anosmia.

Serum phytanic acid levels are elevated. Sensory and motor NCS reveal reduced amplitudes, prolonged latencies, and slowed conduction velocities. Nerve biopsy demonstrates a loss of myelinated nerve fibers, with remaining axons often thinly myelinated and associated with onion bulb formation.

Refsum's disease is genetically heterogeneous but autosomal recessive in nature. Classical Refsum's disease with childhood or early adult onset is caused by mutations in the gene that encodes for phytanoyl-CoA α-hydroxylase (*PAHX*). Less commonly, mutations in the gene encoding peroxin 7 receptor protein (PRX7) are responsible. These mutations lead to the accumulation of phytanic acid in the central and peripheral nervous systems. Treatment is removal of phytanic precursors (phytols: fish oils, dairy products, and ruminant fats) from the diet.

TANGIER DISEASE

Tangier disease is a rare autosomal recessive disorder that can present as (1) asymmetric multiple mononeuropathies, (2) a slowly progressive symmetric polyneuropathy predominantly in the legs, or (3) a pseudo-syringomyelia pattern with dissociated sensory loss (i.e., abnormal pain/temperature perception but preserved position/vibration in the arms [Chap. 442]). The tonsils may appear swollen and yellowish-orange in color, and there may also be splenomegaly and lymphadenopathy.

Tangier disease is caused by mutations in the ATP-binding cassette transporter 1 (*ABC1*) gene, which leads to markedly reduced levels of high-density lipoprotein (HDL) cholesterol levels, whereas triacylglycerol levels are increased. Nerve biopsies reveal axonal degeneration with demyelination and remyelination. Electron microscopy demonstrates abnormal accumulation of lipid in Schwann cells, particularly those encompassing unmyelinated and small myelinated nerves. There is no specific treatment.

PORPHYRIA

Porphyria is a group of inherited disorders caused by defects in heme biosynthesis (Chap. 416). Three forms of porphyria are associated with peripheral neuropathy: acute intermittent porphyria (AIP), hereditary coproporphyria (HCP), and variegate porphyria (VP). The acute neurologic manifestations are similar in each, with the exception that a photosensitive rash is seen with HCP and VP but not in AIP. Attacks of porphyria can be precipitated by certain drugs (usually those metabolized by the P450 system), hormonal changes (e.g., pregnancy, menstrual cycle), and dietary restrictions.

An acute attack of porphyria may begin with sharp abdominal pain. Subsequently, patients may develop agitation, hallucinations, or seizures. Several days later, back and extremity pain followed by weakness ensues, mimicking GBS (Pattern 1, Table 446-2). Weakness can involve the arms or the legs and can be asymmetric, proximal, or distal in distribution, as well as affecting the face and bulbar musculature. Dysautonomia and signs of sympathetic overactivity are common (e.g., pupillary dilation, tachycardia, and hypertension). Constipation, urinary retention, and incontinence can also be seen.

The CSF protein is typically normal or mildly elevated. Liver function tests and hematologic parameters are usually normal. Some patients are hyponatremic due to inappropriate secretion of antidiuretic hormone (Chap. 378). The urine may appear brownish in color secondary to the high concentration of porphyrin metabolites. Accumulation of intermediary precursors of heme (i.e., d-aminolevulinic acid, porphobilinogen, uroporphobilinogen, coproporphyrinogen, and protoporphyrinogen) is found in urine. Specific enzyme activities can also be measured in erythrocytes and leukocytes. The primary abnormalities on EDx are marked reductions in compound motor action potential (CMAP) amplitudes and signs of active axonal degeneration on needle EMG.

The porphyrias are inherited in an autosomal dominant fashion. AIP is associated with porphobilinogen deaminase deficiency, HCP is caused by defects in coproporphyrin oxidase, and VP is associated with protoporphyrinogen oxidase deficiency. The pathogenesis of the neuropathy is not completely understood. Treatment with glucose and hematin may reduce the accumulation of heme precursors. Intravenous glucose is started at a rate of 10–20 g/h. If there is no improvement within 24 h, intravenous hematin 2–5 mg/kg per day for 3–14 days should be administered.

FAMILIAL AMYLOID POLYNEUROPATHY

Familial amyloid polyneuropathy (FAP) is phenotypically and genetically heterogeneous and is caused by mutations in the genes for transthyretin (TTR), apolipoprotein A1, or gelsolin (Chap. 112). The majority of patients with FAP have mutations in the TTR gene. Amyloid deposition may be evident in abdominal fat pad, rectal, or nerve biopsies. The clinical features, histopathology, and EDx reveal abnormalities consistent with a generalized or multifocal, predominantly axonal but occasionally demyelinating, polyneuropathy.

Patients with TTR-related FAP usually develop insidious onset of numbness and painful paresthesias in the distal lower limbs in the third to fourth decade of life, although some patients develop the disorder later in life (Pattern 2, Table 446-2). Carpal tunnel syndrome (CTS) is common. Autonomic involvement can be severe, leading to postural hypotension, constipation or persistent diarrhea, erectile dysfunction, and impaired sweating (Pattern 10, Table 446-2). Amyloid deposition also occurs in the heart, kidneys, liver, and corneas. Patients usually die 10–15 years after the onset of symptoms from cardiac failure or complications from malnutrition. Because the liver produces much of the body's TTR, liver transplantation has been used to treat FAP related to TTR mutations. Serum TTR levels decrease after transplantation, and improvement in clinical and EDx features has been reported. Both tafamidis meglumine (20 mg daily) and diflunisal (250 mg twice daily), which prevent misfolding and deposition of mutated TTR, appear to slow the rate of deterioration in patients with TTR-related FAP. Recently, two different modes of gene therapy that inhibit hepatic production of TTR have been shown to improve neurologic function and quality of life compared to placebo in clinical trials. Inotersen, an antisense oligonucleotide, is given subcutaneously once a week. The main side effects are thrombocytopenia and glomerulonephritis. Patisiran, a small interfering RNA, is give at a dose of 0.3 mg/kg (up to 30 mg) every 3 weeks. Infusion reactions are common; therefore, prophylactic corticosteroids, acetaminophen, and an antihistamine should be administered.

Patients with apolipoprotein A1–related FAP (Van Allen type) usually present in the fourth decade with numbness and painful dysesthesias in the distal limbs. Gradually, the symptoms progress, leading to proximal and distal weakness and atrophy. Although autonomic neuropathy is

not severe, some patients develop diarrhea, constipation, or gastroparesis. Most patients die from systemic complications of amyloidosis (e.g., renal failure) 12–15 years after the onset of the neuropathy.

Gelsolin-related amyloidosis (Finnish type) is characterized by the combination of lattice corneal dystrophy and multiple cranial neuropathies that usually begin in the third decade of life. Over time, a mild generalized sensorimotor polyneuropathy develops. Autonomic dysfunction does not occur.

ACQUIRED NEUROPATHIES

PRIMARY OR AL AMYLOIDOSIS (SEE CHAP. 112)

Besides FAP, amyloidosis can also be acquired. In primary or AL amyloidosis, the abnormal protein deposition is composed of immunoglobulin light chains. AL amyloidosis occurs in the setting of multiple myeloma (MM), Waldenström's macroglobulinemia, lymphoma, other plasmacytomas, or lymphoproliferative disorders, or without any other identifiable disease.

Approximately 30% of patients with AL primary amyloidosis present with a polyneuropathy, most typically painful dysesthesias and burning sensations in the feet (Pattern 2, Table 446-2). However, the trunk can be involved, and some patients manifest with a mononeuropathy multiplex pattern. CTS occurs in 25% of patients and may be the initial manifestation. The neuropathy is slowly progressive, and eventually, weakness develops along with large-fiber sensory loss. Most patients develop autonomic involvement with postural hypertension, syncope, bowel and bladder incontinence, constipation, impotence, and impaired sweating (Pattern 10, Table 446-2). Patients generally die from their systemic illness (renal failure, cardiac disease).

The monoclonal protein may be composed of IgG, IgA, IgM, or only free light chain. Lambda (λ) is more common than κ light chain (>2:1) in AL amyloidosis. The CSF protein is often increased (with normal cell count), and thus, the neuropathy may be mistaken for CIDP (Chap. 447). Nerve biopsies reveal axonal degeneration and amyloid deposition in either a globular or diffuse pattern infiltrating the perineurial, epineurial, and endoneurial connected tissue and in blood vessel walls.

The median survival of patients with primary amyloidosis is <2 years, with death usually from progressive congestive heart failure or renal failure. Chemotherapy with melphalan, prednisone, and colchicine, to reduce the concentration of monoclonal proteins, and autologous stem cell transplantation may prolong survival, but whether the neuropathy improves is controversial.

DIABETIC NEUROPATHY

DM is the most common cause of peripheral neuropathy in developed countries. DM is associated with several types of polyneuropathy: distal symmetric sensory or sensorimotor polyneuropathy, autonomic neuropathy, diabetic neuropathic cachexia, polyradiculoneuropathies, cranial neuropathies, and other mononeuropathies. Risk factors for the development of neuropathy include long-standing, poorly controlled DM and the presence of retinopathy and nephropathy.

Diabetic Distal Symmetric Sensory and Sensorimotor Polyneuropathy (DSPN) DSPN is the most common form of diabetic neuropathy and manifests as sensory loss beginning in the toes that gradually progresses over time up the legs and into the fingers and arms (Pattern 2, Table 446-2). When severe, a patient may develop sensory loss in the trunk (chest and abdomen), initially in the midline anteriorly and later extending laterally. Tingling, burning, deep aching pains may also be apparent. NCS usually show reduced amplitudes and mild to moderate slowing of conduction velocities. Nerve biopsy reveals axonal degeneration, endothelial hyperplasia, and, occasionally, perivascular inflammation. Tight control of glucose can reduce the risk of developing neuropathy or improve the underlying neuropathy. A variety of medications have been used with variable success to treat painful symptoms associated with DSPN, including antiepileptic medications, antidepressants, sodium channel blockers, and other analgesics (Table 446-6).

Diabetic Autonomic Neuropathy Autonomic neuropathy is typically seen in combination with DSPN. The autonomic neuropathy can manifest as abnormal sweating, dysfunctional thermoregulation, dry eyes and mouth, pupillary abnormalities, cardiac arrhythmias, postural hypotension, GI abnormalities (e.g., gastroparesis, postprandial bloating, chronic diarrhea, or constipation), and genitourinary dysfunction (e.g., impotence, retrograde ejaculation, incontinence) (Pattern 10, Table 446-2). Tests of autonomic function are generally abnormal, including sympathetic skin responses and quantitative

TABLE 446-6 Treatment of Painful Sensory Neuropathies

THERAPY	ROUTE	DOSE	SIDE EFFECTS
First-Line			
Lidoderm 5% patch	Apply to painful area	Up to 3 patches qd	Skin irritation
Tricyclic antidepressants (e.g., amitriptyline, nortriptyline)	PO	10–100 mg qhs	Cognitive changes, sedation, dry eyes and mouth, urinary retention, constipation
Gabapentin	PO	300–1200 mg tid	Cognitive changes, sedation, peripheral edema
Pregabalin	PO	50–100 mg tid	Cognitive changes, sedation, peripheral edema
Duloxetine	PO	30–60 mg qd	Cognitive changes, sedation, dry eyes, diaphoresis, nausea, diarrhea, constipation
Second-Line			
Carbamazepine	PO	200–400 mg q 6–8 h	Cognitive changes, dizziness, leukopenia, liver dysfunction
Phenytoin	PO	200–400 mg qhs	Cognitive changes, dizziness, liver dysfunction
Venlafaxine	PO	37.5–150 mg/d	Asthenia, sweating, nausea, constipation, anorexia, vomiting, somnolence, dry mouth, dizziness, nervousness, anxiety, tremor, and blurred vision as well as abnormal ejaculation/orgasm and impotence
Tramadol	PO	50 mg qid	Cognitive changes, gastrointestinal upset
Third-Line			
Mexiletine	PO	200–300 mg tid	Arrhythmias
Other Agents			
EMLA cream	Apply cutaneously	qid	Local erythema
2.5% lidocaine			
2.5% prilocaine			
Capsaicin 0.025–0.075% cream	Apply cutaneously	qid	Painful burning skin

sudomotor axon reflex testing. Sensory and motor NCS generally demonstrate features described above with DSPN.

Diabetic Radiculoplexus Neuropathy (Diabetic Amyotrophy or Bruns-Garland Syndrome) Diabetic radiculoplexus neuropathy is the presenting manifestation of DM in approximately one-third of patients. Typically, patients present with severe pain in the low back, hip, and thigh in one leg. Rarely, the diabetic polyradiculoneuropathy begins in both legs at the same time (Pattern 4, Table 446-2). Atrophy and weakness of proximal and distal muscles in the affected leg become apparent within a few days or weeks. The neuropathy is often accompanied or heralded by severe weight loss. Weakness usually progresses over several weeks or months but can continue to progress for 18 months or more. Subsequently, there is slow recovery, but many are left with residual weakness, sensory loss, and pain. In contrast to the more typical lumbosacral radiculoplexus neuropathy, some patients develop thoracic radiculopathy or, even less commonly, a cervical polyradiculoneuropathy. CSF protein is usually elevated, while the cell count is normal. ESR is often increased. EDx reveals evidence of active denervation in affected proximal and distal muscles in the affected limbs and in paraspinal muscles. Nerve biopsies may demonstrate axonal degeneration along with perivascular inflammation. Patients with severe pain are sometimes treated in the acute period with glucocorticoids, although a randomized controlled trial has yet to be performed, and the natural history of this neuropathy is gradual improvement.

Diabetic Mononeuropathies or Multiple Mononeuropathies The most common mononeuropathies are median neuropathy at the wrist and ulnar neuropathy at the elbow, but peroneal neuropathy at the fibular head and sciatic, lateral femoral, cutaneous, or cranial neuropathies also occur (Pattern 3, Table 446-2). In regard to cranial mononeuropathies, seventh nerve palsies are relatively common but may have other, nondiabetic etiologies. In diabetics, a third nerve palsy is most common, followed by sixth nerve and, less frequently, fourth nerve palsies. Diabetic third nerve palsies are characteristically pupil-sparing (Chap. 32).

HYPOTHYROIDISM

Hypothyroidism is more commonly associated with a proximal myopathy, but some patients develop a neuropathy, most typically CTS. Rarely, a generalized sensory polyneuropathy characterized by painful paresthesias and numbness in both the legs and hands can occur. Treatment is correction of the hypothyroidism.

SJÖGREN'S SYNDROME

Sjögren's syndrome, characterized by the sicca complex of xerophthalmia, xerostomia, and dryness of other mucous membranes, can be complicated by neuropathy (Chap. 361). Most common is a length-dependent axonal sensorimotor neuropathy characterized mainly by sensory loss in the distal extremities (Pattern 2, Table 446-2). A pure small-fiber neuropathy or a cranial neuropathy, particularly involving the trigeminal nerve, can also be seen. Sjögren's syndrome is also associated with sensory neuronopathy/ganglionopathy. Patients with sensory ganglionopathies develop progressive numbness and tingling of the limbs, trunk, and face in a non-length-dependent manner such that symptoms can involve the face or arms more than the legs. The onset can be acute or insidious. Sensory examination demonstrates severe vibratory and proprioceptive loss leading to sensory ataxia.

Patients with neuropathy due to Sjögren's syndrome may have ANAs, SS-A/Ro, and SS-B/La antibodies in the serum, but most do not. NCS demonstrate reduced amplitudes of sensory studies in the affected limbs. Nerve biopsy demonstrates axonal degeneration. Nonspecific perivascular inflammation may be present, but only rarely is there necrotizing vasculitis. There is no specific treatment for neuropathies related to Sjögren's syndrome. When vasculitis is suspected, immunosuppressive agents may be beneficial. Occasionally, the sensory neuronopathy/ganglionopathy stabilizes or improves with immunotherapy, such as intravenous immunoglobulin.

RHEUMATOID ARTHRITIS

Peripheral neuropathy occurs in at least 50% of patients with rheumatoid arthritis (RA) and may be vasculitic in nature (Chap. 358). Vasculitic neuropathy can present with a mononeuropathy multiplex (Pattern 3, Table 446-2), a generalized symmetric pattern of involvement (Pattern 2, Table 446-2), or a combination of these patterns (Chap. 363). Neuropathies may also result from drugs used to treat RA (e.g., tumor necrosis blockers, leflunomide). Nerve biopsy often reveals thickening of the epineurial and endoneurial blood vessels as well as perivascular inflammation or vasculitis, with transmural inflammatory cell infiltration and fibrinoid necrosis of vessel walls. The neuropathy is usually responsive to immunomodulating therapies.

SYSTEMIC LUPUS ERYTHEMATOSUS

Between 2 and 27% of individuals with SLE develop a peripheral neuropathy (Chap. 356). Affected patients typically present with a slowly progressive sensory loss beginning in the feet. Some patients develop burning pain and paresthesias with normal reflexes, and NCS suggest a pure small-fiber neuropathy (Pattern 2, Table 446-2). Less common are multiple mononeuropathies presumably secondary to necrotizing vasculitis (Pattern 3, Table 446-2). Rarely, a generalized sensorimotor polyneuropathy meeting clinical, laboratory, electrophysiologic, and histologic criteria for either GBS or CIDP may occur. Immunosuppressive therapy may be beneficial in SLE patients with neuropathy due to vasculitis. Immunosuppressive agents are less likely to be effective in patients with a generalized sensory or sensorimotor polyneuropathy without evidence of vasculitis. Patients with a GBS or CIDP-like neuropathy should be treated accordingly (Chap. 447).

SYSTEMIC SCLEROSIS (SCLERODERMA)

A distal symmetric, mainly sensory polyneuropathy complicates 5–67% of scleroderma cases (Pattern 2, Table 446-2) (Chap. 360). Cranial mononeuropathies can also develop, most commonly of the trigeminal nerve, producing numbness and dysesthesias in the face. Multiple mononeuropathies also occur (Pattern 3, Table 446-2). The EDx and histologic features of nerve biopsy are those of an axonal sensory greater than motor polyneuropathy.

MIXED CONNECTIVE TISSUE DISEASE (MCTD)

A mild distal axonal sensorimotor polyneuropathy occurs in ~10% of patients with MCTD.

SARCOIDOSIS

The peripheral nervous system or CNS is involved in ~5% of patients with sarcoidosis (Chap. 367). The most common cranial nerve involved is the seventh nerve, which can be affected bilaterally. Some patients develop radiculopathy or polyradiculopathy (Pattern 4, Table 446-2). With a generalized root involvement, the clinical presentation can mimic GBS or CIDP. Patients can also present with multiple mononeuropathies (Pattern 3, Table 446-2) or a generalized, slowly progressive, sensory greater than motor polyneuropathy (Pattern 2, Table 446-2). Some have features of a pure small-fiber neuropathy. EDx reveals an axonal neuropathy. Nerve biopsy can reveal noncaseating granulomas infiltrating the endoneurium, perineurium, or epineurium along with lymphocytic necrotizing angiitis. Neurosarcoidosis may respond to treatment with glucocorticoids or other immunosuppressive agents.

HYPEREOSINOPHILIC SYNDROME

Hypereosinophilic syndrome is characterized by eosinophilia associated with various skin, cardiac, hematologic, and neurologic abnormalities. A generalized peripheral neuropathy or a mononeuropathy multiplex occurs in 6–14% of patients (Pattern 2, Table 446-2).

CELIAC DISEASE (GLUTEN-INDUCED ENTEROPATHY OR NONTROPICAL SPRUE)

Neurologic complications, particularly ataxia and peripheral neuropathy, are estimated to occur in 10% of patients with celiac disease (Chap. 325). A generalized sensorimotor polyneuropathy, pure motor neuropathy, multiple mononeuropathies, autonomic neuropathy,

small-fiber neuropathy, and neuromyotonia have all been reported in association with celiac disease or antigliadin/antiendomysial antibodies (Patterns 2, 3, and 9; Table 446-2). Nerve biopsy may reveal a loss of large myelinated fibers. The neuropathy may be secondary to malabsorption of vitamins B_{12} and E. However, some patients have no appreciable vitamin deficiencies. The pathogenic basis for the neuropathy in these patients is unclear but may be autoimmune in etiology. The neuropathy does not appear to respond to a gluten-free diet. In patients with vitamin B_{12} or vitamin E deficiency, replacement therapy may improve or stabilize the neuropathy.

INFLAMMATORY BOWEL DISEASE

Ulcerative colitis and Crohn's disease may be complicated by GBS, CIDP, generalized axonal sensory or sensorimotor polyneuropathy, small-fiber neuropathy, or mononeuropathy (Patterns 2 and 3, Table 446-2) **(Chap. 326)**. These neuropathies may be autoimmune, nutritional (e.g., vitamin B_{12} deficiency), treatment related (e.g., metronidazole), or idiopathic in nature. An acute neuropathy with demyelination resembling GBS, CIDP, or multifocal motor neuropathy may occur in patients treated with tumor necrosis factor α blockers.

UREMIC NEUROPATHY

Approximately 60% of patients with renal failure develop a polyneuropathy characterized by length-dependent numbness, tingling, allodynia, and mild distal weakness (Pattern 2, Table 446-2). Rarely, a rapidly progressive weakness and sensory loss very similar to GBS can occur that improves with an increase in the intensity of renal dialysis or with transplantation (Pattern 1, Table 446-2). Mononeuropathies can also occur, the most common of which is CTS. Ischemic monomelic neuropathy (see below) can complicate arteriovenous shunts created in the arm for dialysis (Pattern 3, Table 446-2). EDx in uremic patients reveals features of a length-dependent, primarily axonal, sensorimotor polyneuropathy. Sural nerve biopsies demonstrate a loss of nerve fibers (particularly large myelinated nerve fibers), active axonal degeneration, and segmental and paranodal demyelination. The sensorimotor polyneuropathy can be stabilized by hemodialysis and improved with successful renal transplantation.

CHRONIC LIVER DISEASE

A generalized sensorimotor neuropathy characterized by numbness, tingling, and minor weakness in the distal aspects of primarily the lower limbs commonly occurs in patients with chronic liver failure. EDx studies are consistent with a sensory greater than motor axonopathy. Occasionally patients with severe liver disease develop a combined neuropathy and myopathy. Sural nerve biopsy reveals both segmental demyelination and axonal loss. It is not known if hepatic failure in isolation can cause peripheral neuropathy, as the majority of patients have liver disease secondary to other disorders, such as alcoholism or viral hepatitis, which can also cause neuropathy.

CRITICAL ILLNESS POLYNEUROPATHY

The most common causes of acute generalized weakness leading to admission to a medical intensive care unit (ICU) are GBS and myasthenia gravis (Pattern 1, Table 446-2) **(Chaps. 447 and 448)**. However, weakness developing in critically ill patients while in the ICU is usually caused by critical illness polyneuropathy (CIP) or critical illness myopathy (CIM) or, much less commonly, by prolonged neuromuscular blockade. From a clinical and EDx standpoint, it can be quite difficult to distinguish these disorders. Most specialists believe that CIM is more common. Both CIM and CIP develop as a complication of sepsis and multiple organ failure. They usually present as an inability to wean a patient from a ventilator. A coexisting encephalopathy may limit the neurologic examination, in particular the sensory examination. Muscle stretch reflexes are absent or reduced.

Serum creatine kinase (CK) is usually normal; an elevated serum CK would point to CIM as opposed to CIP. NCS reveal absent or markedly reduced amplitudes of motor and sensory studies in CIP, whereas sensory studies are relatively preserved in CIM. Needle EMG usually reveals profuse positive sharp waves and fibrillation potentials, and it is not unusual in patients with severe weakness to be unable to recruit motor unit action potentials. The pathogenic basis of CIP is not known. Perhaps circulating toxins and metabolic abnormalities associated with sepsis and multiorgan failure impair axonal transport or mitochondrial function, leading to axonal degeneration.

LEPROSY (HANSEN'S DISEASE)

Leprosy, caused by the acid-fast bacteria *Mycobacterium leprae*, is the most common cause of peripheral neuropathy in Southeast Asia, Africa, and South America **(Chap. 179)**. Clinical manifestations range from tuberculoid leprosy at one end of the spectrum to lepromatous leprosy at the other end, with borderline leprosy in between. Neuropathies are most common in patients with borderline leprosy. Superficial cutaneous nerves of the ears and distal limbs are commonly affected. Mononeuropathies, multiple mononeuropathies, or a slowly progressive symmetric sensorimotor polyneuropathy may develop (Patterns 2 and 3, Table 446-2). Sensory NCS are usually absent in the lower limb and are reduced in amplitude in the arms. Motor NCS may demonstrate reduced amplitudes in affected nerves but occasionally can reveal demyelinating features. Leprosy is usually diagnosed by skin lesion biopsy. Nerve biopsy can also be diagnostic, particularly when there are no apparent skin lesions. The tuberculoid form is characterized by granulomas, and bacilli are not seen. In contrast, with lepromatous leprosy, large numbers of infiltrating bacilli, T_H2 lymphocytes, and organism-laden, foamy macrophages with minimal granulomatous infiltration are evident. The bacilli are best appreciated using the Fite stain, where they can be seen as red-staining rods often in clusters free in the endoneurium, within macrophages, or within Schwann cells.

Patients are generally treated with multiple drugs: dapsone, rifampin, and clofazimine. Other medications that are used include thalidomide, pefloxacin, ofloxacin, sparfloxacin, minocycline, and clarithromycin. Patients are generally treated for 2 years. Treatment is sometimes complicated by the so-called reversal reaction, particularly in borderline leprosy. The reversal reaction can occur at any time during treatment and develops because of a shift to the tuberculoid end of the spectrum, with an increase in cellular immunity during treatment. The cellular response is upregulated as evidenced by an increased release of tumor necrosis factor α, interferon γ, and interleukin 2, with new granuloma formation. This can result in an exacerbation of the rash and the neuropathy as well as in appearance of new lesions. High-dose glucocorticoids blunt this adverse reaction and may be used prophylactically at treatment onset in high-risk patients. Erythema nodosum leprosum (ENL) is also treated with glucocorticoids or thalidomide.

LYME DISEASE

Lyme disease is caused by infection with *Borrelia burgdorferi*, a spirochete usually transmitted by the deer tick *Ixodes dammini* **(Chap. 186)**. Neurologic complications may develop during the second and third stages of infection. Facial neuropathy is most common and is bilateral in about half of cases, which is rare for idiopathic Bell's palsy. Involvement of nerves is frequently asymmetric. Some patients present with a polyradiculoneuropathy or multiple mononeuropathies (Pattern 3 or 4, Table 446-2). EDx is suggestive of a primary axonopathy. Nerve biopsies can reveal axonal degeneration with perivascular inflammation. Treatment is with antibiotics.

DIPHTHERITIC NEUROPATHY

Diphtheria is caused by the bacteria *Corynebacterium diphtheriae* **(Chap. 150)**. Infected individuals present with flulike symptoms of generalized myalgias, headache, fatigue, low-grade fever, and irritability within a week to 10 days of the exposure. About 20–70% of patients develop a peripheral neuropathy caused by a toxin released by the bacteria. Three to 4 weeks after infection, patients may note decreased sensation in their throat and begin to develop dysphagia, dysarthria, hoarseness, and blurred vision due to impaired accommodation. A generalized polyneuropathy may manifest 2 or 3 months following the initial infection, characterized by numbness, paresthesias, and weakness of the arms and legs and occasionally ventilatory failure (Pattern 1, Table 446-2). CSF protein can be elevated with or without lymphocytic

pleocytosis. EDx suggests a diffuse axonal sensorimotor polyneuropathy. Antitoxin and antibiotics should be given within 48 h of symptom onset. Although early treatment reduces the incidence and severity of some complications (i.e., cardiomyopathy), it does not appear to alter the natural history of the associated peripheral neuropathy. The neuropathy usually resolves after several months.

COVID-19

GBS **(Chap. 447)** has been reported in the setting of acute COVID-19 infection.

HUMAN IMMUNODEFICIENCY VIRUS

HIV infection can result in a variety of neurologic complications, including peripheral neuropathies **(Chap. 202)**. Approximately 20% of HIV-infected individuals develop a neuropathy as a direct result of the virus itself or as a result of other associated viral infections (e.g., CMV) or neurotoxicity secondary to antiviral medications (see below). The major presentations of peripheral neuropathy associated with HIV infection include (1) distal symmetric polyneuropathy (DSP), (2) inflammatory demyelinating polyneuropathy (including both GBS and CIDP), (3) multiple mononeuropathies (e.g., vasculitis, CMV-related), (4) polyradiculopathy (usually CMV-related), (5) autonomic neuropathy, and (6) sensory ganglionitis.

HIV-Related Distal Symmetric Polyneuropathy DSP is the most common form of peripheral neuropathy associated with HIV infection and usually is seen in patients with AIDS. It is characterized by numbness and painful paresthesias involving the distal extremities (Pattern 2, Table 446-2). The pathogenic basis for DSP is unknown but is not due to actual infection of the peripheral nerves. The neuropathy may be immune mediated, perhaps caused by the release of cytokines from surrounding inflammatory cells. Vitamin B_{12} deficiency may contribute in some instances but is not a major cause of most cases of DSP. Older antiretroviral agents (e.g., dideoxycytidine, dideoxyinosine, stavudine) are also neurotoxic and can cause a painful sensory neuropathy.

HIV-Related Inflammatory Demyelinating Polyradiculoneuropathy Both acute inflammatory demyelinating polyneuropathy (AIDP) and CIDP can occur as a complication of HIV infection (Pattern 1, Table 446-2). AIDP usually develops at the time of seroconversion, whereas CIDP can occur any time in the course of the infection. Clinical and EDx features are indistinguishable from idiopathic AIDP or CIDP **(Chap. 447)**. In addition to elevated protein levels, lymphocytic pleocytosis is evident in the CSF, a finding that helps distinguish this HIV-associated polyradiculoneuropathy from idiopathic AIDP/CIDP.

HIV-Related Progressive Polyradiculopathy An acute, progressive lumbosacral polyradiculoneuropathy usually secondary to CMV infection can develop in patients with AIDS (Pattern 4, Table 446-2). Patients present with severe radicular pain, numbness, and weakness in the legs, which is usually asymmetric. CSF is abnormal, demonstrating a high protein level, along with a reduced glucose concentration and notably a neutrophilic pleocytosis. EDx studies reveal features of active axonal degeneration. The polyradiculoneuropathy may improve with antiviral therapy.

HIV-Related Multiple Mononeuropathies Multiple mononeuropathies can also develop in patients with HIV infection, usually in the context of AIDS. Weakness, numbness, paresthesias, and pain occur in the distribution of affected nerves (Pattern 3, Table 446-2). Nerve biopsies can reveal axonal degeneration with necrotizing vasculitis or perivascular inflammation. Glucocorticoid treatment is indicated for vasculitis directly due to HIV infection.

HIV-Related Sensory Neuronopathy/Ganglionopathy Dorsal root ganglionitis is a very rare complication of HIV infection, and neuronopathy can be the presenting manifestation. Patients develop sensory ataxia similar to idiopathic sensory neuronopathy/ganglionopathy (Pattern 9, Table 446-2). NCS reveal reduced amplitudes or absence of sensory nerve action potentials (SNAPs).

HERPES VARICELLA-ZOSTER VIRUS

Peripheral neuropathy from herpes varicella-zoster (HVZ) infection results from reactivation of latent virus or from a primary infection **(Chap. 193)**. Two-thirds of infections in adults are characterized by dermal zoster in which severe pain and paresthesias develop in a dermatomal region followed within a week or two by a vesicular rash in the same distribution (Pattern 3, Table 446-2). Weakness in muscles innervated by roots corresponding to the dermatomal distribution of skin lesions occurs in 5–30% of patients. Approximately 25% of affected patients have continued pain (postherpetic neuralgia [PHN]). A large clinical trial demonstrated that vaccination against zoster reduces the incidence of HVZ among vaccine recipients by 51% and reduces the incidence of PHN by 67%. Treatment of PHN is symptomatic (Table 446-6).

CYTOMEGALOVIRUS

CMV can cause an acute lumbosacral polyradiculopathy and multiple mononeuropathies in patients with HIV infection and in other immune deficiency conditions (Pattern 4, Table 446-2) **(Chap. 195)**.

EPSTEIN-BARR VIRUS

EBV infection has been associated with GBS, cranial neuropathies, mononeuropathy multiplex, brachial plexopathy, lumbosacral radiculoplexopathy, and sensory neuronopathies (Patterns 1, 3, 4, and 9, Table 446-2) **(Chap. 194)**.

HEPATITIS VIRUSES

Hepatitis B and C can cause multiple mononeuropathies related to vasculitis, AIDP, or CIDP (Patterns 1 and 3, Table 446-2) **(Chap. 341)**.

NEUROPATHIES ASSOCIATED WITH MALIGNANCY

Patients with malignancy can develop neuropathies due to (1) a direct effect of the cancer by invasion or compression of the nerves, (2) remote or paraneoplastic effect, (3) a toxic effect of treatment, or (4) as a consequence of immune compromise caused by immunosuppressive medications. The most common associated malignancy is lung cancer, but neuropathies also complicate carcinoma of the breast, ovaries, stomach, colon, rectum, and other organs, including the lymphoproliferative system.

PARANEOPLASTIC SENSORY NEURONOPATHY/GANGLIONOPATHY

Paraneoplastic encephalomyelitis/sensory neuronopathy (PEM/SN) usually complicates small-cell lung carcinoma **(Chap. 94)**. Patients usually present with numbness and paresthesias in the distal extremities that are often asymmetric. The onset can be acute or insidiously progressive. Prominent loss of proprioception leads to sensory ataxia (Pattern 9; Table 446-2). Weakness can be present, usually secondary to an associated myelitis, motor neuronopathy, or concurrent LEMS. Many patients also develop confusion, memory loss, depression, hallucinations or seizures, or cerebellar ataxia. Polyclonal antineuronal antibodies (IgG) directed against a 35- to 40-kDa protein or complex of proteins, the so-called Hu antigen, are found in the sera or CSF in the majority of patients with paraneoplastic PEM/SN. CSF may be normal or may demonstrate mild lymphocytic pleocytosis and elevated protein. PEM/SN is probably the result of antigenic similarity between proteins expressed in the tumor cells and neuronal cells, leading to an immune response directed against both cell types. Treatment of the underlying cancer generally does not affect the course of PEM/SN. However, occasional patients may improve following treatment of the tumor. Unfortunately, plasmapheresis, intravenous immunoglobulin, and immunosuppressive agents have not shown benefit.

NEUROPATHY SECONDARY TO TUMOR INFILTRATION

Malignant cells, in particular leukemia and lymphoma, can infiltrate cranial and peripheral nerves, leading to mononeuropathy, mononeuropathy multiplex, polyradiculopathy, plexopathy, or even a generalized symmetric distal or proximal and distal polyneuropathy (Patterns 1, 2,

3, and 4; Table 446-2). Neuropathy related to tumor infiltration is often painful; it can be the presenting manifestation of the cancer or the heralding symptom of a relapse. The neuropathy may improve with treatment of the underlying leukemia or lymphoma or with glucocorticoids.

NEUROPATHY AS A COMPLICATION OF BONE MARROW TRANSPLANTATION

Neuropathies may develop in patients who undergo bone marrow transplantation (BMT) because of the toxic effects of chemotherapy, radiation, infection, or an autoimmune response directed against the peripheral nerves. Peripheral neuropathy in BMT is often associated with graft-versus-host disease (GVHD). Chronic GVHD shares many features with a variety of autoimmune disorders, and it is possible that an immune-mediated response directed against peripheral nerves is responsible. Patients with chronic GVHD may develop cranial neuropathies, sensorimotor polyneuropathies, multiple mononeuropathies, and severe generalized peripheral neuropathies resembling AIDP or CIDP (Patterns 1, 2, and 3; Table 446-2). The neuropathy may improve by increasing the intensity of immunosuppressive or immunomodulating therapy and resolution of the GVHD.

LYMPHOMA

Lymphomas may cause neuropathy by infiltration or direct compression of nerves or by a paraneoplastic process. The neuropathy can be purely sensory or motor but most commonly is sensorimotor. The pattern of involvement may be symmetric, asymmetric, or multifocal, and the course may be acute, gradually progressive, or relapsing and remitting (Patterns 1, 2, and 3; Table 446-2). EDx can be compatible with either an axonal or demyelinating process. CSF may reveal lymphocytic pleocytosis and an elevated protein. Nerve biopsy may demonstrate endoneurial inflammatory cells in both the infiltrative and the paraneoplastic etiologies. A monoclonal population of cells favors lymphomatous invasion. The neuropathy may respond to treatment of the underlying lymphoma or immunomodulating therapies.

MULTIPLE MYELOMA

MM usually presents in the fifth to seventh decade of life with fatigue, bone pain, anemia, and hypercalcemia **(Chap. 111)**. Clinical and EDx features of neuropathy occur in as many as 40% of patients. The most common pattern is that of a distal, axonal, sensory, or sensorimotor polyneuropathy (Pattern 2; Table 446-2). Less frequently, a chronic demyelinating polyradiculoneuropathy may develop (Pattern 1; Table 446-2) (see POEMS, **Chap. 447**). MM can be complicated by amyloid polyneuropathy and should be considered in patients with painful paresthesias, loss of pinprick and temperature discrimination, and autonomic dysfunction (suggestive of a small-fiber neuropathy) and CTS. Expanding plasmacytomas can compress cranial nerves and spinal roots as well. A monoclonal protein, usually composed of γ or μ heavy chains or κ light chains, may be identified in the serum or urine. EDx usually shows reduced amplitudes with normal or only mildly abnormal distal latencies and conduction velocities. A superimposed median neuropathy at the wrist is common. Abdominal fat pad, rectal, or sural nerve biopsy can be performed to look for amyloid deposition. Unfortunately, the treatment of the underlying MM does not usually affect the course of the neuropathy.

NEUROPATHIES ASSOCIATED WITH MONOCLONAL GAMMOPATHY OF UNCERTAIN SIGNIFICANCE (SEE CHAP. 447)

Toxic Neuropathies Secondary to Chemotherapy Many of the commonly used chemotherapy agents can cause a toxic neuropathy **(Table 446-7)**. The mechanisms by which these agents cause toxic neuropathies vary, as does the specific type of neuropathy produced. The risk of developing a toxic neuropathy or more severe neuropathy appears to be greater in patients with a preexisting neuropathy (e.g., CMT disease, diabetic neuropathy) and those who also take other potentially neurotoxic drugs (e.g., nitrofurantoin, isoniazid, disulfiram, pyridoxine). Chemotherapeutic agents usually cause a sensory greater than motor length-dependent axonal neuropathy or neuronopathy/ganglionopathy (Patterns 2 and 9; Table 446-2).

OTHER TOXIC NEUROPATHIES

Neuropathies can develop as complications of toxic effects of various drugs and other environmental exposures **(Table 446-8)**. The more common neuropathies associated with these agents are discussed here.

CHLOROQUINE AND HYDROXYCHLOROQUINE

Chloroquine and hydroxychloroquine can cause a toxic myopathy characterized by slowly progressive, painless, proximal weakness and atrophy, which is worse in the legs than the arms. In addition, neuropathy can also develop with or without the myopathy leading to sensory loss and distal weakness. The "neuromyopathy" usually appears in patients taking 500 mg daily for a year or more but has been reported with doses as low as 200 mg/d. Serum CK levels are usually elevated due to the superimposed myopathy. NCS reveal mild slowing of motor and sensory NCVs with a mild to moderate reduction in the amplitudes, although NCS may be normal in patients with only the myopathy. EMG demonstrates myopathic muscle action potentials (MUAPs), increased insertional activity in the form of positive sharp waves, fibrillation potentials, and occasionally myotonic potentials, particularly in the proximal muscles. Neurogenic MUAPs and reduced recruitment are found in more distal muscles. Nerve biopsy demonstrates autophagic vacuoles within Schwann cells. Vacuoles may also be evident in muscle biopsies. The pathogenic basis of the neuropathy is not known but may be related to the amphiphilic properties of the drug. These agents contain both hydrophobic and hydrophilic regions that allow them to interact with the anionic phospholipids of cell membranes and organelles. The drug-lipid complexes may be resistant to digestion by lysosomal enzymes, leading to the formation of autophagic vacuoles filled with myeloid debris that may in turn cause degeneration of nerves and muscle fibers. The signs and symptoms of the neuropathy and myopathy are usually reversible following discontinuation of medication.

AMIODARONE

Amiodarone can cause a neuromyopathy similar to chloroquine and hydroxychloroquine. The neuromyopathy typically appears after patients have taken the medication for 2–3 years. Nerve biopsy demonstrates a combination of segmental demyelination and axonal loss. Electron microscopy reveals lamellar or dense inclusions in Schwann cells, pericytes, and endothelial cells. The inclusions in muscle and nerve biopsies have persisted as long as 2 years following discontinuation of the medication.

COLCHICINE

Colchicine can also cause a neuromyopathy. Patients usually present with proximal weakness and numbness and tingling in the distal extremities. EDx reveals features of an axonal polyneuropathy. Muscle biopsy reveals a vacuolar myopathy, whereas sensory nerves demonstrate axonal degeneration. Colchicine inhibits the polymerization of tubulin into microtubules. The disruption of the microtubules probably leads to defective intracellular movement of important proteins, nutrients, and waste products in muscle and nerves.

THALIDOMIDE

Thalidomide is an immunomodulating agent used to treat MM, GVHD, leprosy, and other autoimmune disorders. Thalidomide is associated with severe teratogenic effects as well as peripheral neuropathy that can be dose-limiting. Patients develop numbness, painful tingling, and burning discomfort in the feet and hands and less commonly muscle weakness and atrophy. Even after stopping the drug for 4–6 years, as many as 50% patients continue to have significant symptoms. NCS demonstrate reduced amplitudes or complete absence of SNAPs, with preserved conduction velocities when obtainable. Motor NCS are usually normal. Nerve biopsy reveals a loss of large-diameter myelinated fibers and axonal degeneration. Degeneration of dorsal root ganglion cells has been reported at autopsy.

TABLE 446-7 Toxic Neuropathies Secondary to Chemotherapy

DRUG	MECHANISM OF NEUROTOXICITY	CLINICAL FEATURES	NERVE HISTOPATHOLOGY	EMG/NCS
Vinca alkaloids (vincristine, vinblastine, vindesine, vinorelbine)	Interfere with axonal microtubule assembly; impairs axonal transport	Symmetric, S-M, large-/small-fiber PN; autonomic symptoms common; infrequent cranial neuropathies	Axonal degeneration of myelinated and unmyelinated fibers; regenerating clusters, minimal segmental demyelination	Axonal sensorimotor PN; distal denervation on EMG; abnormal QST, particularly vibratory perception
Cisplatin	Preferential damage to dorsal root ganglia: ? binds to and cross-links DNA ? inhibits protein synthesis ? impairs axonal transport	Predominant large-fiber sensory neuronopathy; sensory ataxia	Loss of large > small myelinated and unmyelinated fibers; axonal degeneration with small clusters of regenerating fibers; secondary segmental demyelination	Low-amplitude or unobtainable SNAPs with normal CMAPs and EMG; abnormal QST, particularly vibratory perception
Taxanes (paclitaxel, docetaxel)	Promotes axonal microtubule assembly; interferes with axonal transport	Symmetric, predominantly sensory PN; large-fiber modalities affected more than small-fiber	Loss of large > small myelinated and unmyelinated fibers; axonal degeneration with small clusters of regenerating fibers; secondary segmental demyelination	Axonal sensorimotor PN; distal denervation on EMG; abnormal QST, particularly vibratory perception
Suramin				
Axonal PN	Unknown; ? inhibition of neurotrophic growth factor binding; ? neuronal lysosomal storage	Symmetric, length-dependent, sensory-predominant PN	None described	Abnormalities consistent with an axonal S-M PN
Demyelinating PN	Unknown; ? immunomodulating effects	Subacute, S-M PN with diffuse proximal and distal weakness; areflexia; increased CSF protein	Loss of large and small myelinated fibers with primary demyelination and secondary axonal degeneration; occasional epi- and endoneurial inflammatory cell infiltrates	Features suggestive of an acquired demyelinating sensorimotor PN (e.g., slow CVs, prolonged distal latencies and F-wave latencies, conduction block, temporal dispersion)
Cytarabine (ARA-C)	Unknown; ? selective Schwann cell toxicity; ? immunomodulating effects	GBS-like syndrome; pure sensory neuropathy; brachial plexopathy	Loss of myelinated nerve fibers; axonal degeneration; segmental demyelination; no inflammation	Axonal, demyelinating, or mixed S-M PN; denervation on EMG
Etoposide (VP-16)	Unknown; ? selective dorsal root ganglia toxicity	Length-dependent, sensory-predominant PN; autonomic neuropathy	None described	Abnormalities consistent with an axonal S-M PN
Bortezomib (Velcade)	Unknown	Length-dependent, sensory, predominantly small-fiber PN	Not reported	Abnormalities consistent with an axonal sensory neuropathy with early small-fiber involvement (abnormal autonomic studies)

Abbreviations: CMAP, compound motor action potential; CSF, cerebrospinal fluid; CVs, conduction velocities; EMG, electromyography; GBS, Guillain-Barré syndrome; NCS, nerve conduction studies; PN, polyneuropathy; QST, quantitative sensory testing; S-M, sensorimotor; SNAP, sensory nerve action potential.

PYRIDOXINE (VITAMIN B_6) TOXICITY

Pyridoxine is an essential vitamin that serves as a coenzyme for transamination and decarboxylation. However, at high doses (116 mg/d), patients can develop a severe sensory neuropathy with dysesthesias and sensory ataxia. NCS reveal absent or markedly reduced SNAP amplitudes with relatively preserved CMAPs. Nerve biopsy reveals axonal loss of fiber at all diameters. Loss of dorsal root ganglion cells with subsequent degeneration of both the peripheral and central sensory tracts have been reported in animal models.

ISONIAZID

One of the most common side effects of isoniazid (INH) is peripheral neuropathy. Standard doses of INH (3–5 mg/kg per day) are associated with a 2% incidence of neuropathy, whereas neuropathy develops in at least 17% of patients taking in excess of 6 mg/kg per d. The elderly, malnourished, and "slow acetylators" are at increased risk for developing the neuropathy. INH inhibits pyridoxal phosphokinase, resulting in pyridoxine deficiency and the neuropathy. Prophylactic administration of pyridoxine 100 mg/d can prevent the neuropathy from developing.

ANTIRETROVIRAL AGENTS

The nucleoside analogues zalcitabine (dideoxycytidine or ddC), didanosine (dideoxyinosine or ddI), stavudine (d4T), lamivudine (3TC), and antiretroviral nucleoside reverse transcriptase inhibitor (NRTI) are used to treat HIV infection. One of the major dose-limiting side effects of these medications is a predominantly sensory, length-dependent, symmetrically painful neuropathy (Pattern 2; Table 446-2). Zalcitabine (ddC) is the most extensively studied of the nucleoside analogues, and at doses >0.18 mg/kg per d, it is associated with a subacute onset of severe burning and lancinating pains in the feet and hands. NCS reveal decreased amplitudes of the SNAPs with normal motor studies. The nucleoside analogues inhibit mitochondrial DNA polymerase, which is the suspected pathogenic basis for the neuropathy. Because of a "coasting effect," patients can continue to worsen even 2–3 weeks after stopping the medication. Following dose reduction, improvement in the neuropathy is seen in most patients after several months (mean time ~10 weeks).

HEXACARBONS (*n*-HEXANE, METHYL *n*-BUTYL KETONE)/GLUE SNIFFER'S NEUROPATHY

n-Hexane and methyl *n*-butyl ketone are water-insoluble industrial organic solvents that are also present in some glues. Exposure through inhalation, accidentally or intentionally (glue sniffing), or through skin absorption can lead to a profound subacute sensory and motor polyneuropathy (Pattern 2; Table 446-2). NCS demonstrate decreased amplitudes of the SNAPs and CMAPs with slightly slow CVs. Nerve biopsy reveals a loss of myelinated fibers and giant axons that are filled with 10-nm neurofilaments. Hexacarbon exposure leads to covalent cross-linking between axonal neurofilaments that results in their aggregation, impaired axonal transport, swelling of the axons, and eventual axonal degeneration.

LEAD

Lead neuropathy is uncommon, but it can be seen in children who accidentally ingest lead-based paints in older buildings and in industrial workers exposed to lead-containing products. The most common presentation of lead poisoning is an encephalopathy; however, symptoms and signs of a primarily motor neuropathy can also occur.

TABLE 446-8 Toxic Neuropathies

DRUG	MECHANISM OF NEUROTOXICITY	CLINICAL FEATURES	NERVE HISTOPATHOLOGY	EMG/NCS
Misonidazole	Unknown	Painful paresthesias and loss of large- and small-fiber sensory modalities and sometimes distal weakness in length-dependent pattern	Axonal degeneration of large, myelinated fibers; axonal swellings; segmental demyelination	Low-amplitude or unobtainable SNAPs with normal or only slightly reduced CMAP amplitudes
Metronidazole	Unknown	Painful paresthesias and loss of large- and small-fiber sensory modalities and sometimes distal weakness in length-dependent pattern	Axonal degeneration	Low-amplitude or unobtainable SNAPs with normal CMAPs
Chloroquine and hydroxychloroquine	Amphiphilic properties may lead to drug-lipid complexes that are indigestible and result in accumulation of autophagic vacuoles	Loss of large- and small-fiber sensory modalities and distal weakness in length-dependent pattern; superimposed myopathy may lead to proximal weakness	Axonal degeneration with autophagic vacuoles in nerves as well as muscle fibers	Low-amplitude or unobtainable SNAPs with normal or reduced CMAP amplitudes; distal denervation on EMG; irritability and myopathic-appearing MUAPs proximally in patients with superimposed toxic myopathy
Amiodarone	Amphiphilic properties may lead to drug-lipid complexes that are indigestible and result in accumulation of autophagic vacuoles	Paresthesias and pain with loss of large- and small-fiber sensory modalities and distal weakness in length-dependent pattern; superimposed myopathy may lead to proximal weakness	Axonal degeneration and segmental demyelination with myeloid inclusions in nerves and muscle fibers	Low-amplitude or unobtainable SNAPs with normal or reduced CMAP amplitudes; can also have prominent slowing of CVs; distal denervation on EMG; irritability and myopathic-appearing MUAPs proximally in patients with superimposed toxic myopathy
Colchicine	Inhibits polymerization of tubulin in microtubules and impairs axoplasmic flow	Numbness and paresthesias with loss of large-fiber modalities in a length-dependent fashion; superimposed myopathy may lead to proximal in addition to distal weakness	Nerve biopsy demonstrates axonal degeneration; muscle biopsy reveals fibers with vacuoles	Low-amplitude or unobtainable SNAPs with normal or reduced CMAP amplitudes; irritability and myopathic-appearing MUAPs proximally in patients with superimposed toxic myopathy
Podophyllin	Binds to microtubules and impairs axoplasmic flow	Sensory loss, tingling, muscle weakness, and diminished muscle stretch reflexes in length-dependent pattern; autonomic neuropathy	Axonal degeneration	Low-amplitude or unobtainable SNAPs with normal or reduced CMAP amplitudes
Thalidomide	Unknown	Numbness, tingling, and burning pain and weakness in a length-dependent pattern	Axonal degeneration; autopsy studies reveal degeneration of dorsal root ganglia	Low-amplitude or unobtainable SNAPs with normal or reduced CMAP amplitudes
Disulfiram	Accumulation of neurofilaments and impaired axoplasmic flow	Numbness, tingling, and burning pain in a length-dependent pattern	Axonal degeneration with accumulation of neurofilaments in the axons	Low-amplitude or unobtainable SNAPs with normal or reduced CMAP amplitudes
Dapsone	Unknown	Distal weakness that may progress to proximal muscles; sensory loss	Axonal degeneration and segmental demyelination	Low-amplitude or unobtainable CMAPs with normal or reduced SNAP amplitudes
Leflunomide	Unknown	Paresthesias and numbness in a length-dependent pattern	Unknown	Low-amplitude or unobtainable SNAPs with normal or reduced CMAP amplitudes
Nitrofurantoin	Unknown	Numbness, painful paresthesias, and severe weakness that may resemble GBS	Axonal degeneration; autopsy studies reveal degeneration of dorsal root ganglia and anterior horn cells	Low-amplitude or unobtainable SNAPs with normal or reduced CMAP amplitudes
Pyridoxine (vitamin B_6)	Unknown	Dysesthesias and sensory ataxia; impaired large-fiber sensory modalities on examination	Marked loss of sensory axons and cell bodies in dorsal root ganglia	Reduced amplitudes or absent SNAPs
Isoniazid	Inhibits pyridoxal phosphokinase leading to pyridoxine deficiency	Dysesthesias and sensory ataxia; impaired large-fiber sensory modalities on examination	Marked loss of sensory axons and cell bodies in dorsal root ganglia and degeneration of the dorsal columns	Reduced amplitudes or absent SNAPs and, to a lesser extent, CMAPs
Ethambutol	Unknown	Numbness with loss of large-fiber modalities on examination	Axonal degeneration	Reduced amplitudes or absent SNAPs
Antinucleosides	Unknown	Dysesthesia and sensory ataxia; impaired large-fiber sensory modalities on examination	Axonal degeneration	Reduced amplitudes or absent SNAPs
Phenytoin	Unknown	Numbness with loss of large-fiber modalities on examination	Axonal degeneration and segmental demyelination	Low-amplitude or unobtainable SNAPs with normal or reduced CMAP amplitudes
Lithium	Unknown	Numbness with loss of large-fiber modalities on examination	Axonal degeneration	Low-amplitude or unobtainable SNAPs with normal or reduced CMAP amplitudes

(*Continued*)

TABLE 446-8 Toxic Neuropathies (Continued)

DRUG	MECHANISM OF NEUROTOXICITY	CLINICAL FEATURES	NERVE HISTOPATHOLOGY	EMG/NCS
Acrylamide	Unknown; may be caused by impaired axonal transport	Numbness with loss of large-fiber modalities on examination; sensory ataxia; mild distal weakness	Degeneration of sensory axons in peripheral nerves and posterior columns, spinocerebellar tracts, mammillary bodies, optic tracts, and corticospinal tracts in the CNS	Low-amplitude or unobtainable SNAPs with normal or reduced CMAP amplitudes
Carbon disulfide	Unknown	Length-dependent numbness and tingling with mild distal weakness	Axonal swellings with accumulation of neurofilaments	Low-amplitude or unobtainable SNAPs with normal or reduced CMAP amplitudes
Ethylene oxide	Unknown; may act as alkylating agent and bind DNA	Length-dependent numbness and tingling; may have mild distal weakness	Axonal degeneration	Low-amplitude or unobtainable SNAPs with normal or reduced CMAP amplitudes
Organophosphates	Bind and inhibit neuropathy target esterase	Early features are those of neuromuscular blockade with generalized weakness; later axonal sensorimotor PN ensues	Axonal degeneration along with degeneration of gracile fasciculus and corticospinal tracts	Early: repetitive firing of CMAPs and decrement with repetitive nerve stimulation; late: axonal sensorimotor PN
Hexacarbons	Unknown; may lead to covalent cross-linking between neurofilaments	Acute, severe sensorimotor PN that may resemble GBS	Axonal degeneration and giant axons swollen with neurofilaments	Features of a mixed axonal and/or demyelinating sensorimotor axonal PN—reduced amplitudes, prolonged distal latencies, conduction block, and slowing of CVs
Lead	Unknown; may interfere with mitochondria	Encephalopathy; motor neuropathy (often resembles radial neuropathy with wrist and finger drop); autonomic neuropathy; bluish-black discoloration of gums	Axonal degeneration of motor axons	Reduction of CMAP amplitudes with active denervation on EMG
Mercury	Unknown; may combine with sulfhydryl groups	Abdominal pain and nephrotic syndrome; encephalopathy; ataxia; paresthesias	Axonal degeneration; degeneration of dorsal root ganglia, calcarine, and cerebellar cortex	Low-amplitude or unobtainable SNAPs with normal or reduced CMAP amplitudes
Thallium	Unknown	Encephalopathy; painful sensory symptoms; mild loss of vibration; distal or generalized weakness may also develop; autonomic neuropathy; alopecia	Axonal degeneration	Low-amplitude or unobtainable SNAPs with normal or reduced CMAP amplitudes
Arsenic	Unknown; may combine with sulfhydryl groups	Abdominal discomfort, burning pain, and paresthesias; generalized weakness; autonomic insufficiency; can resemble GBS	Axonal degeneration	Low-amplitude or unobtainable SNAPs with normal or reduced CMAP amplitudes; may have demyelinating features: prolonged distal latencies and slowing of CVs
Gold	Unknown	Distal paresthesias and reduction of all sensory modalities	Axonal degeneration	Low-amplitude or unobtainable SNAPs

Abbreviations: CMAP, compound motor action potential; CVs, conduction velocities; EMG, electromyography; GBS, Guillain-Barré syndrome; MUAP, muscle action potential; NCS, nerve conduction studies; PN, polyneuropathy; S-M, sensorimotor; SNAP, sensory nerve action potential.

Source: From AA Amato, JA Russell (eds): Neuromuscular Disorders, 2nd ed. McGraw-Hill Education, 2016, Table 20-1, p. 449-451; with permission.

The neuropathy is characterized by an insidious and progressive onset of weakness usually beginning in the arms, in particular involving the wrist and finger extensors, resembling a radial neuropathy. Sensation is generally preserved; however, the autonomic nervous system can be affected (Patterns 2, 3, and 10; Table 446-2). Laboratory investigation can reveal a microcytic hypochromic anemia with basophilic stippling of erythrocytes, an elevated serum lead level, and an elevated serum coproporphyrin level. A 24-h urine collection demonstrates elevated levels of lead excretion. The NCS may reveal reduced CMAP amplitudes, while the SNAPs are typically normal. The pathogenic basis may be related to abnormal porphyrin metabolism. The most important principle of management is to remove the source of the exposure. Chelation therapy with calcium disodium ethylene-diaminetetraacetic acid (EDTA), British anti-Lewisite (BAL), and penicillamine also demonstrates variable efficacy.

MERCURY

Mercury toxicity may occur as a result of exposure to either organic or inorganic mercurials. Mercury poisoning presents with paresthesias in hands and feet that progress proximally and may involve the face and tongue. Motor weakness can also develop. CNS symptoms often overshadow the neuropathy. EDx shows features of a primarily axonal sensorimotor polyneuropathy. The primary site of neuromuscular pathology appears to be the dorsal root ganglia. The mainstay of treatment is removing the source of exposure.

THALLIUM

Thallium can exist in a monovalent or trivalent form and is primarily used as a rodenticide. The toxic neuropathy usually manifests as burning paresthesias of the feet, abdominal pain, and vomiting. Increased thirst, sleep disturbances, and psychotic behavior may be noted. Within the first week, patients develop pigmentation of the hair, an acne-like rash in the malar area of the face, and hyperreflexia. By the second and third weeks, autonomic instability with labile heart rate and blood pressure may be seen. Hyporeflexia and alopecia also occur but may not be evident until the third or fourth week following exposure. With severe intoxication, proximal weakness and involvement of the cranial nerves can occur. Some patients require mechanical ventilation due to respiratory muscle involvement. The lethal dose of thallium is variable, ranging from 8 to 15 mg/kg body weight. Death can result in

<48 h following a particularly large dose. NCS demonstrate features of a primarily axonal sensorimotor polyneuropathy. With acute intoxication, potassium ferric ferrocyanide II may be effective in preventing absorption of thallium from the gut. However, there may be no benefit once thallium has been absorbed. Unfortunately, chelating agents are not very efficacious. Adequate diuresis is essential to help eliminate thallium from the body without increasing tissue availability from the serum.

ARSENIC

Arsenic is another heavy metal that can cause a toxic sensorimotor polyneuropathy. The neuropathy manifests 5–10 days after ingestion of arsenic and progresses for several weeks, sometimes mimicking GBS. The presenting symptoms are typically an abrupt onset of abdominal discomfort, nausea, vomiting, pain, and diarrhea followed within several days by burning pain in the feet and hands. Examination of the skin can be helpful in the diagnosis as the loss of the superficial epidermal layer results in patchy regions of increased or decreased pigmentation on the skin several weeks after an acute exposure or with chronic low levels of ingestion. Mee's lines, which are transverse lines at the base of the fingernails and toenails, do not become evident until 1 or 2 months after the exposure. Multiple Mee's lines may be seen in patients with long fingernails who have had chronic exposure to arsenic. Mee's lines are not specific for arsenic toxicity as they can also be seen following thallium poisoning. Because arsenic is cleared from blood rapidly, the serum concentration of arsenic is not diagnostically helpful. However, arsenic levels are increased in the urine, hair, and fingernails of patients exposed to arsenic. Anemia with stippling of erythrocytes is common, and occasionally, pancytopenia and aplastic anemia can develop. Increased CSF protein levels without pleocytosis can be seen; this can lead to misdiagnosis as GBS. NCS are usually suggestive of an axonal sensorimotor polyneuropathy; however, demyelinating features can be present. Chelation therapy with BAL has yielded inconsistent results; therefore, it is not generally recommended.

NUTRITIONAL NEUROPATHIES

COBALAMIN (VITAMIN B_{12})

Pernicious anemia is the most common cause of cobalamin deficiency. Other causes include dietary avoidance (vegetarians), gastrectomy, gastric bypass surgery, inflammatory bowel disease, pancreatic insufficiency, bacterial overgrowth, and possibly histamine-2 blockers and proton pump inhibitors. An underappreciated cause of cobalamin deficiency is food-cobalamin malabsorption. This typically occurs in older individuals and results from an inability to adequately absorb cobalamin in food protein. No apparent cause of deficiency is identified in a significant number of patients with cobalamin deficiency. The use of nitrous oxide as an anesthetic agent or as a recreational drug can produce acute cobalamin deficiency neuropathy and subacute combined degeneration.

Complaints of numb hands typically appear before lower extremity paresthesias are noted. A preferential large-fiber sensory loss affecting proprioception and vibration with sparing of small-fiber modalities is present; an unsteady gait reflects sensory ataxia. These features, coupled with diffuse hyperreflexia and absent Achilles reflexes, should always focus attention on the possibility of cobalamin deficiency (Patterns 2 and 6; Table 446-2). Optic atrophy and, in severe cases, behavioral changes ranging from mild irritability and forgetfulness to severe dementia and frank psychosis may appear. The full clinical picture of subacute combined degeneration is uncommon. CNS manifestations, especially pyramidal tract signs, may be missing, and in fact, some patients may only exhibit symptoms of peripheral neuropathy.

EDx shows an axonal sensorimotor neuropathy. CNS involvement produces abnormal somatosensory and visual evoked potential latencies. The diagnosis is confirmed by finding reduced serum cobalamin levels. In up to 40% of patients, anemia and macrocytosis are lacking. Serum methylmalonic acid and homocysteine, the metabolites that accumulate when cobalamin-dependent reactions are blocked, are elevated. Antibodies to intrinsic factor are present in ~60% and antiparietal cell antibodies in ~90% of individuals with pernicious anemia.

Cobalamin deficiency can be treated with various regimens of cobalamin. One typical regimen consists of 1000 μg cyanocobalamin IM weekly for 1 month and monthly thereafter. Patients with food cobalamin malabsorption can absorb free cobalamin and therefore can be treated with oral cobalamin supplementation. An oral cobalamin dose of 1000 μg/d should be sufficient. Treatment for cobalamin deficiency usually does not completely reverse the clinical manifestations, and at least 50% of patients exhibit some permanent neurologic deficit.

THIAMINE DEFICIENCY

Thiamine (vitamin B_1) deficiency is an uncommon cause of peripheral neuropathy in developed countries. It is now most often seen as a consequence of chronic alcohol abuse, recurrent vomiting, total parenteral nutrition, and bariatric surgery. Thiamine deficiency polyneuropathy can occur in normal, healthy young adults who do not abuse alcohol but who engage in inappropriately restrictive diets. Thiamine is water-soluble. It is present in most animal and plant tissues, but the greatest sources are unrefined cereal grains, wheat germ, yeast, soybean flour, and pork. Beriberi means "I can't, I can't" in Singhalese, the language of natives of what was once part of the Dutch East Indies (now Sri Lanka). *Dry beriberi* refers to neuropathic symptoms. The term *wet beriberi* is used when cardiac manifestations predominate (in reference to edema). Beriberi was relatively uncommon until the late 1800s when it became widespread among people for whom rice was a dietary mainstay. This epidemic was due to a new technique of processing rice that removed the germ from the rice shaft, rendering the so-called polished rice deficient in thiamine and other essential nutrients.

Symptoms of neuropathy follow prolonged deficiency. These begin with mild sensory loss and/or burning dysesthesias in the toes and feet and aching and cramping in the lower legs. Pain may be the predominant symptom. With progression, patients develop features of a nonspecific generalized polyneuropathy, with distal sensory loss in the feet and hands.

Blood and urine assays for thiamine are not reliable for diagnosis of deficiency. Erythrocyte transketolase activity and the percentage increase in activity (in vitro) following the addition of thiamine pyrophosphate (TPP) may be more accurate and reliable. EDx shows nonspecific findings of an axonal sensorimotor polyneuropathy. When a diagnosis of thiamine deficiency is made or suspected, thiamine replacement should be provided until proper nutrition is restored. Thiamine is usually given intravenously or intramuscularly at a dose of 100 mg/d. Although cardiac manifestations show a striking response to thiamine replacement, neurologic improvement is usually more variable and less dramatic.

VITAMIN E DEFICIENCY

The term *vitamin E* is usually used for α-tocopherol, the most active of the four main types of vitamin E. Because vitamin E is present in animal fat, vegetable oils, and various grains, deficiency is usually due to factors other than insufficient intake. Vitamin E deficiency usually occurs secondary to lipid malabsorption or in uncommon disorders of vitamin E transport. One hereditary disorder is abetalipoproteinemia, a rare autosomal dominant disorder characterized by steatorrhea, pigmentary retinopathy, acanthocytosis, and progressive ataxia. Patients with cystic fibrosis may also have vitamin E deficiency secondary to steatorrhea. There are genetic forms of isolated vitamin E deficiency not associated with lipid malabsorption. Vitamin E deficiency may also occur as a consequence of various cholestatic and hepatobiliary disorders as well as short-bowel syndromes resulting from the surgical treatment of intestinal disorders.

Clinical features may not appear until many years after the onset of deficiency. The onset of symptoms tends to be insidious, and progression is slow. The main clinical features are spinocerebellar ataxia and polyneuropathy, thus resembling Friedreich's ataxia or other spinocerebellar ataxias. Patients manifest progressive ataxia and signs of posterior column dysfunction, such as impaired joint position and vibratory sensation. Because of the polyneuropathy, there is hyporeflexia, but

plantar responses may be extensor as a result of the spinal cord involvement (Patterns 2 and 6; Table 446-2). Other neurologic manifestations may include ophthalmoplegia, pigmented retinopathy, night blindness, dysarthria, pseudoathetosis, dystonia, and tremor. Vitamin E deficiency may present as an isolated polyneuropathy, but this is very rare. The yield of checking serum vitamin E levels in patients with isolated polyneuropathy is extremely low, and this test should not be part of routine practice.

Diagnosis is made by measuring α-tocopherol levels in the serum. EDx shows features of an axonal neuropathy. Treatment is replacement with oral vitamin E, but high doses are not needed. For patients with isolated vitamin E deficiency, treatment consists of 1500–6000 IU/d in divided doses.

VITAMIN B_6 DEFICIENCY

Vitamin B_6, or pyridoxine, can produce neuropathic manifestations from both deficiency and toxicity. Vitamin B_6 toxicity was discussed above. Vitamin B_6 deficiency is most commonly seen in patients treated with isoniazid or hydralazine. The polyneuropathy of vitamin B_6 is nonspecific, manifesting as a generalized axonal sensorimotor polyneuropathy. Vitamin B_6 deficiency can be detected by direct assay. Vitamin B_6 supplementation with 50–100 mg/d is suggested for patients being treated with isoniazid or hydralazine. This same dose is appropriate for replacement in cases of nutritional deficiency.

PELLAGRA (NIACIN DEFICIENCY)

Pellagra is produced by deficiency of niacin. Although pellagra may be seen in alcoholics, this disorder has essentially been eradicated in most Western countries by means of enriching bread with niacin. Nevertheless, pellagra continues to be a problem in a number of underdeveloped regions, particularly in Asia and Africa, where corn is the main source of carbohydrate. Neurologic manifestations are variable; abnormalities can develop in the brain and spinal cord as well as peripheral nerves. When peripheral nerves are involved, the neuropathy is usually mild and resembles beriberi. Treatment is with niacin 40–250 mg/d.

COPPER DEFICIENCY

A syndrome that has only recently been described is myeloneuropathy secondary to copper deficiency. Most patients present with lower limb paresthesias, weakness, spasticity, and gait difficulties (Pattern 6; Table 446-2). Large-fiber sensory function is impaired, reflexes are brisk, and plantar responses are extensor. In some cases, light touch and pinprick sensation are affected, and NCS indicate sensorimotor axonal polyneuropathy in addition to myelopathy.

Hematologic abnormalities are a known complication of copper deficiency; these can include microcytic anemia, neutropenia, and occasionally pancytopenia. Because copper is absorbed in the stomach and proximal jejunum, many cases of copper deficiency occur in the setting of prior gastric surgery. Excess zinc is an established cause of copper deficiency. Zinc upregulates enterocyte production of metallothionine, which results in decreased absorption of copper. Excessive dietary zinc supplements or denture cream containing zinc can produce this clinical picture. Other potential causes of copper deficiency include malnutrition, prematurity, total parenteral nutrition, and ingestion of copper-chelating agents.

Following oral or IV copper replacement, some patients show neurologic improvement, but this may take many months or not occur at all. Replacement consists of oral copper sulfate or gluconate 2 mg one to three times a day. If oral copper replacement is not effective, elemental copper in the copper sulfate or copper chloride forms can be given as 2 mg IV daily for 3–5 days, then weekly for 1–2 months until copper levels normalize. Thereafter, oral daily copper therapy can be resumed. In contrast to the neurologic manifestations, most of the hematologic indices normalize in response to copper replacement therapy.

NEUROPATHY ASSOCIATED WITH GASTRIC SURGERY

Polyneuropathy may occur following gastric surgery for ulcer, cancer, or weight reduction. This usually occurs in the context of rapid, significant weight loss and recurrent, protracted vomiting. The clinical picture is one of acute or subacute sensory loss and weakness. Neuropathy following weight loss surgery usually occurs in the first several months after surgery. Weight reduction surgical procedures include gastrojejunostomy, gastric stapling, vertical banded gastroplasty, and gastrectomy with Roux-en-Y anastomosis. The initial manifestations are usually numbness and paresthesias in the feet (Pattern 2; Table 446-2). In many cases, no specific nutritional deficiency factor is identified.

Management consists of parenteral vitamin supplementation, especially including thiamine. Improvement has been observed following supplementation, parenteral nutritional support, and reversal of the surgical bypass. The duration and severity of deficits before identification and treatment of neuropathy are important predictors of final outcome.

CRYPTOGENIC (IDIOPATHIC) SENSORY AND SENSORIMOTOR POLYNEUROPATHY

Cryptogenic (idiopathic) sensory and sensorimotor polyneuropathy (CSPN) is a diagnosis of exclusion, established after a careful medical, family, and social history; neurologic examination; and directed laboratory testing. Despite extensive evaluation, the cause of polyneuropathy in as many as 50% of all patients is idiopathic. CSPN should be considered a distinct diagnostic subset of peripheral neuropathy. The onset of CSPN is predominantly in the sixth and seventh decades. Patients complain of distal numbness, tingling, and often burning pain that invariably begins in the feet and may eventually involve the fingers and hands ("burning feet syndrome"). Patients exhibit a distal sensory loss to pinprick, touch, and vibration in the toes and feet, and occasionally in the fingers (Pattern 2; Table 446-2). It is uncommon to see significant proprioception deficits, even though patients may complain of gait unsteadiness. However, tandem gait may be abnormal in a minority of cases. Neither subjective nor objective evidence of weakness is a prominent feature. Most patients have evidence of both large- and small-fiber loss on neurologic examination and EDx. Approximately 10% of patients have only evidence of small-fiber involvement. The ankle muscle stretch reflex is frequently absent, but in cases with predominantly small-fiber loss, this may be preserved. The EDx findings range from isolated SNAP abnormalities (usually with loss of amplitude), to evidence for an axonal sensorimotor neuropathy, to a completely normal study (if primarily small fibers are involved). Therapy primarily involves the control of neuropathic pain (Table 446-6) if present. Recently, a large comparative effectiveness study in CSPN showed that the drugs nortriptyline and duloxetine outperformed pregabalin and mexiletine. These drugs should not be used if the patient has only numbness and tingling but no pain.

Although no treatment is available that can reverse an idiopathic distal peripheral neuropathy, the prognosis is good. Progression often does not occur or is minimal, with sensory symptoms and signs progressing proximally up to the knees and elbows. The disorder does not lead to significant motor disability over time. The relatively benign course of this disorder should be explained to patients.

MONONEUROPATHIES/PLEXOPATHIES/RADICULOPATHIES (PATTERN 3; TABLE 446-2)

MEDIAN NEUROPATHY

CTS is a compression of the median nerve in the carpal tunnel at the wrist. The median nerve enters the hand through the carpal tunnel by coursing under the transverse carpal ligament. The symptoms of CTS consist of numbness and paresthesias variably in the thumb, index, middle, and half of the ring finger. At times, the paresthesias can include the entire hand and extend into the forearm or upper arm or can be isolated to one or two fingers. Pain is another common symptom and can be located in the hand and forearm and, at times, in the proximal arm. CTS is common and often misdiagnosed as thoracic outlet syndrome. The signs of CTS are decreased sensation in the median nerve distribution; reproduction of the sensation of tingling when a percussion hammer is tapped over the wrist (Tinel sign) or the

wrist is flexed for 30–60 s (Phalen sign); and weakness of thumb opposition and abduction. EDx is extremely sensitive and shows slowing of sensory and, to a lesser extent, motor median potentials across the wrist. Ultrasound can show focal swelling of the median nerve at the wrist. Treatment options consist of avoidance of precipitating activities; control of underlying systemic-associated conditions if present; nonsteroidal anti-inflammatory medications; neutral (volar) position wrist splints, especially for night use; glucocorticoid/anesthetic injection into the carpal tunnel; and surgical decompression by dividing the transverse carpal ligament. The surgical option should be considered if there is a poor response to nonsurgical treatments; if there is thenar muscle atrophy and/or weakness; and if there are significant denervation potentials on EMG.

Other proximal median neuropathies are very uncommon and include the pronator teres syndrome and anterior interosseous neuropathy. These often occur as a partial form of brachial plexitis.

ULNAR NEUROPATHY AT THE ELBOW— "CUBITAL TUNNEL SYNDROME"

The ulnar nerve passes through the condylar groove between the medial epicondyle and the olecranon. Symptoms consist of paresthesias, tingling, and numbness in the medial hand and half of the fourth and the entire fifth fingers, pain at the elbow or forearm, and weakness. Signs consist of decreased sensation in an ulnar distribution, Tinel's sign at the elbow, and weakness and atrophy of ulnar-innervated hand muscles. The Froment sign indicates thumb adductor weakness and consists of flexion of the thumb at the interphalangeal joint when attempting to oppose the thumb against the lateral border of the second digit. EDx may show slowing of ulnar motor NCV across the elbow with prolonged ulnar sensory latencies. Ultrasound can show swelling of the ulnar nerve around the elbow as well. Treatment consists of avoiding aggravating factors, using elbow pads, and surgery to decompress the nerve in the cubital tunnel. Ulnar neuropathies can also rarely occur at the wrist in the ulnar (Guyon) canal or in the hand, usually after trauma.

RADIAL NEUROPATHY

The radial nerve winds around the proximal humerus in the spiral groove and proceeds down the lateral arm and enters the forearm, dividing into the posterior interosseous nerve and superficial nerve. The symptoms and signs consist of wrist drop; finger extension weakness; thumb abduction weakness; and sensory loss in the dorsal web between the thumb and index finger. Triceps and brachioradialis strength is often normal, and triceps reflex is often intact. Most cases of radial neuropathy are transient compressive (neuropraxic) injuries that recover spontaneously in 6–8 weeks. If there has been prolonged compression and severe axonal damage, it may take several months to recover. Treatment consists of cock-up wrist and finger splints, avoiding further compression, and physical therapy to avoid flexion contracture. If there is no improvement in 2–3 weeks, an EDx study is recommended to confirm the clinical diagnosis and determine the degree of severity.

LATERAL FEMORAL CUTANEOUS NEUROPATHY (MERALGIA PARESTHETICA)

The lateral femoral cutaneous nerve arises from the upper lumbar plexus (spinal levels L2/3), crosses through the inguinal ligament near its attachment to the iliac bone, and supplies sensation to the anterior lateral thigh. The neuropathy affecting this nerve is also known as meralgia paresthetica. Symptoms and signs consist of paresthesias, numbness, and occasionally pain in the lateral thigh. Symptoms are increased by standing or walking and are relieved by sitting. There is normal strength, and knee reflexes are intact. The diagnosis is clinical, and further tests usually are not performed. EDx is only needed to rule out lumbar plexopathy, radiculopathy, or femoral neuropathy. If the symptoms and signs are classic, EMG is not necessary. Symptoms often resolve spontaneously over weeks or months, but the patient may be left with permanent numbness. Treatment consists of weight loss and avoiding tight belts. Analgesics in the form of a lidocaine patch, nonsteroidal agents, and occasionally medications for neuropathic pain can be used (Table 446-6). Rarely, locally injecting the nerve with an anesthetic can be tried. There is no role for surgery.

FEMORAL NEUROPATHY

Femoral neuropathies can arise as complications of retroperitoneal hematoma, lithotomy positioning, hip arthroplasty or dislocation, iliac artery occlusion, femoral arterial procedures, infiltration by hematogenous malignancy, penetrating groin trauma, pelvic surgery including hysterectomy and renal transplantation, and diabetes (a partial form of lumbosacral diabetic plexopathy); some cases are idiopathic. Patients with femoral neuropathy have difficulty extending their knee and flexing the hip. Sensory symptoms occurring either on the anterior thigh and/or medial leg occur in only half of reported cases. A prominent painful component is the exception rather than the rule, may be delayed, and is often self-limited in nature. The quadriceps (patellar) reflex is diminished.

SCIATIC NEUROPATHY

Sciatic neuropathies commonly complicate hip arthroplasty, pelvic procedures in which patients are placed in a prolonged lithotomy position, trauma, hematomas, tumor infiltration, and vasculitis. In addition, many sciatic neuropathies are idiopathic. Weakness may involve all motions of the ankles and toes as well as flexion of the leg at the knee; abduction and extension of the thigh at the hip are spared. Sensory loss occurs in the entire foot and the distal lateral leg. The ankle jerk and, on occasion, the internal hamstring reflex are diminished or more typically absent on the affected side. The peroneal subdivision of the sciatic nerve is typically involved disproportionately to the tibial counterpart. Thus, patients may have only ankle dorsiflexion and eversion weakness with sparing of knee flexion, ankle inversion, and plantar flexion; these features can lead to misdiagnosis of a common peroneal neuropathy.

PERONEAL NEUROPATHY

The sciatic nerve divides at the distal femur into the tibial and peroneal nerve. The common peroneal nerve passes posterior and laterally around the fibular head, under the fibular tunnel. It then divides into the superficial peroneal nerve, which supplies the ankle evertor muscles and sensation over the anterolateral distal leg and dorsum of the foot, and the deep peroneal nerve, which supplies ankle dorsiflexors and toe extensor muscles and a small area of sensation dorsally in the area of the first and second toes.

Symptoms and signs consist of foot drop (ankle dorsiflexion, toe extension, and ankle eversion weakness) and variable sensory loss, which may involve the superficial and deep peroneal pattern. There is usually no pain. Onset may be on awakening in the morning. Peroneal neuropathy needs to be distinguished from L5 radiculopathy. In L5 radiculopathy, ankle invertors and evertors are weak and needle EMG reveals denervation. EDx can help localize the lesion. Peroneal motor conduction velocity shows slowing and amplitude drop across the fibular head. Management consists of rapid weight loss and avoiding leg crossing. Foot drop is treated with an ankle brace. A knee pad can be worn over the lateral knee to avoid further compression. Most cases spontaneously resolve over weeks or months.

RADICULOPATHIES

Radiculopathies are most often due to compression from degenerative joint disease and herniated disks, but there are a number of unusual etiologies **(Table 446-9)**. Degenerative spine disease affects a number of different structures, which narrow the diameter of the neural foramen or canal of the spinal column and compromise nerve root integrity; **these are discussed in detail in Chap. 17**.

PLEXOPATHIES (PATTERN 4; TABLE 446-2)

BRACHIAL PLEXUS

The brachial plexus is composed of three trunks (upper, middle, and lower), with two divisions (anterior and posterior) per trunk **(Fig. 446-2)**. Subsequently, the trunks divide into three cords (medial, lateral, and posterior), and from these, arise the multiple terminal

TABLE 446-9 Causes of Radiculopathy

- Herniated nucleus pulposus
- Degenerative joint disease
- Rheumatoid arthritis
- Trauma
- Vertebral body compression fracture
- Pott's disease
- Compression by extradural mass (e.g., meningioma, metastatic tumor, hematoma, abscess)
- Primary nerve tumor (e.g., neurofibroma, schwannoma, neurinoma)
- Carcinomatous meningitis
- Perineurial spread of tumor (e.g., prostate cancer)
- Acute inflammatory demyelinating polyradiculopathy
- Chronic inflammatory demyelinating polyradiculopathy
- Sarcoidosis
- Amyloidoma
- Diabetic radiculopathy
- Infection (Lyme disease, herpes zoster, HIV, cytomegalovirus, syphilis, schistosomiasis, *Strongyloides*)
- Arachnoiditis (e.g., postsurgical)
- Radiation

nerves innervating the arm. The anterior primary rami of C5 and C6 fuse to form the upper trunk; the anterior primary ramus of C7 continues as the middle trunk, while the anterior rami of C8 and T1 join to form the lower trunk. There are several disorders commonly associated with brachial plexopathy.

Immune-Mediated Brachial Plexus Neuropathy Immune-mediated brachial plexus neuropathy (IBPN) goes by various terms, including *acute brachial plexitis, neuralgic amyotrophy*, and *Parsonage-Turner syndrome*. IBPN usually presents with an acute onset of severe pain in the shoulder region. The intense pain usually lasts several days to a few weeks, but a dull ache can persist. Individuals who are affected may not appreciate weakness of the arm early in the course because the pain limits movement. However, as the pain dissipates, weakness and often sensory loss are appreciated. Attacks can occasionally recur.

Clinical findings are dependent on the distribution of involvement (e.g., specific trunk, divisions, cords, or terminal nerves). The most common pattern of IBPN involves the upper trunk or a single or multiple mononeuropathies primarily involving the suprascapular, long thoracic, or axillary nerves. Additionally, the phrenic and anterior interosseous nerves may be concomitantly affected. Any of these nerves may also be affected in isolation. EDx is useful to confirm and localize the site(s) of involvement. Empirical treatment of severe pain with glucocorticoids is often used in the acute period.

Brachial Plexopathies Associated with Neoplasms Neoplasms involving the brachial plexus may be primary nerve tumors, local cancers expanding into the plexus (e.g., Pancoast lung tumor or lymphoma), and metastatic tumors. Primary brachial plexus tumors are less common than the secondary tumors and include schwannomas, neurinomas, and neurofibromas. Secondary tumors affecting the brachial plexus are more common and are always malignant. These may arise from local tumors, expanding into the plexus. For example, a Pancoast tumor of the upper lobe of the lung may invade or compress the lower trunk, whereas a primary lymphoma arising from the cervical or axillary lymph nodes may also infiltrate the plexus. Pancoast tumors typically present as an insidious onset of pain in the upper arm, sensory disturbance in the medial aspect of the forearm and hand, and weakness and atrophy of the intrinsic hand muscles along with an ipsilateral Horner's syndrome. Chest computed tomography (CT) scans or magnetic resonance imaging (MRI) can demonstrate extension of the tumor into the plexus. Metastatic involvement of the brachial plexus may occur with spread of breast cancer into the axillary lymph nodes and local spread into the nearby nerves.

Perioperative Plexopathies (Median Sternotomy) The most common surgical procedures associated with brachial plexopathy as a complication are those that involve median sternotomies (e.g., open-heart surgeries and thoracotomies). Brachial plexopathies occur in as many as 5% of patients following a median sternotomy and typically affect the lower trunk. Thus, individuals manifest with sensory disturbance affecting the medial aspect of forearm and hand along with weakness of the intrinsic hand muscles. The mechanism is related to the stretch of the lower trunk, so most individuals who are affected recover within a few months.

Lumbosacral Plexus The lumbar plexus arises from the ventral primary rami of the first to the fourth lumbar spinal nerves (Fig. 446-3). These nerves pass downward and laterally from the vertebral column within the psoas major muscle. The femoral nerve derives from the dorsal branches of the second to the fourth lumbar ventral rami. The obturator nerve arises from the ventral branches

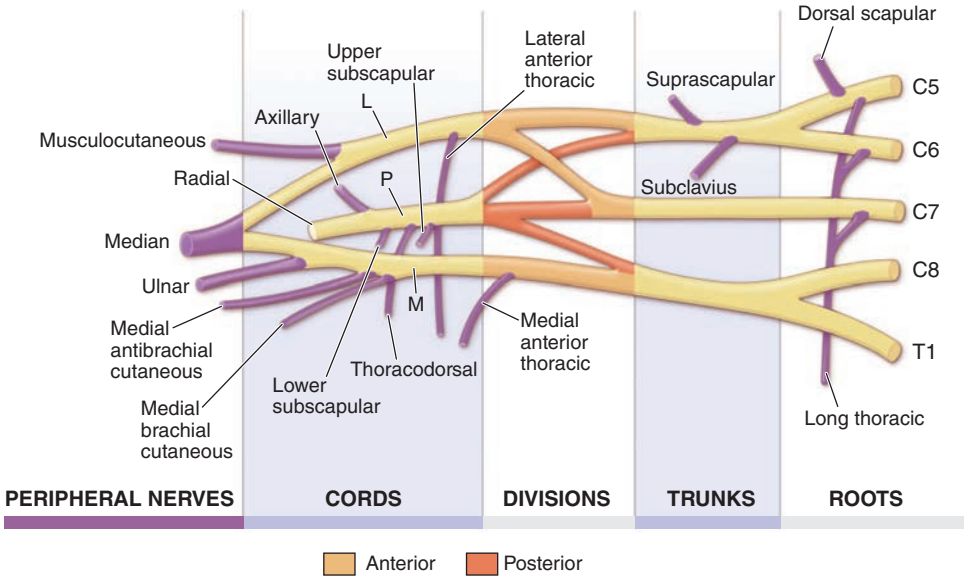

FIGURE 446-2 Brachial plexus anatomy. L, lateral; M, medial; P, posterior. *(Reproduced with permission J Goodgold: Anatomical Correlates of Clinical Electromyography. Baltimore, Williams and Wilkins, 1974.)*

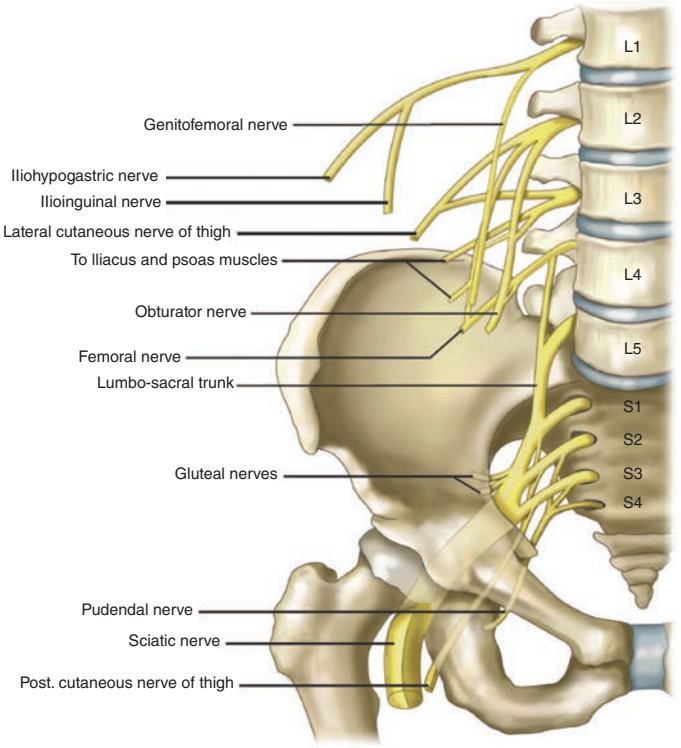

FIGURE 446-3 Lumbosacral plexus. *(From AA Amato, JA Russell (eds): Neuromuscular Disorders, 2nd ed. McGraw-Hill Education, 2016, Figure 24-3, p. 542, with permission.)*

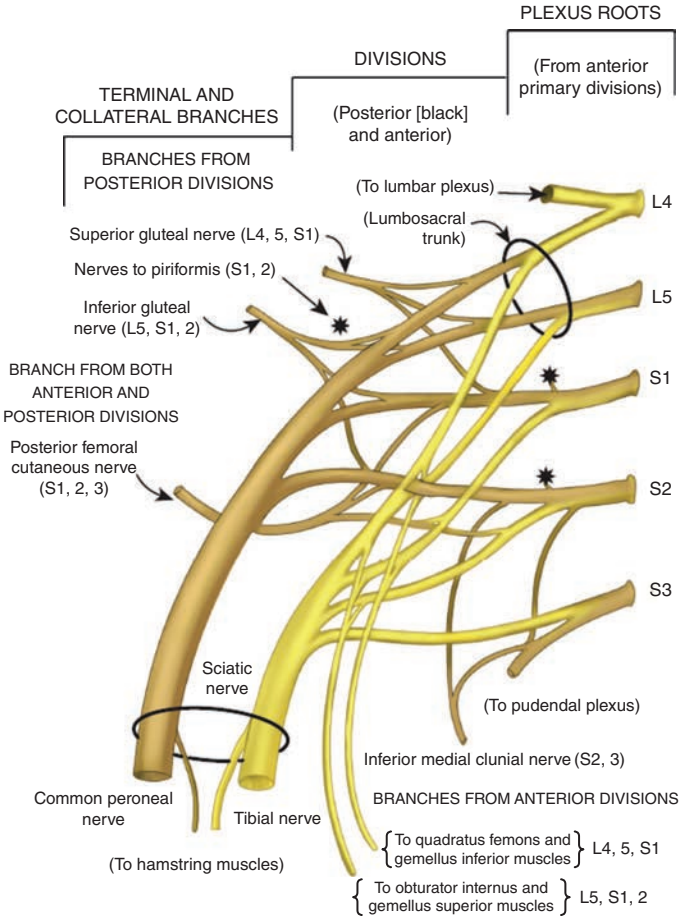

FIGURE 446-4 Lumbosacral trunk sacral plexus and sciatic nerve. *(From AA Amato, JA Russell (eds): Neuromuscular Disorders, 2nd ed. McGraw-Hill Education, 2016, Figure 24-4, p. 542, with permission.)*

of the same lumbar rami. The lumbar plexus communicates with the sacral plexus by the lumbosacral trunk, which contains some fibers from the fourth and all of the fibers from the fifth lumbar ventral rami **(Fig. 446-4)**.

The sacral plexus is the part of the lumbosacral plexus that is formed by the union of the lumbosacral trunk with the ventral rami of the first to fourth sacral nerves. The plexus lies on the posterior and posterolateral wall of the pelvis with its components converging toward the sciatic notch. The lateral trunk of the sciatic nerve (which forms the common peroneal nerve) arises from the union of the dorsal branches of the lumbosacral trunk (L4, L5) and the dorsal branches of the S1 and S2 spinal nerve ventral rami. The medial trunk of the sciatic nerve (which forms the tibial nerve) derives from the ventral branches of the same ventral rami (L4-S2).

LUMBOSACRAL PLEXOPATHIES

Plexopathies are typically recognized when motor, sensory, and if applicable, reflex deficits occur in multiple nerve and segmental distributions confined to one extremity. If localization within the lumbosacral plexus can be accomplished, designation as a lumbar plexopathy, a sacral plexopathy, a lumbosacral trunk lesion, or a panplexopathy is the best localization that can be expected. Although lumbar plexopathies may be bilateral, usually occurring in a stepwise and chronologically dissociated manner, sacral plexopathies are more likely to behave in this manner due to their closer anatomic proximity. The differential diagnosis of plexopathy includes disorders of the conus medullaris and cauda equina (polyradiculopathy). If there is a paucity of pain and sensory involvement, motor neuron disease should be considered as well.

The causes of lumbosacral plexopathies are listed in **Table 446-10**. Diabetic radiculopathy (discussed above) is a fairly common cause of painful leg weakness. Lumbosacral plexopathies are a well-recognized complication of retroperitoneal hemorrhage. Various primary and metastatic malignancies can affect the lumbosacral plexus as well; these include carcinoma of the cervix, endometrium, and ovary; osteosarcoma; testicular cancer; MM; lymphoma; acute myelogenous leukemia; colon cancer; squamous cell carcinoma of the rectum; adenocarcinoma of unknown origin; and intraneural spread of prostate cancer.

RECURRENT NEOPLASTIC DISEASE OR RADIATION-INDUCED PLEXOPATHY

The treatment for various malignancies is often radiation therapy, the field of which may include parts of the brachial plexus. It can be difficult in such situations to determine if a new brachial or lumbosacral plexopathy is related to tumor within the plexus or from radiation-induced nerve damage. Radiation can be associated with microvascular abnormalities and fibrosis of surrounding tissues, which can damage the axons and the Schwann cells. Radiation-induced plexopathy can develop months or years following therapy and is dose dependent.

TABLE 446-10 Lumbosacral Plexopathies: Etiologies

- Retroperitoneal hematoma
- Psoas abscess
- Malignant neoplasm
- Benign neoplasm
- Radiation
- Amyloid
- Diabetic radiculoplexus neuropathy
- Idiopathic radiculoplexus neuropathy
- Sarcoidosis
- Aortic occlusion/surgery
- Lithotomy positioning
- Hip arthroplasty
- Pelvic fracture
- Obstetric injury

Tumor invasion is usually painful and more commonly affects the lower trunk, whereas radiation injury is often painless and affects the upper trunk. Imaging studies such as MRI and CT scans are useful but can be misleading, especially when there is small microscopic invasion of the plexus. EMG can be informative if myokymic discharges are appreciated, as this finding strongly suggests radiation-induced damage.

EVALUATION AND TREATMENT OF PLEXOPATHIES

Most patients with plexopathies will undergo both imaging with MRI and EDx evaluations. Severe pain from acute idiopathic lumbosacral plexopathy may respond to a short course of glucocorticoids.

447 Guillain-Barré Syndrome and Other Immune-Mediated Neuropathies

Stephen L. Hauser, Anthony A. Amato

GUILLAIN-BARRÉ SYNDROME

Guillain-Barré syndrome (GBS) is an acute, frequently severe, and fulminant polyradiculoneuropathy that is autoimmune in nature. It occurs year-round at a rate of between 10 to 20 cases per million annually; in the United States, ~5000–6000 cases occur per year. Males are at slightly higher risk for GBS than females, and in Western countries, adults are more frequently affected than children.

Clinical Manifestations GBS manifests as a rapidly evolving areflexic motor paralysis with or without sensory disturbance. The usual pattern is an ascending paralysis that may be first noticed as rubbery legs. Weakness typically evolves over hours to a few days and is frequently accompanied by tingling dysesthesias in the extremities. The legs are usually more affected than the arms, and facial diparesis is present in 50% of affected individuals. The lower cranial nerves are also frequently involved, causing bulbar weakness with difficulty handling secretions and maintaining an airway; the diagnosis in these patients may initially be mistaken for brainstem ischemia. Pain in the neck, shoulder, back, or diffusely over the spine is also common in the early stages of GBS, occurring in ~50% of patients. Most patients require hospitalization, and in different series, up to 30% require ventilatory assistance at some time during the illness. The need for mechanical ventilation is associated with more severe weakness on admission, a rapid tempo of progression, and the presence of facial and/or bulbar weakness during the first week of symptoms. Fever and constitutional symptoms are absent at the onset and, if present, cast doubt on the diagnosis. Deep tendon reflexes attenuate or disappear within the first few days of onset. Cutaneous sensory deficits (e.g., loss of pain and temperature sensation) are usually relatively mild, but functions subserved by large sensory fibers, such as deep tendon reflexes and proprioception, are more severely affected. Bladder dysfunction may occur in severe cases but is usually transient. If bladder dysfunction is a prominent feature and comes early in the course or there is a sensory level on examination, diagnostic possibilities other than GBS should be considered, particularly spinal cord disease **(Chap. 442)**. Once clinical worsening stops and the patient reaches a plateau (almost always within 4 weeks of onset), further progression is unlikely.

Autonomic involvement is common and may occur even in patients whose GBS is otherwise mild. The usual manifestations are loss of vasomotor control with wide fluctuations in blood pressure, postural hypotension, and cardiac dysrhythmias. These features require close monitoring and management and can be fatal. Pain is another common feature of GBS; in addition to the acute pain described above, a deep aching pain may be present in weakened muscles that patients liken to having overexercised the previous day. Other pains in GBS include dysesthetic pain in the extremities as a manifestation of sensory nerve fiber involvement. These pains are self-limited and often respond to standard analgesics **(Chap. 13)**.

Several subtypes of GBS are recognized, as determined primarily by electrodiagnostic (EDx) and pathologic distinctions **(Table 447-1)**. The most common variant is acute inflammatory demyelinating polyneuropathy (AIDP). Additionally, there are two "axonal" or "nodal/paranodal" variants, which are often clinically severe: the acute motor axonal neuropathy (AMAN) and acute motor sensory axonal neuropathy (AMSAN) subtypes. In addition, a range of limited or regional GBS syndromes are also encountered. Notable among these is the Miller Fisher syndrome (MFS), which presents as rapidly evolving ataxia and areflexia of limbs without weakness, and ophthalmoplegia, often with pupillary paralysis. The MFS variant accounts for ~5% of all cases and is strongly associated with antibodies to the ganglioside GQ1b (see "Immunopathogenesis," below). Other regional variants of GBS include (1) pure sensory forms; (2) ophthalmoplegia with anti-GQ1b antibodies as part of severe motor-sensory GBS; (3) GBS with severe bulbar and facial paralysis, sometimes associated with antecedent cytomegalovirus (CMV) infection and anti-GM2 antibodies; and (4) acute pandysautonomia **(Chap. 440)**.

Antecedent Events Approximately 70% of cases of GBS occur 1–3 weeks after an acute infectious process, usually respiratory or gastrointestinal. Culture and seroepidemiologic techniques show that 20–30% of all cases occurring in North America, Europe, and Australia are preceded by infection or reinfection with *Campylobacter jejuni*. A similar proportion is preceded by a human herpes virus infection, often CMV or Epstein-Barr virus. Other viruses (e.g., HIV, hepatitis E, Zika) and also *Mycoplasma pneumoniae* have been identified as agents involved in antecedent infections, as have recent immunizations. The swine influenza vaccine, administered widely in the United States in 1976, is the most notable example. Influenza vaccines in use from 1992 to 1994, however, resulted in only one additional case of GBS per million persons vaccinated, and the more recent seasonal influenza

TABLE 447-1 Subtypes of Guillain-Barré Syndrome (GBS)

SUBTYPE	FEATURES	ELECTRODIAGNOSIS	PATHOLOGY
Acute inflammatory demyelinating polyneuropathy (AIDP)	Adults affected more than children; 90% of cases in Western world; recovery rapid; anti-GM1 antibodies (<50%)	Demyelinating	First attack on Schwann cell surface; widespread myelin damage, macrophage activation, and lymphocytic infiltration; variable secondary axonal damage
Acute motor axonal neuropathy (AMAN)	Children and young adults; prevalent in China and Mexico; may be seasonal; recovery rapid; anti-GD1a antibodies	Axonal	First attack at motor nodes of Ranvier; macrophage activation, few lymphocytes, frequent periaxonal macrophages; extent of axonal damage highly variable
Acute motor sensory axonal neuropathy (AMSAN)	Mostly adults; uncommon; recovery slow, often incomplete; closely related to AMAN	Axonal	Same as AMAN, but also affects sensory nerves and roots; axonal damage usually severe
Miller Fisher syndrome (MFS)	Adults and children; ophthalmoplegia, ataxia, and areflexia; anti-GQ1b antibodies (90%)	Axonal or demyelinating	Few cases examined; resembles AIDP

vaccines appear to confer a GBS risk of <1 per million. Epidemiologic studies looking at H1N1 vaccination demonstrated at most only a slight increased risk of GBS. Meningococcal vaccinations (Menactra) do not appear to carry an increased risk. Older-type rabies vaccine, prepared in nervous system tissue, is implicated as a trigger of GBS in developing countries where it is still used; the mechanism is presumably immunization against neural antigens. GBS also occurs more frequently than can be attributed to chance alone in patients with lymphoma (including Hodgkin's disease), in HIV-seropositive individuals, and in patients with systemic lupus erythematosus (SLE). GBS, other inflammatory neuropathies, and myositis can also occur as a complication of immune checkpoint inhibitors used to treat various cancers.

C. jejuni has also been implicated in summer outbreaks of AMAN among children and young adults exposed to chickens in rural China. Infection by Zika virus recently has been implicated in the increased incidence of GBS in Brazil and other endemic regions. Recently, GBS has been reported with SARS-CoV-2 infection during the COVID-19 pandemic, but a causal relationship has not been established. There appears to be an increased risk of GBS with SARS-CoV-2 vaccines using adenovirus vectors, but not the messenger RNA vaccines.

Immunopathogenesis Several lines of evidence support an autoimmune basis for acute inflammatory demyelinating polyneuropathy (AIDP), the most common and best-studied type of GBS; the concept extends to all of the subtypes of GBS (Table 447-1).

It is likely that both cellular and humoral immune mechanisms contribute to tissue damage in AIDP. T-cell activation is suggested by the finding that elevated levels of cytokines and cytokine receptors are present in serum (interleukin [IL] 2, soluble IL-2 receptor) and in cerebrospinal fluid (CSF) (IL-6, tumor necrosis factor α, interferon γ). AIDP is also closely analogous to an experimental T cell–mediated immunopathy designated *experimental allergic neuritis* (EAN). EAN is induced in laboratory animals by immune sensitization against protein fragments derived from peripheral nerve proteins and, in particular, against the P2 protein. Based on analogy to EAN, it was initially thought that AIDP was likely to be primarily a T cell–mediated disorder; however, abundant data now suggest that autoantibodies directed against T cell–independent nonprotein determinants may be central to many cases.

Circumstantial evidence suggests that all GBS results from immune responses to nonself antigens (infectious agents, vaccines) that misdirect to host nerve tissue through a resemblance-of-epitope (molecular mimicry) mechanism **(Fig. 447-1)**. The neural targets are likely to be glycoconjugates, specifically gangliosides **(Table 447-2; Fig. 447-2)**. Gangliosides are complex glycosphingolipids that contain one or more sialic acid residues; various gangliosides participate in cell-cell interactions (including those between axons and glia), modulation of receptors, and regulation of growth. They are typically exposed on the plasma membrane of cells, rendering them susceptible to an antibody-mediated attack. Gangliosides and other glycoconjugates are present in large quantity in human nervous tissues and in key sites, such as nodes of Ranvier. Antiganglioside antibodies, most frequently to GM1, are common in GBS (20–50% of cases), particularly in AMAN and AMSAN, and in those cases, they are preceded by *C. jejuni* infection. Some AIDP autoantibodies may recognize glycolipid heterocomplexes, rather than single species, present on cell membranes. Furthermore, isolates of *C. jejuni* from stool cultures of patients with GBS have surface glycolipid structures that antigenically cross react with gangliosides, including GM1, concentrated in human nerves. Sialic acid residues from pathogenic *C. jejuni* strains can also trigger activation of dendritic cells via signaling through Toll-like receptor 4 (TLR4), promoting B-cell differentiation and further amplifying humoral autoimmunity. Another line of evidence implicating humoral autoimmunity is derived from cases of GBS that followed intravenous administration of bovine brain gangliosides for treatment of various neuropathies; 5–15 days after injection, some recipients developed AMAN with high titers of anti-GM1 antibodies that recognized epitopes at nodes of Ranvier and motor endplates. Experimentally, anti-GM1 antibodies can trigger complement-mediated injury at paranodal axon-glial junctions, disrupting the clustering of sodium channels and likely contributing to conduction block (see "Pathophysiology," below).

Anti-GQ1b IgG antibodies are found in >90% of patients with MFS (Table 447-2; Fig. 447-2), and titers of IgG are highest early in the course. Anti-GQ1b antibodies are not found in other forms of GBS unless there is extraocular motor nerve involvement. A possible explanation for this association is that extraocular motor nerves are enriched in GQ1b gangliosides in comparison to limb nerves. In addition, a monoclonal anti-GQ1b antibody raised against *C. jejuni* isolated from a patient with MFS blocked neuromuscular transmission experimentally.

Taken together, these observations provide strong but still inconclusive evidence that autoantibodies play an important pathogenic role in GBS. Although antiganglioside antibodies have been studied most intensively, other antigenic targets may also be important. Proof that these antibodies are pathogenic requires that they be capable of mediating disease following direct passive transfer to naïve hosts; this has not yet been demonstrated, although one case of possible maternal-fetal transplacental transfer of GBS has been described.

In AIDP, an early step in the induction of tissue damage appears to be complement deposition along the outer surface of the Schwann cell. Activation of complement initiates a characteristic vesicular disintegration of the myelin sheath and also leads to recruitment of activated macrophages, which participate in damage to myelin and axons. In AMAN, the pattern is different in that complement is deposited along with IgG at the nodes of Ranvier along large motor axons. Interestingly, in cases of AMAN, antibodies against GD1a appear to have a fine specificity that favors binding to motor rather than sensory nerve roots, even though this ganglioside is expressed on both fiber types.

Pathophysiology In the demyelinating forms of GBS, the basis for flaccid paralysis and sensory disturbance is conduction block. This finding, demonstrable electrophysiologically, implies that the axonal connections remain intact. Hence, recovery can take place rapidly as remyelination occurs. In severe cases of demyelinating GBS, secondary

Subtypes and variants	IgG autoantibodies to
Guillain-Barré syndrome	
Acute inflammatory demyelinating polyneuropathy	None
Facial variant: Facial diplegia and paresthesia	None
Acute motor axonal neuropathy	GM1, GD1a
More and less extensive forms	
Acute motor-sensory axonal neuropathy	GM1, GD1a
Acute motor-conduction-block neuropathy	GM1, GD1a
Pharyngeal-cervical-brachial weakness	GT1a>GQ1b>>GD1a
Miller Fisher syndrome	GQ1b, GT1a
Incomplete forms	
Acute ophthalmoparesis (without ataxia)	GQ1b, GT1a
Acute ataxic neuropathy (without ophthalmoplegia)	GQ1b, GT1a
CNS variant: Bickerstaff's brainstem encephalitis	GQ1b, GT1a

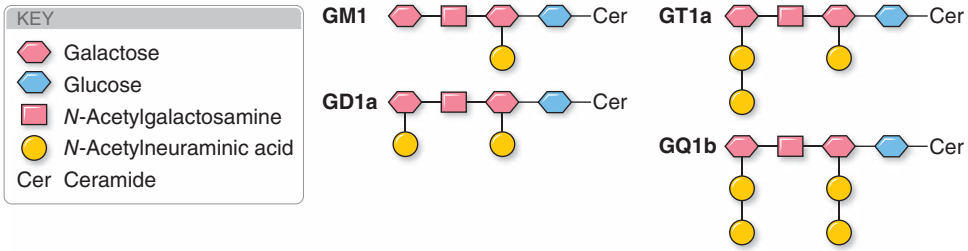

FIGURE 447-1 Spectrum of disorders in Guillain-Barré syndrome and associated antiganglioside antibodies. IgG autoantibodies against GM1 or GD1a are strongly associated with acute motor axonal neuropathy (AMAN), as well as the more extensive acute motor-sensory axonal neuropathy (AMSAN), and the less extensive acute motor-conduction-block neuropathy. IgG anti-GQ1b antibodies, which cross-react with GT1a, are strongly associated with Miller Fisher syndrome, its incomplete forms (acute ophthalmoparesis [without ataxia] and acute ataxic neuropathy [without ophthalmoplegia]), and its more extensive form, Bickerstaff's brainstem encephalitis. Pharyngeal-cervical-brachial weakness is categorized as a localized form of acute motor axonal neuropathy or an extensive form of Miller Fisher syndrome. Half of patients with pharyngeal-cervical-brachial weakness have IgG anti-GT1a antibodies, which often cross-react with GQ1b. IgG anti-GD1a antibodies have also been detected in a small percentage of patients. The anti-GQ1b antibody syndrome includes Miller Fisher syndrome, acute ophthalmoparesis, acute ataxic neuropathy, Bickerstaff's brainstem encephalitis, and pharyngeal-cervical-brachial weakness. The presence of clinical overlap also indicates that Miller Fisher syndrome is part of a continuous spectrum with these conditions. Patients who have had Guillain-Barré syndrome overlapped with Miller Fisher syndrome or with its related conditions have IgG antibodies against GM1 or GD1a as well as against GQ1b or GT1a, supporting a link between AMAN and anti-GQ1b syndrome. *(From N Yuki, H-P Hartung: Guillain-Barré syndrome. N Engl J Med 366:2294, 2012. Copyright © 2012 Massachusetts Medical Society. Reprinted with permission from Massachusetts Medical Society.)*

axonal degeneration usually occurs; its extent can be estimated electrophysiologically. More secondary axonal degeneration correlates with a slower rate of recovery and a greater degree of residual disability. With AMAN and AMSAN, a primary axonal pattern is encountered electrophysiologically (low-amplitude compound muscle action potentials). The implication has been that axons have degenerated and become disconnected from their targets, specifically the neuromuscular junctions, and must therefore regenerate for recovery to take place. However, the rapid recover in many cases suggests the low amplitudes are often from reversible conduction block due to binding of antibodies to ion channel proteins in the nodes and paranodes. In severe cases, axonal degeneration can occur, and it is in these cases that recovery is much slower.

Laboratory Features CSF findings are distinctive, consisting of an elevated CSF protein level (1–10 g/L [100–1000 mg/dL]) without accompanying pleocytosis. The CSF is often normal when symptoms have been present for ≤48 h; by the end of the first week, the level of protein is usually elevated. A transient increase in the CSF white cell count (10–100/μL) occurs on occasion in otherwise typical GBS; however, a sustained CSF pleocytosis suggests an alternative diagnosis (viral myelitis) or a concurrent diagnosis such as unrecognized HIV infection, leukemia or lymphoma with infiltration of nerves, or neurosarcoidosis. EDx features are mild or absent in the early stages of GBS and lag behind the clinical evolution. In AIDP, the earliest features are prolonged F-wave latencies, prolonged distal latencies, and reduced amplitudes of compound muscle action potentials (CMAPs), probably owing to the predilection for involvement of nerve roots and distal motor nerve terminals early in the course. Later, slowing of conduction velocity, conduction block, and temporal dispersion may be appreciated (Table 447-1). Occasionally, sensory nerve action potentials (SNAPs) may be normal in the feet (e.g., sural nerve) when abnormal in the arms. This is also a sign that the patient does not have one of the more typical "length-dependent" polyneuropathies. As mentioned, in AMAN and AMSAN, the principal EDx finding is reduced amplitude of CMAPs (and also SNAPS with AMSAN) without conduction slowing or prolongation of distal latencies, which early on is caused by conduction block but later can be due to axonal degeneration.

Diagnosis GBS is a descriptive entity. The diagnosis of AIDP is made by recognizing the pattern of rapidly evolving paralysis with areflexia, absence of fever or other systemic symptoms, and characteristic antecedent events. In 2011, the Brighton Collaboration developed a new set of case definitions for GBS in response to needs of epidemiologic studies of vaccination and assessing risks of GBS (Table 447-3). These criteria have subsequently been validated. Other disorders that may enter into the differential diagnosis include acute myelopathies (especially with prolonged back pain and sphincter disturbances); diphtheria (early oropharyngeal disturbances); Lyme polyradiculitis and other tick-borne paralyses; porphyria (abdominal pain, seizures, psychosis); vasculitic neuropathy (check erythrocyte sedimentation rate, described below); poliomyelitis and acute flaccid myelitis (wild-type poliovirus, West Nile virus, enterovirus D68, enterovirus A71, Japanese encephalitis virus, and the wild-type poliovirus); CMV polyradiculitis (in immunocompromised patients); critical illness neuropathy or myopathy; neuromuscular junction disorders such as myasthenia gravis and botulism (pupillary reactivity lost early); poisonings with organophosphates, thallium, or arsenic; paralytic shellfish poisoning; or severe hypophosphatemia (rare). Cases of acute flaccid myelitis may pose particular challenges

TABLE 447-2 Principal Antiglycolipid Antibodies Implicated in Immune Neuropathies

CLINICAL PRESENTATION	ANTIBODY TARGET	USUAL ISOTYPE
Acute Immune Neuropathies (Guillain-Barré Syndrome)		
Acute inflammatory demyelinating polyneuropathy (AIDP)	No clear patterns GM1 most common	IgG (polyclonal)
Acute motor axonal neuropathy (AMAN)	GD1a, GM1, GM1b, GalNAc–GD1a (<50% for any)	IgG (polyclonal)
Miller Fisher syndrome (MFS)	GQ1b (>90%)	IgG (polyclonal)
Acute pharyngeal cervicobrachial neuropathy (APCBN)	GT1a (? most)	IgG (polyclonal)
Chronic Immune Neuropathies		
Chronic inflammatory demyelinating polyneuropathy (CIDP) (75%)	Approximately 10% to CNTN1 or NF155, less often to NF140/186 and Caspr1, and even more rarely to P0, myelin P2 protein, or PMP22	IgG4 with CNTN1, NF155, NF140/186, Caspr1 Rare IgM with NF155
CIDP-M (MGUS associated) (25%)	Neural binding sites	IgG, IgA (monoclonal)
Chronic sensory > motor neuropathy	SGPG, SGLPG (on MAG) (50%)	IgM (monoclonal)
	Uncertain (50%)	IgM (monoclonal)
Multifocal motor neuropathy (MMN)	GM1, GalNAc–GD1a, others (25–50%)	IgM (polyclonal, monoclonal)
Chronic sensory ataxic neuropathy	GD1b, GQ1b, and other b-series gangliosides	IgM (monoclonal)

Abbreviations: CIDP-M, CIDP with a monoclonal gammopathy; Caspr1, contactin associated protein-1; CNTN1, contactin-1; MAG, myelin-associated glycoprotein; MGUS, monoclonal gammopathy of undetermined significance; NF140/186, neurofascin 140/186; NF155, neurofascin 155; SGPG, sulfoglucuronyl paragloboside; SGLPG, sulfoglucuronyl lactosaminyl paragloboside.

in distinguishing these from GBS because sphincter disturbances are often absent.

Laboratory tests are helpful primarily to exclude mimics of GBS. CSF pleocytosis is seen with poliomyelitis, acute flaccid myelitis, and Lyme and CMV polyradiculitis. EDx features may be minimal early in GBS, and the CSF protein level may not rise until the end of the first week. If the diagnosis is strongly suspected, treatment should be initiated without waiting for evolution of the characteristic EDx and CSF findings to occur. GBS patients with risk factors for HIV or with CSF pleocytosis should have a serologic test for HIV.

TREATMENT

Guillain-Barré Syndrome

In the vast majority of patients with GBS, treatment should be initiated as soon after diagnosis as possible. Each day counts; ~2 weeks after the first motor symptoms, it is not known whether immunotherapy is still effective. If the patient has already reached the plateau stage, then treatment probably is no longer indicated, unless the patient has severe motor weakness and one cannot exclude the possibility that an immunologic attack is still ongoing. Either high-dose intravenous immune globulin (IVIg) or plasmapheresis (PLEX) can be initiated, as they are equally effective for typical GBS. A combination of the two therapies is not significantly better than either alone. IVIg is often the initial therapy chosen because of its ease of administration and good safety record. IVIg is usually administered as five daily infusions for a total dose of 2 g/kg body weight. There is some evidence that GBS autoantibodies are neutralized by anti-idiotypic antibodies present in IVIg preparations, perhaps accounting for the therapeutic effect. A course of PLEX usually consists of ~40–50 mL/kg plasma exchange (PE) 4–5 times over 7–10 days. Meta-analysis of randomized clinical trials indicates that treatment reduces the need for mechanical ventilation by nearly half (from 27 to 14% with PLEX) and increases the likelihood of full recovery at 1 year (from 55 to 68%). Functionally significant improvement may occur toward the end of the first week of treatment or may be delayed for several weeks. The lack of noticeable improvement following a course of IVIg or PLEX is not an indication to treat with the alternate treatment. However, there are occasional patients who are treated early in the course of GBS and improve, who then relapse within a month. Brief retreatment with the original therapy is usually effective in such cases. Glucocorticoids have not been found to be effective in GBS. Occasional patients with very mild forms of GBS, especially those who appear to have already reached a plateau when initially seen, may be managed conservatively without IVIg or PLEX.

In the worsening phase of GBS, most patients require monitoring in a critical care setting, with particular attention to vital capacity, heart rhythm, blood pressure, nutrition, deep-vein thrombosis prophylaxis, cardiovascular status, early consideration (after 2 weeks of intubation) of tracheotomy, and chest physiotherapy. As noted, ~30% of patients with GBS require ventilatory assistance, sometimes for prolonged periods of time (several weeks or longer). Frequent turning and assiduous skin care are important, as are daily range-of-motion exercises to avoid joint contractures and daily reassurance as to the generally good outlook for recovery.

Prognosis and Recovery Approximately 85% of patients with GBS achieve a full functional recovery within several months to a year, although minor findings on examination (such as areflexia) may persist and patients often complain of continued symptoms, including fatigue. The mortality rate is <5% in optimal settings; death usually results from secondary pulmonary complications. The outlook is worst in patients with severe proximal motor and sensory axonal damage. Such axonal damage may be either primary or secondary in nature (see "Pathophysiology," above), but in either case, successful regeneration cannot occur. Other factors that worsen the outlook for recovery are advanced age, a fulminant or severe attack, and a delay in the onset of treatment. Between 5 and 10% of patients with typical GBS have one or more late relapses; many of these cases are then classified as chronic inflammatory demyelinating polyneuropathy (CIDP).

CHRONIC INFLAMMATORY DEMYELINATING POLYNEUROPATHY

CIDP is distinguished from GBS by its chronic course. In other respects, this neuropathy shares many features with the common demyelinating form of GBS, including elevated CSF protein levels and the EDx findings of acquired demyelination. Most cases occur in adults, and males are affected slightly more often than females. The incidence of CIDP is lower than that of GBS, but due to the protracted course, the prevalence is greater. As with GBS, CIDP and its variants can be triggered by use of immune checkpoint inhibitors used to treat various cancers.

Clinical Manifestations Onset is usually gradual over a few months or longer, but in a few cases, the initial attack is indistinguishable from that of GBS. An acute-onset form of CIDP may mimic GBS but should be considered if it deteriorates >9 weeks after onset or relapses at least three times. Symptoms are both motor and sensory in most cases. Weakness of the limbs is usually symmetric but can be strikingly asymmetric in multifocal acquired demyelinating sensory and motor (MADSAM) neuropathy variant (Lewis-Sumner syndrome) in which discrete peripheral nerves are involved. There is considerable

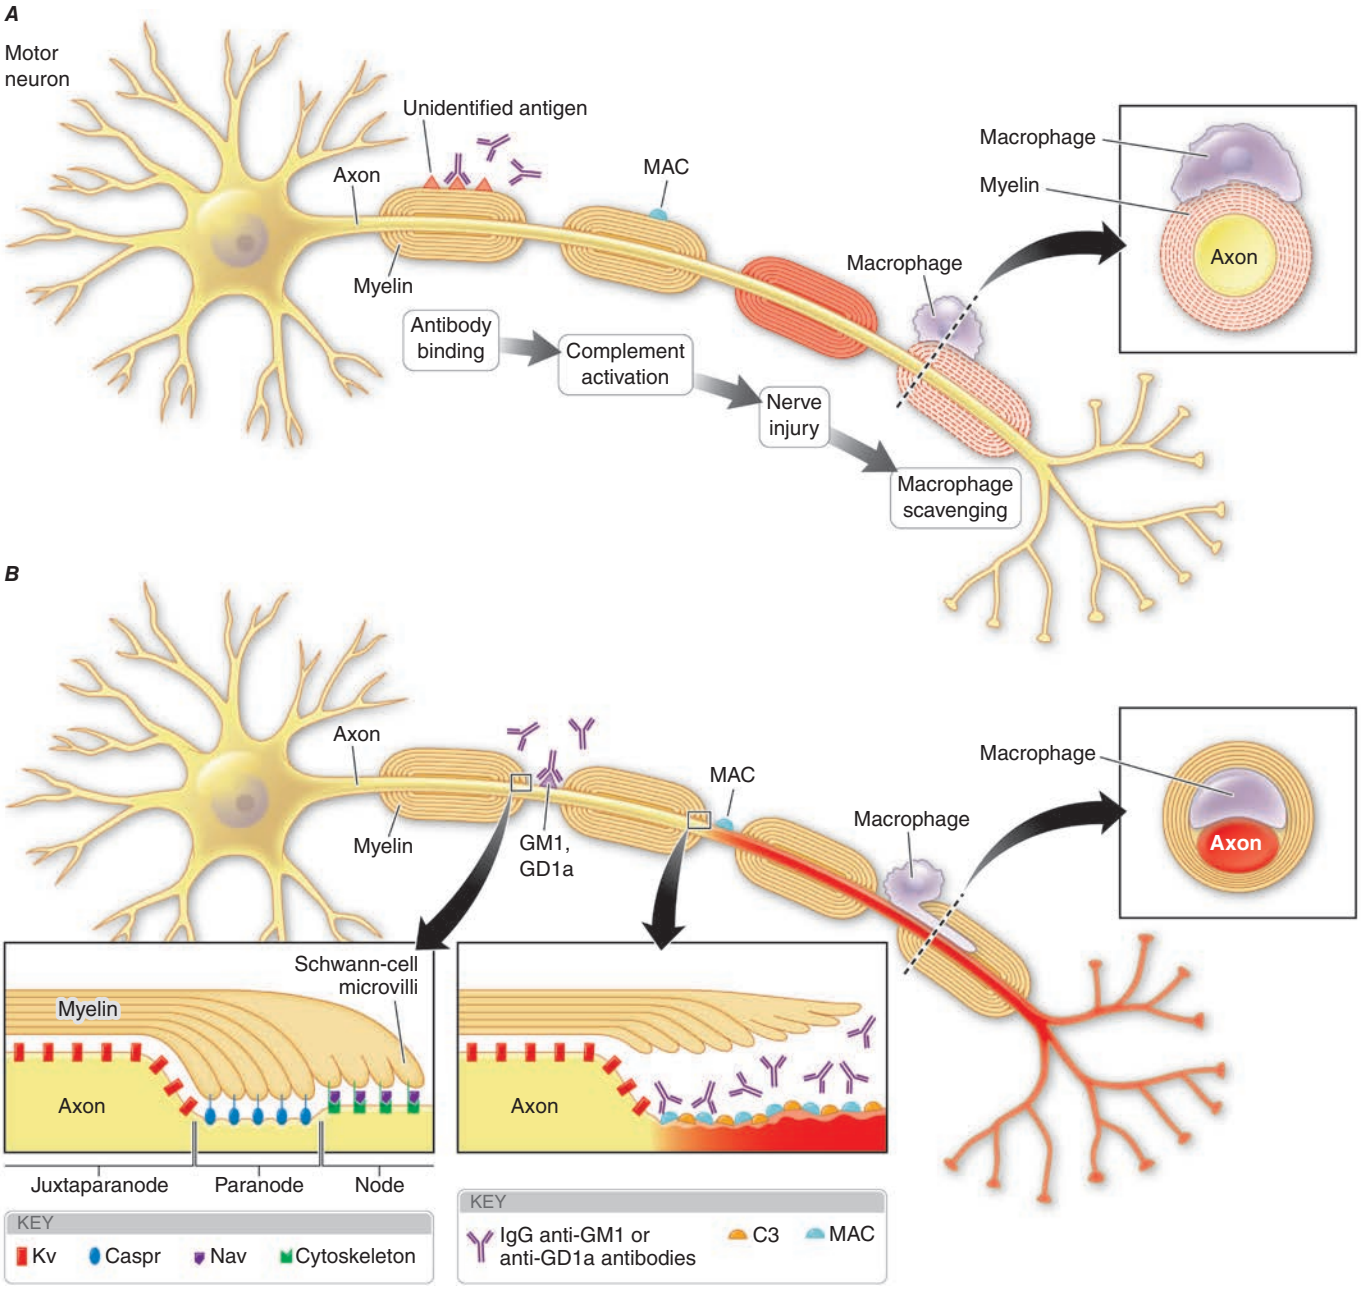

FIGURE 447-2 Possible immune mechanisms in Guillain-Barré syndrome (GBS). Panel ***A*** shows the immunopathogenesis of AIDP. Although autoantigens have yet to be unequivocally identified, autoantibodies may bind to myelin antigens and activate complement. This is followed by the formation of membrane-attack complex (MAC) on the outer surface of Schwann cells and the initiation of vesicular degeneration. Macrophages subsequently invade myelin and act as scavengers to remove myelin debris. Panel ***B*** shows the immunopathogenesis of acute axonal forms of GBS (acute motor axonal neuropathy [AMAN] and acute motor-sensory axonal neuropathy [AMSAN]). Myelinated axons are divided into four functional regions: the nodes of Ranvier, paranodes, juxtaparanodes, and internodes. Gangliosides GM1 and GD1a are strongly expressed at the nodes of Ranvier, where the voltage-gated sodium (Nav) channels are localized. Contactin-associated protein (Caspr) and voltage-gated potassium (Kv) channels are respectively present at the paranodes and juxtaparanodes. IgG anti-GM1 or anti-GD1a autoantibodies bind to the nodal axolemma, leading to MAC formation. This results in the disappearance of Nav clusters and the detachment of paranodal myelin, which can lead to nerve-conduction failure and muscle weakness. Axonal degeneration may follow at a later stage. Macrophages subsequently invade from the nodes into the periaxonal space, scavenging the injured axons. *(From N Yuki, H-P Hartung: Guillain-Barré syndrome. N Engl J Med 366:2294, 2012. Copyright © 2012 Massachusetts Medical Society. Reprinted with permission from Massachusetts Medical Society.)*

variability from case to case. Some patients experience a chronic progressive course, whereas others, usually younger patients, have a relapsing and remitting course. A small proportion have cranial nerve findings, including external ophthalmoplegia. Some have only motor findings, and a small proportion present with a relatively pure syndrome of sensory ataxia. The latter can be seen in the chronic inflammatory sensory polyradiculopathy (CISP) variant of CIDP in which demyelination predominantly occurs at the sensory roots or with the distal acquired demyelinating symmetric (DADS) variant.

Approximately, 10% of cases are associated with IgG4 isotype antibodies directed against contactin-1 (CNTN1) or neurofascin 155 (NF155), with early axonal damage, severe distal motor involvement, or sensory ataxia with tremor. Less commonly, IgM anti-NF140/186 CIDP associated with sensory ataxia but without tremor, low-amplitude CMAPs (conduction block or axonal degeneration), and nephrotic syndrome have also been reported. Anti-contactin associated protein-1 (Caspr1) antibodies occur in CIDP associated with severe neuropathic pain.

CIDP tends to ameliorate over time with treatment; the result is that many years after onset, nearly 75% of patients have reasonable functional status. Death from CIDP is uncommon.

Diagnosis The diagnosis rests on characteristic clinical, CSF, and electrophysiologic findings. The CSF is usually acellular with an

TABLE 447-3 Brighton Criteria for Diagnosis of Guillain-Barré Syndrome (GBS) and Miller Fisher Syndrome

Clinical case definitions for diagnosis of GBS

Level 1 of diagnostic certainty

Bilateral AND flaccid weakness of the limbs
AND
Decreased or absent deep tendon reflexes in weak limbs
AND
Monophasic illness pattern and interval between onset and nadir of weakness between 12 h and 28 days and subsequent clinical plateau
AND
Electrophysiologic findings consistent with GBS
AND
Cytoalbuminologic dissociation (i.e., elevation of CSF protein level above laboratory normal value AND CSF total white cell count <50 cells/μL)
AND
Absence of an identified alternative diagnosis for weakness

Level 2 of diagnostic certainty

Bilateral AND flaccid weakness of the limbs
AND
Decreased or absent deep tendon reflexes in weak limbs
AND
Monophasic illness pattern and interval between onset and nadir of weakness between 12 h and 28 days and subsequent clinical plateau
AND
CSF total white cell count <50 cells/μL (with or without CSF protein elevation above laboratory normal value)
OR
If CSF not collected or results not available, electrophysiologic studies consistent with GBS
AND
Absence of identified alternative diagnosis for weakness

Level 3 of diagnostic certainty

Bilateral and flaccid weakness of the limbs
AND
Decreased or absent deep tendon reflexes in weak limbs
AND
Monophasic illness pattern and interval between onset and nadir of weakness between 12 h and 28 days and subsequent clinical plateau
AND
Absence of identified alternative diagnosis for weakness

Clinical case definitions for diagnosis of Miller Fisher syndrome

Level 1 of diagnostic certainty

Bilateral ophthalmoparesis and bilateral reduced or absent tendon reflexes, and ataxia
AND
Absence of limb weakness
AND
Monophasic illness pattern and interval between onset and nadir of weakness between 12 h and 28 days and subsequent clinical plateau
AND
Cytoalbuminologic dissociation (i.e., elevation of cerebrospinal protein above the laboratory normal and total CSF white cell count <50 cells/μL)
AND
Nerve conduction studies are normal, OR indicate involvement of sensory nerves only
AND
No alterations in consciousness or corticospinal tract signs
AND
Absence of identified alternative diagnosis

Level 2 of diagnostic certainty

Bilateral ophthalmoparesis and bilateral reduced or absent tendon reflexes and ataxia
AND
Absence of limb weakness
AND
Monophasic illness pattern and interval between onset and nadir of weakness between 12 h and 28 days and subsequent clinical plateau
AND
CSF with a total white cell count <50 cells/μL) (with or without CSF protein elevation above laboratory normal value)
OR
Nerve conduction studies are normal, OR indicate involvement of sensory nerves only
AND
No alterations in consciousness or corticospinal tract signs
AND
Absence of identified alternative diagnosis

Level 3 of diagnostic certainty

Bilateral ophthalmoparesis and bilateral reduced or absent tendon reflexes and ataxia
AND
Absence of limb weakness
AND
Monophasic illness pattern and interval between onset and nadir of weakness between 12 h and 28 days and subsequent clinical plateau
AND
No alterations in consciousness or corticospinal tract signs
AND
Absence of identified alternative diagnosis

Abbreviation: CSF, cerebrospinal fluid.

elevated protein level, sometimes several times normal. As with GBS, a CSF pleocytosis should lead to the consideration of HIV infection, leukemia or lymphoma, and neurosarcoidosis. EDx findings reveal variable degrees of conduction slowing, prolonged distal latencies, distal and temporal dispersion of CMAPs, and conduction block as the principal features. In particular, the presence of conduction block is a certain sign of an acquired demyelinating process. Evidence of axonal loss, presumably secondary to demyelination, is present in >50% of patients. Serum protein electrophoresis with immunofixation is indicated to search for monoclonal gammopathy and associated conditions (see "Monoclonal Gammopathy of Undetermined Significance," below). MRI can demonstrate enlarged nerves, clumping of cauda equina, and enhancement. Ultrasound is cheaper and often more readily available and can likewise show enlargement of nerves at the roots or more distally. Studies have shown that imaging completements EDx findings and increases sensitivity. In all patients with presumptive CIDP, it is also reasonable to exclude vasculitis, collagen vascular disease (especially SLE), chronic hepatitis, HIV infection, amyloidosis, and diabetes mellitus. Other associated conditions include inflammatory bowel disease and lymphoma.

Pathogenesis Biopsy in typical CIDP reveals little inflammation and onion-bulb changes (imbricated layers of attenuated Schwann cell processes surrounding an axon) that result from recurrent demyelination and remyelination (Fig. 447-1). The response to therapy suggests that CIDP is immune-mediated; CIDP responds to glucocorticoids, whereas GBS does not. Passive transfer of demyelination into experimental animals has been accomplished using IgG purified from the serum of some patients with CIDP, lending support for a humoral autoimmune pathogenesis. A minority of patients have serum antibodies

against P0, myelin P2 protein, or PMP22 (proteins whose genes are mutated in certain forms of hereditary Charcot-Marie-Tooth neuropathy). As previously mentioned, antibodies of IgG4 isotype directed against CNTN1, NF155, NF140/186, and Caspr1 have been associated with early nodal and paranodal damage with and a poor response to IVIg. CNTN1 and its partner Caspr1 interact with NF155 at paranodal axoglial junctions. Passive transfer of IgG4 CNTN1 antibodies produces paranodal damage and ataxia in rodents. It is also of interest that a CIDP-like illness developed spontaneously in the nonobese diabetic (NOD) mouse when the immune co-stimulatory molecule B7-2 (CD86) was genetically deleted; this suggests that CIDP can result from altered triggering of T cells by antigen-presenting cells.

As many as 25% of patients with clinical features of CIDP also have a monoclonal gammopathy of undetermined significance (MGUS), discussed below. Cases associated with monoclonal IgA or IgG kappa usually respond to treatment as favorably as cases without a monoclonal gammopathy. Patients with IgM-kappa monoclonal gammopathy and antibodies directed against myelin-associated glycoprotein (MAG) have a distinct demyelinating polyneuropathy with more sensory findings, usually only distal weakness, and a poor response to immunotherapy.

TREATMENT

Chronic Inflammatory Demyelinating Polyneuropathy

Most authorities initiate treatment for CIDP when progression is rapid or walking is compromised. If the disorder is mild, management can be expectant, awaiting spontaneous remission. Controlled studies have shown that high-dose IVIg, subcutaneous Ig (scIg), PLEX, and glucocorticoids are all more effective than placebo. Initial therapy is usually with IVIg, administered as 2.0 g/kg body weight given in divided doses over 2–5 days; three monthly courses are generally recommended before concluding a patient has failed treatment. If the patient responds, the infusion intervals can be gradually increased or the dosage decreased (e.g., starting at 1 g/kg every 3–4 weeks). Patients who require more frequent IVIg, experience side effects with IVIg (headaches), have poor venous access, or find it more convenient are treated with scIg (2–3 times a week such that the total dosage per month is the same or slightly higher than the monthly dosage of IVIg). PLEX, which appears to be as effective as IVIg, is initiated at 2–3 treatments per week for 6 weeks; periodic retreatment may also be required. Treatment with glucocorticoids is another option (60–80 mg prednisone PO daily for 1–2 months, followed by a gradual dose reduction of 10 mg per month as tolerated), but long-term adverse effects including bone demineralization, gastrointestinal bleeding, and cushingoid changes are problematic. As many as one-third of patients with CIDP fail to respond adequately to the initial therapy chosen; a different treatment should then be tried. Patients who fail therapy with IVIg, scIg, PLEX, and glucocorticoids may benefit from treatment with immunosuppressive agents such as azathioprine, methotrexate, cyclosporine, and cyclophosphamide, either alone or as adjunctive therapy. CIDP associated with anti-CNTN1, NF155, NF140/186, and Caspr1 antibodies (IgG4 subclass antibodies) is typically refractory to IVIg, but several studies suggest a response to rituximab. Use of these therapies requires periodic reassessment of their risks and benefits. In patients with a CIDP-like neuropathy who fail to respond to treatment, it is important to evaluate for POEMS syndrome (*p*olyneuropathy, *o*rganomegaly, *e*ndocrinopathy, *m*onoclonal gammopathy, *s*kin changes; see below).

MULTIFOCAL MOTOR NEUROPATHY

Multifocal motor neuropathy (MMN) is a distinctive but uncommon neuropathy that presents as slowly progressive motor weakness and atrophy evolving over years in the distribution of selected nerve trunks, associated with sites of persistent focal motor conduction block in the same nerve trunks. Sensory fibers are relatively spared. The arms are affected more frequently than the legs, and >75% of all patients are male. Some cases have been confused with lower motor neuron forms of amyotrophic lateral sclerosis **(Chap. 437)**. Less than 50% of patients present with high titers of polyclonal IgM antibody to the ganglioside GM1. It is uncertain how this finding relates to the discrete foci of persistent motor conduction block, but high concentrations of GM1 gangliosides are normal constituents of nodes of Ranvier in peripheral nerve fibers. Pathology reveals demyelination and mild inflammatory changes at the sites of conduction block.

Most patients with MMN respond to high-dose IVIg or scIg (dosages as for CIDP, above); periodic retreatment is required (usually at least monthly) to maintain the benefit. Some refractory patients have responded to rituximab or cyclophosphamide. Glucocorticoids and PE are not effective.

NEUROPATHIES WITH MONOCLONAL GAMMOPATHY

MULTIPLE MYELOMA

Clinically overt polyneuropathy occurs in ~5% of patients with the commonly encountered type of multiple myeloma, which exhibits either lytic or diffuse osteoporotic bone lesions. These neuropathies are sensorimotor, are usually mild and slowly progressive but may be severe, and generally do not reverse with successful suppression of the myeloma. In most cases, EDx and pathologic features are consistent with a process of axonal degeneration.

In contrast, myeloma with osteosclerotic features, although representing only 3% of all myelomas, is associated with polyneuropathy in one-half of cases. These neuropathies, which may also occur with solitary plasmacytoma, are distinct because they (1) are demyelinating or mixed axonal and demyelinating by EDx, have elevated CSF protein, and clinically resemble CIDP; (2) often respond to radiation therapy or removal of the primary lesion; (3) are associated with different monoclonal proteins and light chains (almost always lambda as opposed to primarily kappa in the lytic type of multiple myeloma); (4) are typically refractory to standard treatments of CIDP; and (5) may occur in association with other systemic findings including thickening of the skin, hyperpigmentation, hypertrichosis, organomegaly, endocrinopathy, anasarca, and clubbing of fingers. These are features of POEMS syndrome. Levels of vascular endothelial growth factor (VEGF) are increased in the serum, and this factor is thought to somehow play a pathogenic role in this syndrome. Treatment of the neuropathy is best directed at the osteosclerotic myeloma using surgery, radiotherapy, chemotherapy, or autologous peripheral blood stem cell transplantation.

Neuropathies are also encountered in other systemic conditions with gammopathy, including Waldenström macroglobulinemia, primary systemic amyloidosis, and cryoglobulinemic states (mixed essential cryoglobulinemia, some cases of hepatitis C).

MONOCLONAL GAMMOPATHY OF UNDETERMINED SIGNIFICANCE

Chronic polyneuropathies occurring in association with MGUS are usually associated with the immunoglobulin isotypes IgG, IgA, and IgM. Most patients present with isolated sensory symptoms in their distal extremities and have EDx features of an axonal sensory or sensorimotor polyneuropathy. These patients otherwise resemble idiopathic sensory polyneuropathy, and the MGUS might just be coincidental. They usually do not respond to immunotherapies designed to reduce the concentration of the monoclonal protein. Some patients, however, present with generalized weakness and sensory loss and EDx studies indistinguishable from CIDP without monoclonal gammopathy (see "Chronic Inflammatory Demyelinating Polyneuropathy," above), and their response to immunosuppressive agents is also similar. An exception is the syndrome of IgM-kappa monoclonal gammopathy associated with an indolent, long-standing, sometimes static

sensory neuropathy, frequently with tremor and sensory ataxia. Most patients are men and aged >50 years. In the majority, the monoclonal IgM immunoglobulin binds to a normal peripheral nerve constituent, MAG, found in the paranodal regions of Schwann cells. Binding appears to be specific for a polysaccharide epitope that is also found in other normal peripheral nerve myelin glycoproteins, P0 and PMP22, and also in other normal nerve-related glycosphingolipids (Fig. 447-1). In the MAG-positive cases, IgM paraprotein is incorporated into the myelin sheaths of affected patients and widens the spacing of the myelin lamellae, thus producing a distinctive ultrastructural pattern. Demyelination and remyelination are the hallmarks of the lesions, but axonal loss develops over time. These anti-MAG polyneuropathies are typical refractory to immunotherapy. In a small proportion of patients (30% at 10 years), MGUS will in time evolve into frankly malignant conditions such as multiple myeloma or lymphoma.

VASCULITIC NEUROPATHY

Peripheral nerve involvement is common in polyarteritis nodosa (PAN), appearing in half of all cases clinically and in 100% of cases at postmortem studies **(Chap. 363)**. The most common pattern is multifocal (asymmetric) motor-sensory neuropathy (mononeuropathy multiplex) due to ischemic lesions of nerve trunks and roots; however, some cases of vasculitic neuropathy present as a distal, symmetric sensorimotor polyneuropathy. Symptoms of neuropathy are a common presenting complaint in patients with PAN. The EDx findings are those of an axonal process. Small- to medium-sized arteries of the vasa nervorum, particularly the epineural vessels, are affected in PAN, resulting in a widespread ischemic neuropathy. A high frequency of neuropathy occurs in eosinophilic granulomatosis with polyangiitis (Churg-Strauss syndrome [CSS]).

Systemic vasculitis should always be considered when a subacute or chronically evolving mononeuropathy multiplex occurs in conjunction with constitutional symptoms (fever, anorexia, weight loss, loss of energy, malaise, and nonspecific pains). Diagnosis of suspected vasculitic neuropathy is made by a combined nerve and muscle biopsy, with serial section or skip-serial techniques.

Approximately one-third of biopsy-proven cases of vasculitic neuropathy are "nonsystemic" in that the vasculitis appears to affect only peripheral nerves. Constitutional symptoms are absent, and the course is more indolent than that of PAN. The erythrocyte sedimentation rate may be elevated, but other tests for systemic disease are negative. Nevertheless, clinically silent involvement of other organs is likely, and vasculitis is frequently found in muscle biopsied at the same time as nerve.

Vasculitic neuropathy may also be seen as part of the vasculitis syndrome occurring in the course of other connective tissue disorders. The most frequent is rheumatoid arthritis, but ischemic neuropathy due to involvement of vasa nervorum may also occur in mixed cryoglobulinemia, Sjögren's syndrome, granulomatosis with polyangiitis (formerly known as Wegener's), hypersensitivity angiitis, SLE, and progressive systemic sclerosis.

Some vasculitides are associated with antineutrophil cytoplasmic antibodies (ANCAs), which in turn are subclassified as cytoplasmic (cANCA) or perinuclear (pANCA). cANCAs are directed against proteinase 3 (PR3), whereas pANCAs target myeloperoxidase (MPO). PR3/cANCAs are associated with eosinophilic granulomatosis with polyangiitis, whereas MPO/pANCAs are typically associated with microscopic polyangiitis, CSS, and less commonly PAN. Of note, MPO/pANCA has also been seen in minocycline-induced vasculitis.

Management of these neuropathies, including the "nonsystemic" vasculitic neuropathy, consists of treatment of the underlying condition as well as the aggressive use of glucocorticoids and cyclophosphamide. Use of these immunosuppressive agents has resulted in dramatic improvements in outcome, with 5-year survival rates now >80%. Clinical trials found that the combination of rituximab and glucocorticoids is not inferior to cyclophosphamide and glucocorticoids. Thus, combination therapy with glucocorticoids and rituximab is recommended as the standard initial treatment, particularly for ANCA-associated vasculitis. Mepolizumab, an anti-IL-5 monoclonal antibody, when added to standard care, is also effective for treatment of eosinophilic granulomatosis with polyangiitis.

ANTI-Hu PARANEOPLASTIC NEUROPATHY (CHAP. 94)

This uncommon immune-mediated disorder manifests as a sensory neuronopathy (i.e., selective damage to sensory nerve bodies in dorsal root ganglia). The onset is often asymmetric with dysesthesias and sensory loss in the limbs that soon progress to affect all limbs, the torso, and the face. Marked sensory ataxia, pseudoathetosis, and inability to walk, stand, or even sit unsupported are frequent features and are secondary to the extensive deafferentation. Subacute sensory neuronopathy may be idiopathic, but more than half of cases are paraneoplastic, primarily related to lung cancer, and most of those are small-cell lung cancer (SCLC). Diagnosis of the underlying SCLC requires awareness of the association, testing for the paraneoplastic antibody, and often positron emission tomography (PET) scanning for the tumor. The target antigens are a family of RNA-binding proteins (HuD, HuC, and Hel-N1) that in normal tissues are only expressed by neurons. The same proteins are usually expressed by SCLC, triggering in some patients an immune response characterized by antibodies and cytotoxic T cells that cross-react with the Hu proteins of the dorsal root ganglion neurons, resulting in immune-mediated neuronal destruction. An encephalomyelitis may accompany the sensory neuronopathy and presumably has the same pathogenesis. Neurologic symptoms usually precede, by ≤6 months, the identification of SCLC. The sensory neuronopathy runs its course in a few weeks or months and stabilizes, leaving the patient disabled. Most cases are unresponsive to treatment with glucocorticoids, IVIg, PE, or immunosuppressant drugs.

448 Myasthenia Gravis and Other Diseases of the Neuromuscular Junction

Anthony A. Amato

Myasthenia gravis (MG) is a neuromuscular junction (NMJ) disorder characterized by weakness and fatigability of skeletal muscles. The underlying defect is a decrease in the number of available acetylcholine receptors (AChRs) at NMJs due to an antibody-mediated autoimmune attack. Treatment now available for MG is highly effective, although a specific cure has remained elusive.

PATHOPHYSIOLOGY

At the NMJ (Fig. 448-1, Video 448-1), acetylcholine (ACh) is synthesized in the motor nerve terminal and stored in vesicles (quanta). When an action potential travels down a motor nerve and reaches the nerve terminal, ACh from 150 to 200 vesicles is released and combines with AChRs that are densely packed at the peaks of postsynaptic folds. The AChR consists of five subunits (2α, 1β, 1δ, 1γ, or ε) arranged around a central pore. When ACh combines with the binding sites on the α subunits of the AChR, the channel in the AChR opens, permitting the rapid entry of cations, chiefly sodium, which produces depolarization at the end-plate region of the muscle fiber. If the depolarization is sufficiently large, it initiates an action potential that is propagated along the muscle fiber, triggering muscle contraction. This process is rapidly terminated by hydrolysis of ACh by acetylcholinesterase (AChE), which is present within the synaptic folds, and by diffusion of ACh away from the receptor.

In MG, the fundamental defect is a decrease in the number of available AChRs at the postsynaptic muscle membrane. In addition, the postsynaptic folds are flattened, or "simplified." These changes result in decreased efficiency of neuromuscular transmission. Therefore, although ACh is released normally, it produces small end-plate potentials that may fail to trigger muscle action potentials. Failure of transmission results in weakness of muscle contraction.

The amount of ACh released per impulse normally declines on repeated activity (termed *presynaptic rundown*). In the myasthenic

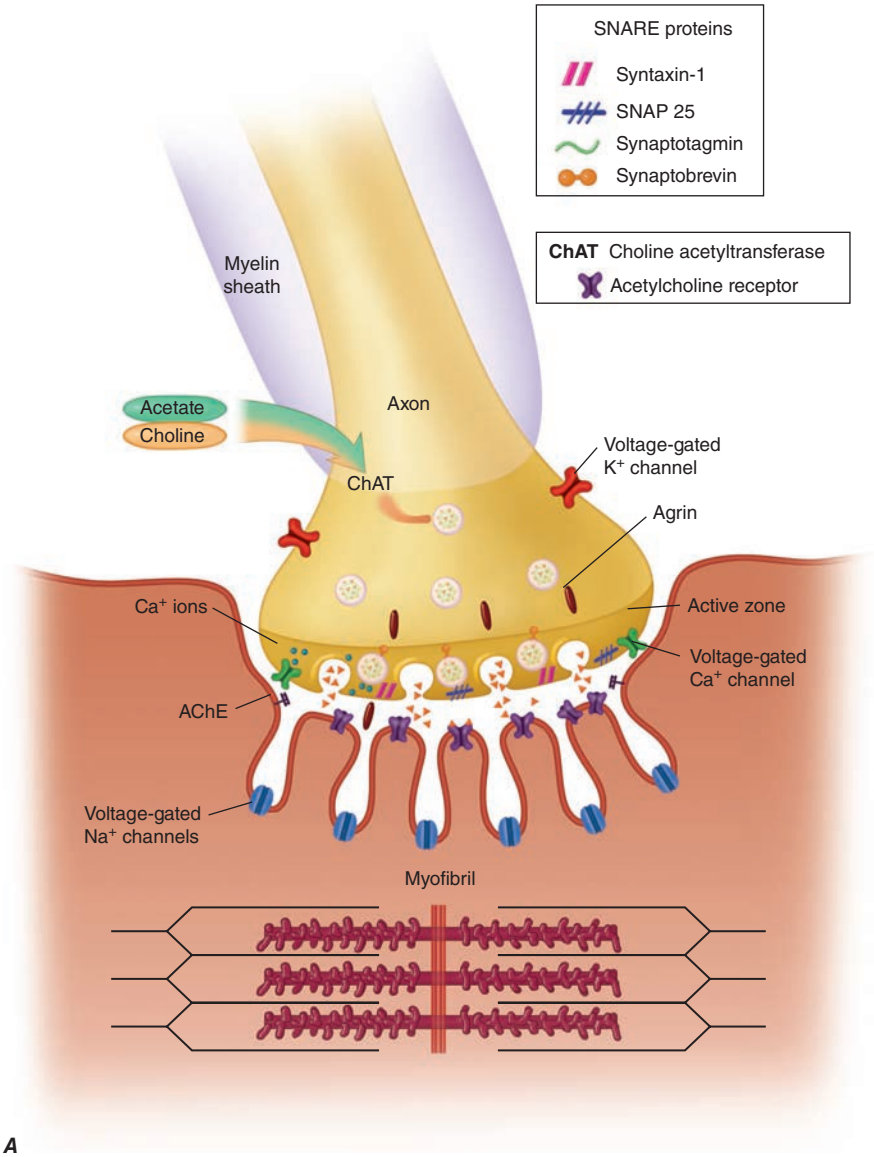

FIGURE 448-1 Illustrations of (*A*) a normal presynaptic neuromuscular junction, (*B*) a normal postsynaptic terminal, and (*C*) a myasthenic neuromuscular junction. AChE, acetylcholinesterase. See text for description of normal neuromuscular transmission. The myasthenia gravis (MG) junction demonstrates a reduced number of acetylcholine receptors (AChRs); flattened, simplified postsynaptic folds; and a widened synaptic space. See Video 448-1 also. *(From AA Amato, J Russell: Neuromuscular Disorders, 2nd ed. New York, McGraw-Hill, 2016, Figures 25-3 [p 588], 25-4 [p 589], and 25-5 [p 590]; with permission.)*

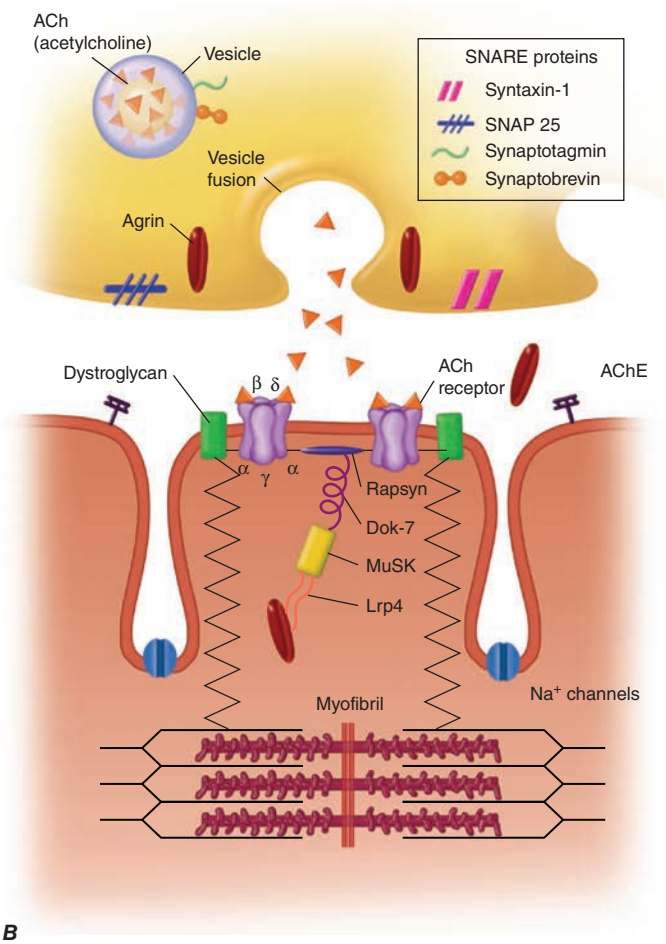
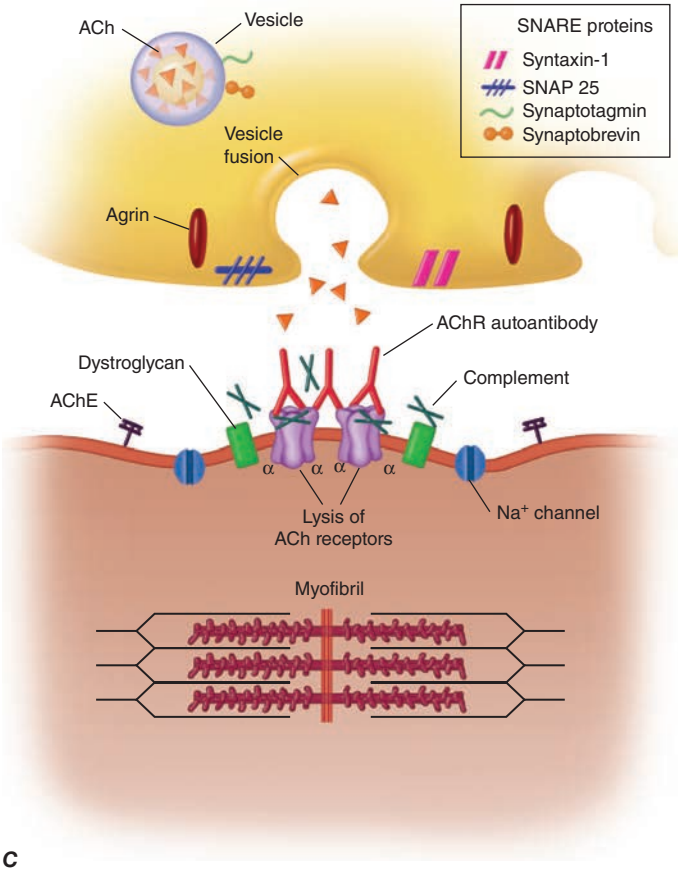


B



C

FIGURE 448-1 (*Continued*)

patient, the decreased efficiency of neuromuscular transmission combined with the normal rundown results in the activation of fewer and fewer muscle fibers by successive nerve impulses and hence increasing weakness, or *myasthenic fatigue*. This mechanism also accounts for the decremental response to repetitive nerve stimulation seen on electrodiagnostic testing.

MG is an autoimmune disorder most commonly caused by anti-AChR antibodies. The anti-AChR antibodies reduce the number of available AChRs at NMJs by three distinct mechanisms: (1) accelerated turnover of AChRs by a mechanism involving cross-linking and rapid endocytosis of the receptors; (2) damage to the postsynaptic muscle membrane by the antibody in collaboration with complement; and (3) blockade of the active site of the AChR (i.e., the site that normally binds Ach). An immune response to muscle-specific kinase (MuSK), a protein involved in AChR clustering at the NMJ, can also result in MG, with reduction of AChRs demonstrated experimentally. Anti-MuSK antibody occurs in ~10% of patients (~40% of AChR antibody–negative patients), whereas 1–3% have antibodies to another protein at the NMJ—low-density lipoprotein receptor-related protein 4 (LRP4)—that is also important for clustering of AChRs. The pathogenic antibodies are IgG and are T-cell dependent. Thus, immunotherapeutic strategies directed against either the antibody-producing B cells or helper T cells are effective in this antibody-mediated disease.

How the autoimmune response is initiated and maintained in MG is not completely understood, but the thymus appears to play a role in this process. The thymus is abnormal in ~75% of patients with AChR antibody–positive MG; in ~65%, the thymus is "hyperplastic," with the presence of active germinal centers detected histologically, although the hyperplastic thymus is not necessarily enlarged. An additional 10% of patients have thymic tumors (thymomas). Muscle-like cells within the thymus (myoid cells), which express AChRs on their surface, may serve as a source of autoantigen and trigger the autoimmune reaction within the thymus gland.

CLINICAL FEATURES

MG has a prevalence as high as 200 in 100,000. It affects individuals in all age groups, but peak incidences occur in women in their twenties and thirties and in men in their fifties and sixties. Overall, women are affected more frequently than men, in a ratio of ~3:2. The cardinal features are *weakness* and *fatigability* of muscles. The weakness increases during repeated use (fatigue) or late in the day and may improve following rest or sleep. The course of MG is often variable. Exacerbations and remissions may occur, particularly during the first few years after the onset of the disease. Unrelated infections or systemic disorders can lead to increased myasthenic weakness and may precipitate "crisis" (see below).

The distribution of muscle weakness often has a characteristic pattern. The cranial muscles, particularly the lids and extraocular muscles (EOMs), are typically involved early in the course of MG; diplopia and ptosis are common initial complaints. Facial weakness produces a "snarling" expression when the patient attempts to smile. Weakness in chewing is most noticeable after prolonged effort, as in chewing meat. Speech may have a nasal timbre caused by weakness of the palate or a dysarthric "mushy" quality due to tongue weakness. Difficulty in swallowing may occur as a result of weakness of the palate, tongue, or pharynx, giving rise to nasal regurgitation or aspiration of liquids or food. Bulbar weakness and more frequent episodes of respiratory depression can be especially prominent in MuSK antibody–positive MG. In ~85% of patients, the weakness becomes generalized, affecting the limb muscles as well. If weakness remains restricted to the EOMs for 3 years, it is likely that it will not become generalized, and these patients are said to have *ocular MG*. The limb weakness in MG is often proximal and may be asymmetric. Despite the muscle weakness, deep

TABLE 448-1 Diagnosis of Myasthenia Gravis (MG)

History
Diplopia, ptosis, dysarthria, dysphagia, dyspnea
Weakness in characteristic distribution: proximal limbs, neck extensors, generalized
Fluctuation and fatigue: worse with repeated activity, improved by rest
Effects of previous treatments
Physical examination
Evaluation for ptosis at rest and following 1 min of exercise, extraocular muscles and subjective diplopia, orbicularis oculi and oris strength, jaw opening and closure
Assessment of muscle strength in neck and extremities
Weakness following repeated shoulder abduction
Vital capacity measurement
Absence of other neurologic signs
Laboratory testing
Anti-AChR radioimmunoassay: ~85% positive in generalized MG; 50% in ocular MG; definite diagnosis if positive; negative result does not exclude MG; ~40% of AChR antibody–negative patients with generalized MG have anti-MuSK antibodies and ~2% have LRP-4 antibodies
Repetitive nerve stimulation: decrement of >10% at 3 Hz: highly probable
Single-fiber electromyography: blocking and jitter, with normal fiber density; confirmatory, but not specific
Edrophonium chloride (Enlon®) 2 mg + 8 mg IV; highly probable diagnosis if unequivocally positive
Ice-pack test looking for improvement in ptosis is very sensitive
For ocular or cranial MG: exclude intracranial lesions by CT or MRI

Abbreviations: AChR, acetylcholine receptor; CT, computed tomography; LRP4, lipoprotein receptor-related protein 4; MRI, magnetic resonance imaging; MuSK, muscle-specific tyrosine kinase.

tendon reflexes are preserved. If ventilatory weakness becomes requires respiratory assistance, the patient is said to be in *crisis*.

DIAGNOSIS AND EVALUATION (TABLE 448-1)

The diagnosis is suspected on the basis of weakness and fatigability in the typical distribution described above, without loss of reflexes or impairment of sensation or other neurologic function. The suspected diagnosis should always be confirmed definitively before treatment is undertaken; this is essential because (1) other treatable conditions may closely resemble MG and (2) the treatment of MG may involve surgery and the prolonged use of drugs with potentially adverse side effects.

Ice-Pack Test If a patient has ptosis, application of a pack of ice over a ptotic eye often results in improvement if the ptosis is due to an NMJ defect. This is hypothesized to be due to less depletion of quanta of AChR in the cold and reduced activity of AChE at the NMJ. It is a quick and easy test to do in the clinic or at the bedside of a hospitalized patient.

Autoantibodies Associated with MG As previously mentioned, anti-AChR antibodies are detectable in the serum of ~85% of all myasthenic patients but in only ~50% of patients with weakness confined to the ocular muscles. The presence of anti-AChR antibodies is virtually diagnostic of MG, but a negative test does not exclude the disease. The measured level of anti-AChR antibody does not correspond well with the severity of MG in different patients. Antibodies to MuSK are present in ~40% of AChR antibody–negative patients with generalized MG. MuSK antibodies are rarely present in AChR antibody–positive patients or in patients with MG limited to ocular muscles. These antibodies may interfere with clustering of AChRs at NMJs. A small proportion of MG patients without antibodies to AChR or MuSK have antibodies to LRP4. Interestingly, antibodies against agrin also have been found in rare patients with MG. Agrin is a protein derived from motor nerves that normally binds to LRP4 and is important for normal clustering of AChRs at NMJ. Additionally, anti-striated muscle antibodies directed against titin and other skeletal muscle components are found in ~30% of myasthenics without thymoma, 24% of thymoma patients without myasthenia, and 70–80% of patients with both myasthenia and thymoma. Furthermore, antibodies directed against Netrin-1 receptors and Caspr2 (contactin-associated protein-like 2) often coexist and are associated in patients with thymoma who have MG and neuromyotonia or Morvan's syndrome.

Electrodiagnostic Testing Repetitive nerve stimulation may provide helpful diagnostic evidence of MG. Anti-AChE medication should be stopped 6–12 h before testing. It is best to test weak muscles or proximal muscle groups. Electrical stimulation is delivered at a rate of two or three per second to the appropriate nerves, and action potentials are recorded from the muscles. In normal individuals, the amplitude of the evoked muscle action potentials does not change by >10% at these rates of stimulation. However, in myasthenic patients, there is a rapid reduction of >10% in the amplitude of the evoked responses.

Anticholinesterase Test Drugs that inhibit the enzyme AChE allow ACh to interact repeatedly with the limited number of AChRs in MG, producing improvement in muscle strength. Edrophonium is used most commonly for diagnostic testing because of the rapid onset (30 s) and short duration (~5 min) of its effect. An objective end point must be selected to evaluate the effect of edrophonium, such as weakness of EOMs, impairment of speech, or the length of time that the patient can maintain the arms in forward. An initial IV dose of 2 mg of edrophonium is given. If definite improvement occurs, the test is considered positive and is terminated. If there is no change, the patient is given an additional 8 mg IV. The dose is administered in two parts because some patients react to edrophonium with side effects such as nausea, diarrhea, salivation, fasciculations, and rarely with severe symptoms of syncope or bradycardia. Atropine (0.6 mg) should be drawn up in a syringe and ready for IV administration if these symptoms become troublesome. The edrophonium test is now reserved for patients with clinical findings that are suggestive of MG but who have negative antibody, electrodiagnostic testing, or ice-pack test. False-positive tests occur in occasional patients with other neurologic disorders, such as amyotrophic lateral sclerosis (Chap. 437), and in placebo-reactors. False-negative or equivocal tests may also occur.

Pulmonary Function Tests (Chap. 284) Measurements of ventilatory function are valuable because of the frequency and seriousness of respiratory impairment in myasthenic patients.

Differential Diagnosis Other conditions that cause weakness of the cranial and/or somatic musculature include the nonautoimmune congenital myasthenia, drug-induced myasthenia, Lambert-Eaton myasthenic syndrome (LEMS), neurasthenia, hyperthyroidism (Graves' disease), botulism, intracranial mass lesions, oculopharyngeal dystrophy, and mitochondrial myopathy (Kearns-Sayre syndrome, progressive external ophthalmoplegia). Treatment with immune checkpoint inhibitors for cancer may also result in autoimmune MG. Myositis and myocarditis are also often found in combination with MG as a complication of checkpoint inhibitors (Chap. 365). Symptoms typically begin after the first or second cycle of treatment, with ptosis, diplopia, and bulbar and occasionally extremity weakness. Patients usually improve when the immune checkpoint inhibitor is discontinued and a short course of glucocorticoids or intravenous immunoglobulin (IVIg) is administered. Treatment with penicillamine (used for scleroderma or rheumatoid arthritis) has also been associated with MG. Aminoglycoside antibiotics or procainamide can cause exacerbation of weakness in myasthenic patients; very large doses can cause neuromuscular weakness in normal individuals.

The *congenital myasthenic syndromes (CMS)* comprise a rare heterogeneous group of disorders of the NMJ that are not autoimmune but rather are due to genetic mutations in which virtually any component of the NMJ may be affected. Alterations in function of the presynaptic nerve terminal, in the various subunits of the AChR, AChE, or the other molecules involved in end-plate development or maintenance, have been identified in the different forms of CMS. These disorders share many of the clinical features of autoimmune MG, including weakness and fatigability of proximal or distal extremity muscles

TABLE 448-2 Congenital Myasthenic Syndromes (CMS)

CMS SUBTYPE	GENE	CLINICAL FEATURES	ELECTROPHYSIOLOGIC FEATURES	RESPONSE TO ACHE INHIBITORS	TREATMENT
Presynaptic Disorders					
CMS with paucity of ACh release	*CHAT; CHT*	AR; early onset, respiratory failure at birth, episodic apnea, improvement with age	Decremental response to RNS	Improve	AChE inhibitors; 3,4-DAP
Synaptic Disorders					
AChE deficiency	*COLQ*	AR; early onset; variable severity; axial weakness with scoliosis; apnea; +/– EOM involvement, slow or absent pupillary responses	After discharges on nerve stimulation and decrement on RNS	Worsen	Albuterol; ephedrine; 3,4-DAP; avoid AChE inhibitors
Postsynaptic Disorders Involving AChR Deficiency or Kinetics					
Primary AChR deficiency	AChR subunit genes	AR; early onset; variable severity; fatigue; typical MG features	Decremental response to RNS	Improve	AChE inhibitors; 3,4-DAP
AChR kinetic disorder: slow channel syndrome	AChR subunit genes	AD; onset childhood to early adult; weak forearm extensors and neck; respiratory weakness; variable severity	After discharges on nerve stimulation and decrement on RNS	Worsen	Fluoxetine and quinidine; avoid AChE inhibitors
AChR kinetic disorder: fast channel syndrome	AChR subunit genes	AR; early onset; mild to severe; ptosis, EOM involvement; weakness and fatigue	Decremental response to RNS	Improve	AChE inhibitors; caution with 3,4-DAP
Postsynaptic Disorders Involving Abnormal Clustering/Function of AChR					
	DOK 7	AR; limb girdle weakness with ptosis but no EOM involvement	Decremental response to RNS	Variable	Albuterol; ephedrine; may worsen with AChE inhibitors
	Rapsyn	AR; early onset with hypotonia, respiratory failure, and arthrogryposis at birth to early adult onset resembling MG	Decremental response to RNS	Variable	Albuterol
	Agrin	AR; limb girdle or distal weakness, apnea	Decremental response to RNS	Variable	Albuterol; may worsen with AChE inhibitors
	MuSK	AR; congenital or childhood onset of ptosis, EOM and progressive limb girdle weakness	Decremental response to RNS	Variable	Variable response to AChE inhibitors and 3,4-DAP Positive response to albuterol
	LRP4	AR; congenital onset with hypotonia; ventilatory failure, mild ptosis, and EOM weakness	Decremental response to RNS	Worsen	Worsen with AChE inhibitors
Other Postsynaptic Disorders					
Limb-girdle CMS with tubular aggregates	*GFPT1; DPAGT1; ALG2; ALG14; DPAGT1*	AR; limb-girdle weakness usually without ptosis or EOM weakness; onset in infancy or early adult	Decremental response to RNS	Variable	Albuterol; ephedrine; variable response to AChE inhibitors and 3,4-DAP; albuterol
Congenital muscular dystrophy with myasthenia	*Plectin*	AR; infantile or childhood onset of generalized weakness including ptosis and EOM; epidermolysis bullosa simplex; elevated CK	Decremental response to RNS	Variable	No response to AChE and 3,4-DAP

Abbreviations: ACh, acetylcholine; AChE, acetylcholinesterase; AChR, acetylcholine receptor; AD, autosomal dominant; AR, autosomal recessive; CHAT, choline acetyl transferase; CHT, sodium-dependent high-affinity choline transport 1; CK, creatine kinase; CMA, congenital myasthenic syndrome; COLQ, collaganic tail of endplate acetylcholinesterase; 3,4-DAP, 3,4-diaminopyridine; Dok7, downstream of tyrosine kinase 7; DPAGT1, UDP-N-acetylglucosamine-dolichyl-phosphate N-acetylglucosamine phosphotransferase; EOM, extraocular muscle; GFPT1, glutamine-fructose-6-phosphate aminotransferase 1; LRP4, lipoprotein receptor-related protein 4; MG, myasthenia gravis; MuSK, muscle specific kinase; RNS, repetitive nerve stimulation.

Source: From AA Amato, J Russell: *Neuromuscular Disorders*, 2nd ed. McGraw-Hill, 2016, Table 26-2, p. 627; with permission.

and often involving EOMs and the eyelids similar to the distribution in autoimmune MG. CMS should be suspected when symptoms of myasthenia have begun in infancy or childhood, but they can present in early adulthood. As in acquired autoimmune MG, repetitive nerve stimulation is associated with a decremental response. Some forms (e.g., AChE deficiency, prolonged open channel syndrome) have a feature of after-discharges that are not seen in MG. An additional clue is the absence of AChR and MuSK antibodies, although these are absent in ~10% of generalized MG patients (so-called double seronegative MG).

The prevalence of CMS is estimated at ~3.8 per 100,000. The most common genetic defects occur in the ε subunit of the AChR, accounting for ~50% of CMS cases, with mutations in the genes encoding for rapsin, COLQ, DOK7, agrin, and GFPT together accounting for ~40%. In most of the recessively inherited forms of CMS, the mutations are heteroallelic; that is, different mutations affecting each of the two alleles are present. Features of the most common forms of CMS are summarized in Table 448-2. Molecular analysis is required for precise elucidation of the defect; this may lead to helpful treatment as well as genetic counseling. Some forms of CMS improve with AChE inhibitors, while others (e.g., slow channel syndrome, AChE deficiency, DOK7-related CMS) actually worsen. Fluoxetine and quinidine can be useful for slow channel syndrome, and albuterol for mutations affecting AChE, DOK7, rapsyn, and agrin. Additionally, ephedrine and 3,4-diaminopyridine (3,4-DAP) may be of benefit in some forms of CMS.

LEMS is a presynaptic disorder of the NMJ that can cause weakness similar to that of MG. The proximal muscles of the lower limbs are most commonly affected, but other muscles may be involved as well. Cranial nerve findings, including ptosis of the eyelids and diplopia, occur in up to 70% of patients and resemble features of MG. However,

the two conditions are usually readily distinguished because patients with LEMS have depressed or absent reflexes and experience autonomic changes such as dry mouth and impotence. Nerve stimulation produces an initial low-amplitude compound muscle action potential and, at low rates of repetitive stimulation (2–3 Hz), a decremental responses as seen in MG; however, at high rates (20–50 Hz) or following brief exercise, incremental responses occur. LEMS is caused by autoantibodies directed against P/Q-type calcium channels at the motor nerve terminals detected in ~85% of LEMS patients. These autoantibodies impair the release of ACh from nerve terminals. In young adults, particularly women, LEMS is not associated with an underlying cancer. However, in older adults, most LEMS is associated with malignancy, most commonly small-cell lung cancer (SCLC). The tumor cells may express calcium channels that stimulate the autoimmune response. Treatment of LEMS involves plasmapheresis and immunotherapy, as for MG. 3,4-DAP and pyridostigmine can also help with symptoms. 3,4-DAP acts by blocking potassium channels, which results in prolonged depolarization of the motor nerve terminals and thus enhances ACh release. Pyridostigmine prolongs the action of ACh, allowing repeated interactions with AChRs.

Botulism **(Chap. 153)** is due to potent bacterial toxins produced by any of eight different strains of *Clostridium botulinum*. The toxins enzymatically cleave specific proteins essential for the release of ACh from the motor nerve terminal, thereby interfering with neuromuscular transmission. Most commonly, botulism is caused by ingestion of improperly prepared food containing toxin. Rarely, the nearly ubiquitous spores of *C. botulinum* may germinate in wounds. In infants, the spores may germinate in the gastrointestinal (GI) tract and release toxin, causing muscle weakness. Patients present with myasthenia-like bulbar weakness (e.g., diplopia, dysarthria, dysphagia) and lack sensory symptoms and signs. Weakness may generalize to the limbs and may result in respiratory failure. Reflexes are present early, but they may be diminished as the disease progresses. Mentation is normal. Autonomic findings include paralytic ileus, constipation, urinary retention, dilated or poorly reactive pupils, and dry mouth. The demonstration of toxin in serum by bioassay is definitive, but the results usually take a relatively long time to be completed and may be negative. Nerve stimulation studies reveal reduced compound muscle action potential (CMAP) amplitudes that increase following high-frequency repetitive stimulation. Treatment includes ventilatory support and aggressive inpatient supportive care (e.g., nutrition, deep-vein thrombosis prophylaxis) as needed. Antitoxin should be given as early as possible to be effective and can be obtained through the Centers for Disease Control and Prevention. A preventive vaccine is available for laboratory workers or other highly exposed individuals.

Neurasthenia is the historic term for a myasthenia-like fatigue syndrome without an organic basis. These patients may present with subjective symptoms of weakness and fatigue, but muscle testing usually reveals the "give-away weakness" characteristic of nonorganic disorders; the complaint of fatigue in these patients means tiredness or apathy rather than decreasing muscle power on repeated effort. *Hyperthyroidism* is readily diagnosed or excluded by tests of thyroid function, which should be carried out routinely in patients with suspected MG. Abnormalities of thyroid function (hyper- or hypothyroidism) may increase myasthenic weakness. Diplopia resembling that in MG may occasionally be due to an intracranial mass lesion that compresses nerves to the EOMs (e.g., sphenoid ridge meningioma), but magnetic resonance imaging (MRI) of the head and orbits usually reveals the lesion.

Progressive external ophthalmoplegia is a rare condition resulting in weakness of the EOMs, which may be accompanied by weakness of the proximal muscles of the limbs and other systemic features. Most patients with this condition have mitochondrial disorders that can be detected by genetic testing or with muscle biopsy **(Chap. 449)**.

Search for Associated Conditions (Table 448-3) Myasthenic patients have an increased incidence of several associated disorders. Thymic abnormalities occur in ~75% of AChR antibody–positive patients, as noted above. Neoplastic change (thymoma) may produce enlargement of the thymus, which is detected by chest computed tomography (CT). A thymic shadow on CT scan may normally be present through young adulthood, but enlargement of the thymus in a patient age >40 years is highly suspicious of thymoma. Hyperthyroidism occurs in 3–8% of patients and may aggravate the myasthenic weakness. Thyroid function tests should be obtained in all patients with suspected MG. Other autoimmune disorders, most commonly systemic lupus erythematosus and rheumatoid arthritis, can coexist with MG; associations also occur with neuromyelitis optica, neuromyotonia, Morvan's syndrome (encephalitis, insomnia, confusion, hallucinations, autonomic dysfunction, and neuromyotonia), rippling muscle disease, granulomatous myositis/myocarditis, and chronic inflammatory demyelinating polyneuropathy.

TABLE 448-3 Disorders Associated with Myasthenia Gravis and Recommended Laboratory Tests

Associated disorders
Disorders of the thymus: thymoma, hyperplasia
Other autoimmune neurologic disorders: chronic inflammatory demyelinating polyneuropathy, neuromyelitis optica
Other autoimmune disorders: Hashimoto's thyroiditis, Graves' disease, rheumatoid arthritis, systemic lupus erythematosus, skin disorders, family history of autoimmune disorder
Disorders or circumstances that may exacerbate myasthenia gravis: hyperthyroidism or hypothyroidism, occult infection, medical treatment for other conditions (see Table 448-4)
Disorders that may interfere with therapy: tuberculosis, diabetes, peptic ulcer, gastrointestinal bleeding, renal disease, hypertension, asthma, osteoporosis, obesity
Recommended laboratory tests or procedures
CT or MRI of chest
Tests for antinuclear antibodies, rheumatoid factor
Thyroid function tests
Testing for tuberculosis
Fasting blood glucose, hemoglobin A_{1c}
Pulmonary function tests
Bone densitometry

Abbreviations: CT, computed tomography; MRI, magnetic resonance imaging.

An infection of any kind can exacerbate typical MG and should be sought carefully in patients with relapses. Because of the side effects of glucocorticoids and other immunotherapies used in the treatment of MG, a thorough medical investigation should be undertaken, searching specifically for evidence of chronic or latent infection (such as tuberculosis or hepatitis), hypertension, diabetes, renal disease, and glaucoma.

TREATMENT

Myasthenia Gravis

The prognosis has improved strikingly as a result of advances in treatment. Nearly all myasthenic patients can be returned to full productive lives with proper therapy. The most useful treatments for MG include anticholinesterase medications, glucocorticoids and other immunosuppressive agents, thymectomy, plasmapheresis, IVIg, rituximab, and complement inhibitors (eculizumab) **(Fig. 448-2)**.

ANTICHOLINESTERASE MEDICATIONS

Anticholinesterase medication produces at least partial improvement in most myasthenic patients, although improvement is complete in only a few. Patients with anti-MuSK MG generally obtain less benefit from anticholinesterase agents than those with AChR antibodies and may actually worsen. Pyridostigmine is the most widely used anticholinesterase drug and is initiated at a dosage of 30–60 mg three to four times daily. The beneficial action of oral pyridostigmine begins within 15–30 min and lasts for 3–4 h, but individual responses vary. The frequency and amount of the dose should be tailored to the patient's individual requirements

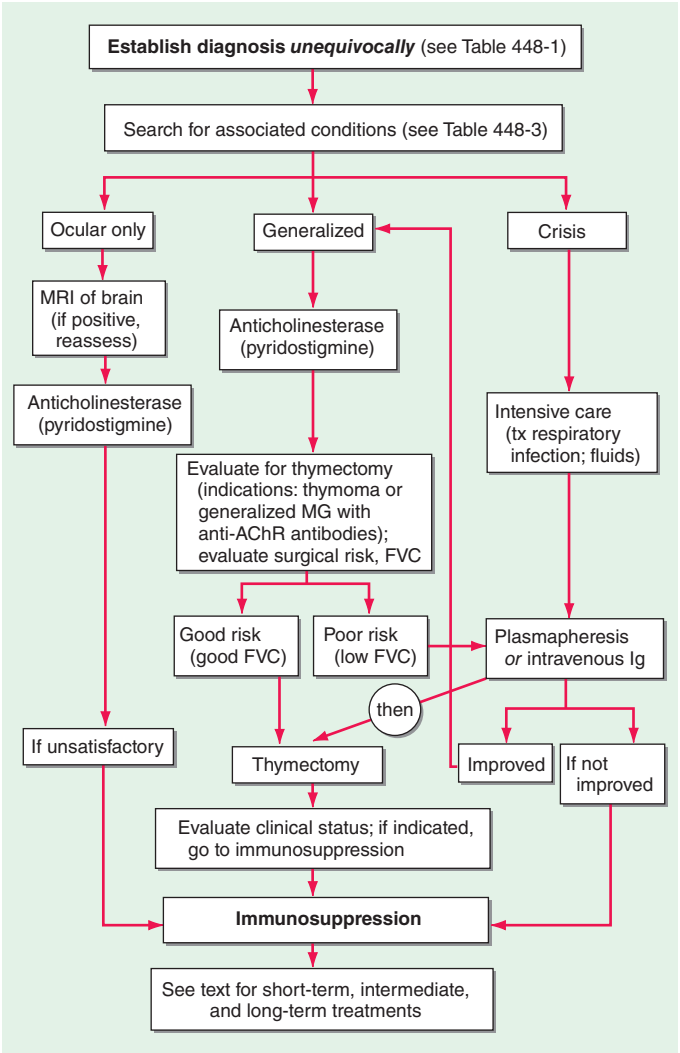


FIGURE 448-2 Algorithm for the management of myasthenia gravis. FVC, forced vital capacity; MRI, magnetic resonance imaging.

throughout the day. For example, patients with weakness in chewing and swallowing may benefit by taking the medication before meals so that peak strength coincides with mealtimes. Long-acting pyridostigmine may occasionally be useful to get the patient through the night but should not be used for daytime medication because of variable absorption. The maximum useful dose of pyridostigmine rarely exceeds 300 mg daily. Overdosage with anticholinesterase medication may cause increased weakness and other side effects. In some patients, muscarinic side effects of the anticholinesterase medication (diarrhea, abdominal cramps, salivation, nausea) may limit the dose tolerated. Atropine/diphenoxylate or loperamide is useful for the treatment of GI symptoms.

THYMECTOMY

Two separate issues should be distinguished: (1) surgical removal of thymoma, and (2) thymectomy as a treatment for MG. Surgical removal of a thymoma is necessary because of the possibility of local tumor spread, although most thymomas are histologically benign. A large international trial of extended transternal thymectomy in nonthymomatous, AChR antibody–positive, generalized MG demonstrated that participants who underwent thymectomy had improved strength and function, required less prednisone and fewer additions of second-line agents (e.g., azathioprine), and fewer hospitalizations for exacerbations lasting at least 5 years. Whether or not less invasive thymectomy may be beneficial is unknown. Also, patients with ocular myasthenia, MuSK-positive, and seronegative MG were excluded from the study; retrospective and anecdotal evidence suggests that these patients may not benefit from thymectomy. Thymectomy should never be carried out as an emergency procedure, but only when the patient is adequately prepared. If necessary, treatment with IVIg or plasmapheresis may be used before surgery to maximize strength in weak patients.

IMMUNOTHERAPY

The choice of immunotherapy should be guided by the relative benefits and risks for the individual patient and the urgency of treatment. It is helpful to develop a treatment plan based on short-term, intermediate-term, and long-term objectives. For example, if immediate improvement is essential either because of the severity of weakness or because of the patient's need to return to activity as soon as possible, IVIg should be administered or plasmapheresis should be undertaken. For the intermediate term, glucocorticoids and cyclosporine or tacrolimus generally produce clinical improvement within a period of 1–3 months. The beneficial effects of azathioprine and mycophenolate mofetil usually begin after many months (as long as a year), but these drugs have advantages for the long-term treatment of patients with MG. There is a growing body of evidence that rituximab is effective in patients with MuSK antibody. Complement inhibition with intravenous eculizumab can improve MG within 1–3 months but is expensive and requires a loading dose of 4 weekly infusions followed by every-other-week infusions for maintenance.

Glucocorticoid Therapy Glucocorticoids, when used properly, produce improvement in myasthenic weakness in the great majority of patients. To minimize adverse side effects, prednisone should be given in a single dose rather than in divided doses throughout the day. In patients with only mild or moderate weakness, the initial dose should be relatively low (15–25 mg/d) to avoid the early weakening that occurs in 10–15% of patients treated initially with a high-dose regimen. The dose is increased stepwise, as tolerated by the patient (usually by 5 mg/d at 2- to 3-day intervals), until there is marked clinical improvement or a dose of 50–60 mg/d is reached. In patients with more severe weakness and those already in the hospital, starting at a high dose is reasonable. Patients are maintained on the dose that controls their symptoms for about a month, and then the dosage is slowly tapered (no faster than 10 mg a month until on 20 mg daily and then by 2.5–5 mg a month) to determine the minimum effective dose, and close monitoring is required. Some patients can be managed without the addition of other immunotherapies. Patients on long-term glucocorticoid therapy must be followed carefully to prevent or treat adverse side effects. The most common errors in glucocorticoid treatment of myasthenic patients include (1) insufficient persistence—improvement may be delayed and gradual; (2) tapering the dosage too early, too rapidly, or excessively; and (3) lack of attention to prevention and treatment of side effects.

The management of patients treated with glucocorticoids is discussed in Chap. 386.

Other Immunotherapies Mycophenolate mofetil, azathioprine, cyclosporine, tacrolimus, rituximab, eculizumab, and occasionally cyclophosphamide are effective in many patients, either alone or in various combinations.

Mycophenolate mofetil is widely used because of its presumed effectiveness and relative lack of side effects. A dose of 1–1.5 g bid is recommended. Its mechanism of action involves inhibition of purine synthesis by the de novo pathway. Since lymphocytes have only the de novo pathway, but lack the alternative salvage pathway that is present in all other cells, mycophenolate inhibits proliferation of lymphocytes but not proliferation of other cells. It does not kill or eliminate preexisting autoreactive lymphocytes, and therefore, clinical improvement may be delayed for many months to a year, until the preexisting autoreactive lymphocytes die spontaneously. The advantage of mycophenolate lies in its relative lack of adverse side effects, with only occasional production of GI symptoms, rare development of leukopenia, and very small risks of malignancy or

progressive multifocal leukoencephalopathy inherent in nearly all immunosuppressive treatments. Although two published studies did not show positive outcomes, most experts attribute the negative results to flaws in the trial designs, and mycophenolate is widely used for long-term treatment of myasthenic patients.

Azathioprine has long been used for MG, and a randomized, clinical trial demonstrated that it was effective in reducing the dosage of prednisone necessary to control symptoms. However, the beneficial effect can take a year or more to become evident. Approximately 10–15% of patients are unable to tolerate azathioprine because of idiosyncratic reactions consisting of flulike symptoms of fever and malaise, bone marrow suppression, or abnormalities of liver function. An initial dose of 50 mg/d is given for about a week to test for these side effects. If this dose is tolerated, it is increased gradually to ~2–3 mg/kg of total body weight or until the white blood count falls to 3000–4000/μL. Allopurinol should never be used in combination with azathioprine because the two drugs share a common degradation pathway; the result may be severe bone marrow suppression due to increased effects of the azathioprine.

The calcineurin inhibitors cyclosporine and tacrolimus seem to be effective in MG and appear to work more rapidly than azathioprine and mycophenolate. However, they are associated with more frequent severe side effects including hypertension and nephrotoxicity. The usual dose of cyclosporine is 4–5 mg/kg per d, and the average dose of tacrolimus is 0.07–0.1 mg/kg per d, given in two equally divided doses. "Trough" blood levels are measured 12 h after the evening dose. The therapeutic range for the trough level of cyclosporine is 150–200 ng/L, and for tacrolimus, it is 5–15 ng/L.

Rituximab (Rituxan) is a monoclonal antibody that binds to the CD20 molecule on B lymphocytes. It is widely used for the treatment of B-cell lymphomas and has also proven successful in the treatment of several autoimmune diseases including rheumatoid arthritis, pemphigus, and some IgM-related neuropathies. There is a growing literature on the benefit of rituximab in MuSK antibody–positive MG, which was previously more difficult to treat than anti-AChR–positive MG. A large, randomized trial of AChR antibody–positive generalized MG failed to demonstrate efficacy. The usual dose is 1 g IV on two occasions 2 weeks apart. Periodically, a repeat course needs to be administered; some MuSK patients go 2–3 years between infusions.

Eculizumab, a monoclonal antibody that binds to the terminal complement component 5 (C5), demonstrated efficacy in a large phase 3 clinical trial. The drug is administered intravenously every 2 weeks. Complement inhibition increases the risk of meningococcal infection, so ideally, a first series of vaccinations is given prior to initiation, and many recommend antibiotic prophylaxis (penicillin) while patients receive therapy. A benefit of eculizumab is that it works within 1–3 months and patients can often wean down on other immunotherapies. There are promising early results from other complement inhibitors, including subcutaneously administered drugs. For the rare refractory MG patient, a course of high-dose cyclophosphamide may induce long-lasting benefit. At high doses, cyclophosphamide eliminates mature lymphocytes but spares hematopoietic precursors (stem cells), because they express the enzyme aldehyde dehydrogenase, which hydrolyzes cyclophosphamide. This procedure is reserved for refractory patients and should be administered only in a facility fully familiar with this approach. Maintenance immunotherapy after treatment is usually required to sustain the beneficial effect.

PLASMAPHERESIS AND INTRAVENOUS IMMUNOGLOBULIN

Plasmapheresis has been used therapeutically in MG. Plasma, which contains the pathogenic antibodies, is mechanically separated from the blood cells, which are returned to the patient. A course of five exchanges (3–4 L per exchange) is generally administered over a 10- to 14-day period. Plasmapheresis produces a short-term reduction in anti-AChR antibodies, with clinical improvement in many patients. It is useful as a temporary expedient in seriously affected patients or to improve the patient's condition prior to surgery (e.g., thymectomy).

The indications for the use of IVIg are the same as those for plasma exchange: to produce rapid improvement to help the patient through a difficult period of myasthenic weakness or prior to surgery. This treatment has the advantages of not requiring special equipment or large-bore venous access. The usual dose is 2 g/kg, which is typically administered over 2–5 days. Improvement occurs in ~70% of patients, beginning during treatment or within a week and continuing for weeks to months. The mechanism of action of IVIg is not known; the treatment has no consistent long-term effect on the measurable amount of circulating AChR antibody. Adverse reactions are generally not serious but may include headache, fluid overload, and rarely aseptic meningitis or renal failure. IVIg or plasma exchange is occasionally used in combination with other immunosuppressive therapy for maintenance treatment of difficult MG.

INVESTIGATIONAL TREATMENTS

Early results of fragment crystalized neonatal receptor (FcRn) blockers also appear promising. FcRn bind immunoglobulins, thereby rescuing them from lysosomal destruction. Blocking this receptor allows for degradation of anti-AChR, anti-MuSK, anti-LR4, and other antibodies, reducing their levels to 60–85% within 1–2 months. Several trials of different FcRn blockers are underway.

MANAGEMENT OF MYASTHENIC CRISIS

Myasthenic crisis is defined as an exacerbation of weakness sufficient to endanger life; it usually includes ventilatory failure caused by diaphragmatic and intercostal muscle weakness. Treatment should be carried out in intensive care units staffed with teams experienced in the management of MG. The possibility that deterioration could be due to excessive anticholinesterase medication ("cholinergic crisis") is best excluded by temporarily stopping anticholinesterase drugs. The most common cause of crisis is intercurrent infection. This should be treated immediately because the mechanical and immunologic defenses of the patient can be assumed to be compromised. The myasthenic patient with fever and early infection should be treated like other immunocompromised patients. Early and effective antibiotic therapy, ventilatory assistance, and pulmonary physiotherapy are essentials of the treatment program. As discussed above, plasmapheresis or IVIg is frequently helpful in hastening recovery.

DRUGS TO AVOID IN MYASTHENIC PATIENTS

Many drugs can potentially exacerbate weakness in patients with MG **(Table 448-4)**. As a rule, the listed drugs should be avoided whenever possible.

PATIENT ASSESSMENT

To evaluate the effectiveness of treatment as well as drug-induced side effects, it is important to assess the patient's clinical status systematically at baseline and on repeated interval examinations. Following the patient with spirometry with determination of forced vital capacity and mean inspiratory and expiratory pressures is important.

PROGNOSIS

Approximately 20% of patients with MG achieve a sustained remission and can be tapered off all immunotherapies. There does not appear to be a correlation between disease severity and likelihood of remission. Thymectomy may increase the chance of achieving remission in anti-AChR MG, but the large randomized trial was too short in duration to examine this endpoint; rather, the results revealed only that thymectomy was efficacious and led to less use of glucocorticoids and second-line agents. Mortality from MG diminished greatly during the twentieth century, changing from a "grave" illness with mortality of nearly 70% a century ago, to 2–30% by the 1950s, with contemporary estimates in the 1–2% range. Anti-MuSK patients generally were more difficult to treat than anti-AChR MG in the past. However, recent series

TABLE 448-4 Drugs with Interactions in Myasthenia Gravis (MG)

Drugs That May Exacerbate MG
Antibiotics
Aminoglycosides: e.g., streptomycin, tobramycin, kanamycin
Quinolones: e.g., ciprofloxacin, levofloxacin, ofloxacin, gatifloxacin
Macrolides: e.g., erythromycin, azithromycin
Nondepolarizing muscle relaxants for surgery
D-Tubocurarine (curare), pancuronium, vecuronium, atracurium
Beta-blocking agents
Propranolol, atenolol, metoprolol
Local anesthetics and related agents
Procaine, Xylocaine in large amounts
Procainamide (for arrhythmias)
Botulinum toxin
Botox exacerbates weakness
Quinine derivatives
Quinine, quinidine, chloroquine, mefloquine (Lariam)
Magnesium
Decreases acetylcholine release
Penicillamine
May cause MG
Check point inhibitors
May cause MG and other autoimmune neuromuscular disorders (e.g., myositis, inflammatory neuropathy)
Drugs with Important Interactions in MG
Cyclosporine and tacrolimus
Broad range of drug interactions, which may raise or lower levels.
Azathioprine
Avoid allopurinol—combination may result in myelosuppression.

suggest that rituximab is effective in this subgroup, thereby reducing these risks and improving the prognosis. Nonparaneoplastic LEMS is usually responsive to immunotherapy and symptomatic treatment with pyridostigmine and 3,4-DAP. In older adults, LEMS is most often paraneoplastic, and screening for an underlying tumor is indicated (Chap. 94). Recent studies suggest that survival in patients with LEMS has improved, for uncertain reasons and likely not due to earlier diagnosis and treatment of the tumor. There is wide variability in age of onset, severity, and prognosis of the many types of CMS.

GLOBAL ISSUES

The incidence of MG and its subtypes varies in different populations, for example, occurring in ~2–10/10^6 individuals in the United States and the Netherlands and up to 20/10^6 individuals in Spain. Estimates of prevalence in different parts of the world range widely from 2–200/10^6. The age of onset may also be influenced by geographic and/or ethnic differences. Juvenile-onset MG is uncommon in Western populations but may represent more than half of cases in Asians. MuSK MG appears to be more common in the Mediterranean area of Europe than in northern Europe and is also more common in the northern regions of East Asia than in the southern regions. A concern during the COVID-19 pandemic is whether MG patients on immunosuppressive therapies might be at increased risk of infection or developing a more severe course. Furthermore, flares of MG can be triggered by infection, and contracting COVID-19 may lead to an exacerbation, including MG crisis. I have not reduced the dosage of immunosuppressive medications in MG patients who are doing well but have been more likely to manage worsening disease by treating with IVIg rather than increasing the dosage of, or adding new, immunosuppressive agents. Patients are strongly advised to wear masks and maintain social distancing. An international panel has published guidelines for management of MG patients during this crisis.

449 Muscular Dystrophies and Other Muscle Diseases

Anthony A. Amato, Robert H. Brown, Jr.

Myopathies are disorders with structural changes or functional impairment of muscle and can be differentiated from other diseases of the motor unit (e.g., lower motor neuron or neuromuscular junction pathologies) by characteristic clinical and laboratory findings. **Myasthenia gravis and related disorders are discussed in Chap. 448; inflammatory myopathies are discussed in Chap. 365.**

CLINICAL FEATURES

The most important aspect of assessing individuals with neuromuscular disorders is taking a thorough history of the patient's symptoms, disease progression, and past medical and family history, as well as performing a detailed neurologic examination. Based on this and additional laboratory workup (e.g., serum creatine kinase [CK], electromyography [EMG]), one can usually localize the site of the lesion to muscle (as opposed to motor neurons, peripheral nerves, or neuromuscular junction) and the pattern of muscle involvement. It is this pattern of muscle involvement that is most useful in narrowing the differential diagnosis (Table 449-1). Most myopathies present with proximal, symmetric limb weakness with preserved reflexes and sensation. However, asymmetric and predominantly distal weakness can be seen in some myopathies. An associated sensory loss suggests a peripheral neuropathy or a central nervous system (CNS) abnormality

TABLE 449-1 Myopathies by Pattern of Weakness/Muscle Involvement

Proximal (Limb-Girdle) Weakness

Most dystrophies (e.g., dystrophinopathies, limb-girdle, myofibrillar myopathy, myotonic dystrophy type 2, rare FSHD)
Congenital myopathies (e.g., central core, multiminicore, centronuclear, nemaline rod)
Metabolic myopathies (e.g., glycogen and lipid storage diseases)
Mitochondrial myopathies
Inflammatory myopathies (DM, PM, IMNM, anti-synthetase syndrome)
Toxic myopathies (see Table 449-6)
Endocrine myopathies
Neuromuscular junction disorders (myasthenia gravis, LEMS, congenital myasthenia, botulism, **see Chap. 448**)

Distal Weakness

Distal muscular dystrophies/myofibrillar myopathy (see Table 449-5)
Congenital myopathies (e.g., late-onset centronuclear and nemaline rod myopathies)
Metabolic
- Glycogen storage disease (e.g., brancher and debrancher deficiency, rarely McArdle disease)
- Lipid storage disease (e.g., neutral lipid storage myopathy, multiacyldehydrogenase deficiency)

NMJ disorders (e.g., rare myasthenia gravis and congenital myasthenia)

Proximal Arm/Distal Leg Weakness (Scapuloperoneal or Humeroperonal) Weakness

Facioscapulohumeral muscular dystrophy (FSHD)
Scapuloperoneal myopathy and neuropathy
Myofibrillar myopathies
Emery-Dreifuss muscular dystrophy (EDMD)
Bethlem myopathy

Distal Arm/Proximal Leg Weakness

Inclusion body myositis (usually wrist and finger flexors in arms, hip flexors and knee extensors in legs, and asymmetric)
Myotonic dystrophy (uncommon presentation)

Axial Muscle Weakness

Inflammatory (cervicobrachial myositis)
sIBM and hIBM
Myotonic dystrophy 2
Isolated neck extensor myopathy/bent spine syndrome
FSHD
Late-onset central core (*RYR1* mutations)
Sporadic late-onset nemaline rod with or without a monoclonal gammopathy
Metabolic (late-onset Pompe, McArdle disease, lipid storage, mitochondrial)
Hyperparathyroidism/osteomalacia/vitamin D deficiency
Myasthenia gravis

Eye Muscle Weakness (Ptosis/Ophthalmoparesis)

Ptosis without ophthalmoparesis
- Myotonic dystrophy
- Congenital myopathies
- Neuromuscular junction disorders

Ptosis with ophthalmoparesis
- Oculopharyngeal dystrophy
- Mitochondrial myopathy
- hIBM type 3
- Neuromuscular junction disorders

Episodic Weakness or Myoglobinuria

Related to exercise
- Glycogenoses (e.g., McArdle disease, etc.)
- Lipid disorders (e.g., CPT2 deficiency)
- Mitochondrial myopathies (e.g., cytochrome B deficiency)

Not related to exercise
- *RYR1* mutations can cause malignant hyperthermia, episodic rhabdomyolysis/myoglobinuria, and atypical periodic paralysis
- Other causes of malignant hyperthermia

Drugs/toxins (e.g., statins)
- Prolonged/intensive eccentric exercise
- Inflammatory (e.g., PM/DM—rare, viral/bacterial infections)

Delayed or unrelated to exercise
- Periodic paralysis (e.g., hereditary hyper- or hypokalemic, thyrotoxic, associated renal tubular acidosis, acquired electrolyte imbalance)
- NMJ disorders

Muscle Stiffness/Decreased Ability to Relax

Myotonic dystrophy 1 and 2
Myotonia congenita
Paramyotonia congenita
Hyperkalemic periodic paralysis with myotonia
Potassium aggravated myotonia
Schwartz-Jampel syndrome
Other: rippling muscle disease (acquired and hereditary), acquired neuromyotonia (Isaacs' syndrome), stiff-person syndrome, Brody's disease

Abbreviations: DM, dermatomyositis; hIBM, hereditary inclusion body myopathy; IMNM, immune-mediated necrotizing myopathy; LEMS, Lambert-Eaton myasthenic syndrome; NMJ, neuromuscular junction; PM, polymyositis; sIBM, sporadic inclusion body myositis.

(e.g., myelopathy) rather than a myopathy. On occasion, disorders affecting the motor nerve cell bodies in the spinal cord (anterior horn cell disease), the neuromuscular junction, or peripheral nerves can mimic findings of myopathy.

Muscle Weakness Symptoms of muscle weakness can be either intermittent or persistent. Disorders causing *intermittent weakness* (Table 449-1 and **Fig. 449-1**) include myasthenia gravis, periodic paralyses (hypokalemic or hyperkalemic), and metabolic energy deficiencies of glycolysis (especially myophosphorylase deficiency), fatty acid utilization (carnitine palmitoyltransferase [CPT] deficiency), and some mitochondrial myopathies. The states of energy deficiency cause activity-related muscle breakdown accompanied by myoglobinuria.

Most muscle disorders cause *persistent weakness* (Table 449-1 and **Fig. 449-2**). In the majority of these, including most types of muscular dystrophy and inflammatory myopathies, the proximal muscles are weaker than the distal and are symmetrically affected, and the facial muscles are spared, a pattern referred to as *limb-girdle weakness*. The differential diagnosis is more restricted for other patterns of weakness. Facial weakness (difficulty with eye closure and impaired smile) and scapular winging **(Fig. 449-3)** are characteristic of facioscapulohumeral dystrophy (FSHD). Facial and distal limb weakness associated with hand grip myotonia is virtually diagnostic of myotonic dystrophy type 1. When other cranial nerve muscles are weak, causing ptosis or extraocular muscle weakness, the most important disorders to consider include neuromuscular junction disorders, oculopharyngeal muscular dystrophy, mitochondrial myopathies, or some of the congenital myopathies (Table 449-1). A pathognomonic pattern characteristic of inclusion body myositis is atrophy and weakness of the flexor forearm (e.g., wrist and finger flexors) and quadriceps muscles that is often asymmetric. Less frequently seen, but important diagnostically, are the axial myopathies that predominantly affect the paraspinal muscles and include dropped head syndrome indicative of selective neck extensor muscle weakness. The most important neuromuscular diseases associated with this axial muscle weakness include myasthenia gravis, amyotrophic lateral sclerosis, late-onset core or nemaline rod myopathy,

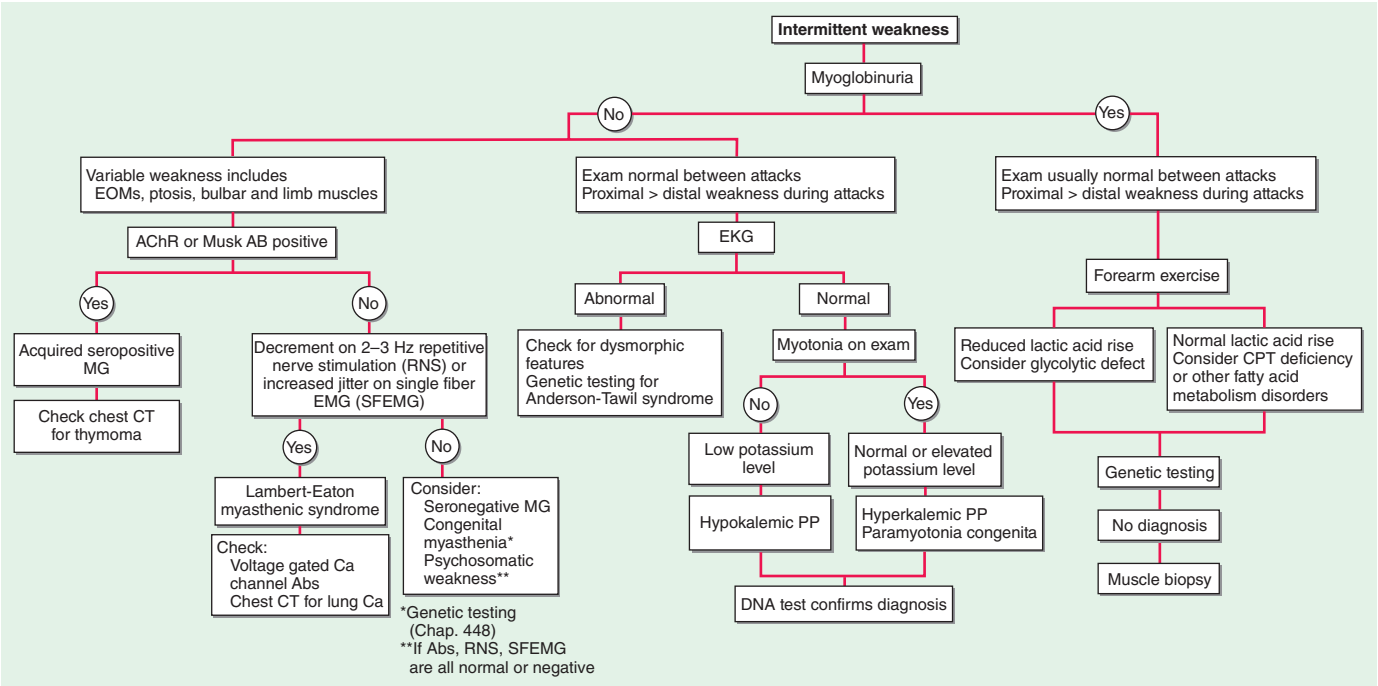

FIGURE 449-1 Diagnostic evaluation of intermittent weakness. AChR AB, acetylcholine receptor antibody; CPT, carnitine palmitoyltransferase; EKG, electrocardiogram; EMG, electromyogram; EOMs, extraocular muscles; MG, myasthenia gravis; PP, periodic paralysis.

hyperparathyroidism, focal myositis, and some forms of inclusion body myopathy. A final pattern, recognized because of preferential distal extremity weakness, is seen in the distal myopathies.

It is important to examine functional capabilities to help disclose certain patterns of weakness (Table 449-1 and **Table 449-2**). The Gower sign **(Fig. 449-4)** is particularly useful. Observing the gait of an individual may disclose a lordotic posture caused by combined trunk and hip weakness, frequently exaggerated by toe walking **(Fig. 449-5)**. A waddling gait is caused by the inability of weak hip muscles to prevent hip drop or hip dip. Hyperextension of the knee (genu recurvatum or back-kneeing) is characteristic of quadriceps muscle weakness; and a steppage gait, due to foot drop, accompanies distal weakness.

Any disorder causing muscle weakness may be accompanied by *fatigue*, referring to an inability to maintain or sustain a force (pathologic fatigability). This condition must be differentiated from asthenia, a type of fatigue caused by excess tiredness or lack of energy. Associated symptoms may help differentiate asthenia and pathologic fatigability. Asthenia is often accompanied by a tendency to avoid physical activities, complaints of daytime sleepiness, necessity for frequent naps, and

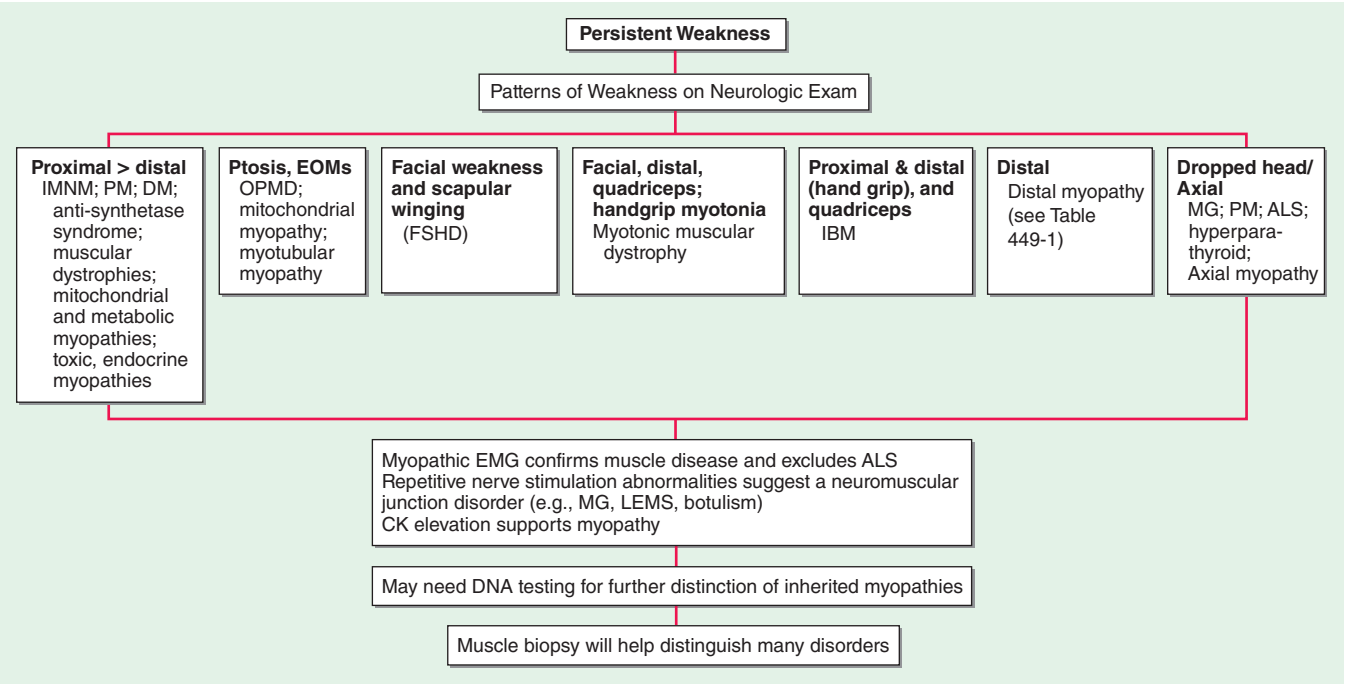

FIGURE 449-2 Diagnostic evaluation of persistent weakness. Examination reveals one of seven patterns of weakness. The pattern of weakness in combination with the laboratory evaluation leads to a diagnosis. ALS, amyotrophic lateral sclerosis; CK, creatine kinase; DM, dermatomyositis; EMG, electromyography; EOMs, extraocular muscles; FSHD, facioscapulohumeral dystrophy; IBM, inclusion body myositis; IMNM, immune-mediated necrotizing myopathy; MG, myasthenia gravis; OPMD, oculopharyngeal muscular dystrophy; PM, polymyositis.

FIGURE 449-3 Facioscapulohumeral dystrophy with prominent scapular winging.

difficulty concentrating on activities such as reading. There may be feelings of overwhelming stress and depression. In contrast, pathologic fatigability occurs in disorders of neuromuscular transmission and in disorders altering energy production, including defects in glycolysis, lipid metabolism, or mitochondrial energy production. Pathologic fatigability also occurs in chronic myopathies because of difficulty accomplishing a task with less muscle. Pathologic fatigability is accompanied by abnormal clinical or laboratory findings. Fatigue without those supportive features almost never indicates a primary muscle disease.

Muscle Pain (Myalgias), Cramps, and Stiffness Some myopathies can be associated with muscle pain, cramps, contractures, stiff or rigid muscles, or inability to relax the muscles (e.g., myotonia) (Table 449-1). *Muscle cramps* are abrupt in onset, short in duration, triggered by voluntary muscle contraction, and may cause abnormal posturing of the joint. Muscle cramps often occur in neurogenic disorders, especially motor neuron disease **(Chap. 437)**, radiculopathies, and polyneuropathies **(Chap. 446)**, but are not a feature of most primary muscle diseases.

A *muscle contracture* is different from a muscle cramp. In both conditions, the muscle becomes hard, but a contracture is associated with energy failure in glycolytic disorders. The muscle is unable to relax after an active muscle contraction. The EMG shows electrical silence. Confusion is created because contracture also refers to a muscle that cannot be passively stretched to its proper length (fixed contracture) because of fibrosis. In some muscle disorders, especially in Emery-Dreifuss muscular dystrophy (EDMD) and Bethlem myopathy, fixed contractures occur early and represent distinctive features of the disease.

TABLE 449-2 Observations on Examination That Disclose Muscle Weakness

FUNCTIONAL IMPAIRMENT	MUSCLE WEAKNESS
Inability to forcibly close eyes	Upper facial muscles
Impaired pucker	Lower facial muscles
Inability to raise head from prone position	Neck extensor muscles
Inability to raise head from supine position	Neck flexor muscles
Inability to raise arms above head	Proximal arm muscles (may be only scapular stabilizing muscles)
Inability to walk without hyperextending knee (back-kneeing or genu recurvatum)	Knee extensor muscles
Inability to walk with heels touching the floor (toe walking)	Shortening of the Achilles tendon
Inability to lift foot while walking (steppage gait or foot drop)	Anterior compartment of leg
Inability to walk without a waddling gait	Hip muscles
Inability to get up from the floor without climbing up the extremities (Gowers' sign)	Hip, thigh, and trunk muscles
Inability to get up from a chair without using arms	Hip muscles

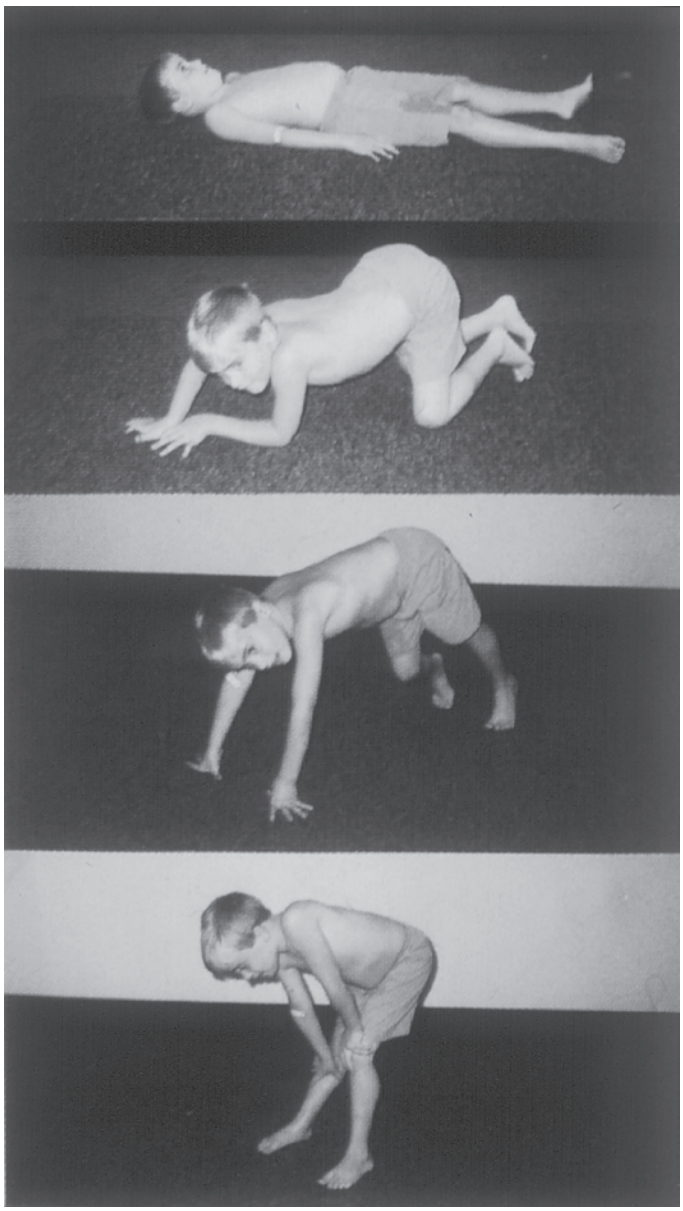

FIGURE 449-4 Gower sign showing a patient using his arms to climb up the legs in attempting to get up from the floor.

Myotonia is a condition of prolonged muscle contraction followed by slow muscle relaxation. It always follows muscle activation (action myotonia), usually voluntary, but may be elicited by mechanical stimulation (percussion myotonia) of the muscle. Myotonia typically causes difficulty in releasing objects after a firm grasp. In myotonic muscular dystrophy type 1 (DM1), distal weakness usually accompanies myotonia, whereas in DM2, proximal muscles are more affected. Myotonia also occurs with *myotonia congenita* (a chloride channel disorder), but in this condition, muscle weakness is not prominent. Myotonia may also be seen in individuals with sodium channel mutations (*hyperkalemic periodic paralysis* or *potassium-sensitive myotonia*). Another sodium channelopathy, *paramyotonia congenita* (PC), also is associated with muscle stiffness. In contrast to other disorders associated with myotonia in which the myotonia is eased by repetitive activity, PC is named for a paradoxical phenomenon whereby the myotonia worsens with repetitive activity. Potassium-aggravated myotonia is an allelic

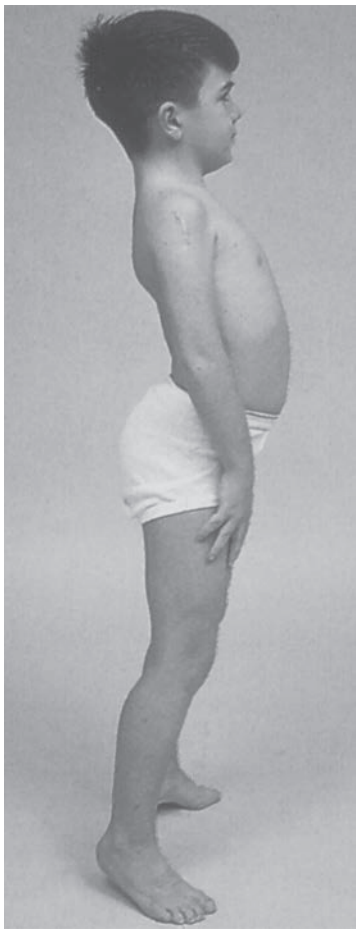

FIGURE 449-5 Lordotic posture, exaggerated by standing on toes, associated with trunk and hip weakness.

disorder in which myotonia is brought on by consumption of too much potassium-containing foods.

Muscle stiffness can refer to different phenomena. Some patients with inflammation of joints and periarticular surfaces feel stiff. This condition is different from the disorders of hyperexcitable motor nerves causing stiff or rigid muscles. In *stiff-person syndrome*, spontaneous discharges of the motor neurons of the spinal cord cause involuntary muscle contractions mainly involving the axial (trunk) and proximal lower extremity muscles. The gait becomes stiff and labored, with hyperlordosis of the lumbar spine. Superimposed episodic muscle spasms are precipitated by sudden movements, unexpected noises, and emotional upset. The muscles relax during sleep. Serum antibodies against glutamic acid decarboxylase are present in approximately two-thirds of cases. In *acquired neuromyotonia* (*Isaacs' syndrome*), there is hyperexcitability of the peripheral nerves manifesting as continuous muscle fiber activity in the form of widespread fasciculations and myokymia with impaired muscle relaxation. Muscles of the leg are stiff, and the constant contractions of the muscle cause increased sweating of the extremities. This peripheral nerve hyperexcitability is mediated by antibodies that target voltage-gated potassium channels.

There are two painful muscle conditions of particular importance, neither of which is associated with muscle weakness. *Fibromyalgia* is a common, yet poorly understood myofascial pain syndrome in which patients complain of severe muscle pain and tenderness, severe fatigue, and often poor sleep. Serum CK, erythrocyte sedimentation rate (ESR), EMG, and muscle biopsy are normal **(Chap. 373)**. *Polymyalgia rheumatica* occurs mainly in patients aged >50 years and is characterized by stiffness and pain in the shoulders, lower back, hips, and thighs **(Chap. 363)**. The ESR and CRP are elevated, while serum CK, EMG, and muscle biopsy are normal.

Muscle Enlargement and Atrophy In most myopathies, muscle tissue is replaced by fat and connective tissue, but the size of the muscle is usually not affected. However, in many limb-girdle muscular dystrophies, enlarged calf muscles are typical. The enlargement represents true muscle hypertrophy; thus, the term *pseudohypertrophy* should be avoided when referring to these patients. The calf muscles remain very strong even late in the course of these disorders. Muscle enlargement can also result from infiltration by sarcoid granulomas, amyloid deposits, bacterial and parasitic infections, and focal myositis. In contrast, muscle atrophy is characteristic of other myopathies. In Miyoshi myopathy, which can be caused by mutations in the genes that encode for dysferlin and anoctamin 5, there is a predilection for early atrophy of the gastrocnemius muscles, particularly the medial aspect. Atrophy of the humeral muscles is characteristic of FSHD and EDMD.

LABORATORY EVALUATION

Various tests can be used to evaluate a suspected myopathy, including CK levels, endocrine studies (e.g., thyroid function tests, parathyroid hormone and vitamin D levels), autoantibodies (associated with myositis and systemic disorders), forearm exercise test, muscle biopsy, and genetic testing. Electrodiagnostic studies can be useful to differentiate myopathies from other neuromuscular disorders (motor neuron disease, peripheral neuropathies, neuromuscular junction disorders) but, in most instances, do not help distinguish the specific type of myopathy.

Serum Enzymes CK is the most sensitive measure of muscle damage. The MM isoenzyme predominates in skeletal muscle, whereas CK-myocardial bound (CK-MB) is the marker for cardiac muscle. Serum CK can be elevated in normal individuals without provocation, presumably on a genetic basis or after strenuous activity, trauma, a prolonged muscle cramp, or a generalized seizure. Aspartate aminotransferase (AST), alanine aminotransferase (ALT), aldolase, and lactate dehydrogenase (LDH) are enzymes sharing an origin in both muscle and liver. Problems arise when the levels of these enzymes are found to be elevated in a routine screening battery, leading to the erroneous assumption that liver disease is present when in fact muscle could be the cause. An elevated γ-glutamyl transferase (GGT) helps to establish a liver origin because this enzyme is not found in muscle. Rarely, aldose can be elevated in an inflammatory myopathy when CK, AST, and ALT are normal, signifying that the inflammation predominantly affects the perimysium (dermatomyositis, graft-versus-host disease) or the surrounding fascia (fasciitis).

Electrodiagnostic Studies EMG, repetitive nerve stimulation, and nerve conduction studies (NCS) **(Chap. 446)** are helpful in differentiating myopathies from motor neuron disease, neuropathies, and neuromuscular junction diseases. Routine NCS are typically normal in myopathies, but reduced amplitudes of compound muscle action potentials may be seen in atrophied muscles. The needle EMG may reveal irritability on needle insertion and spontaneously that is suggestive of a myopathy with active necrosis or muscle membrane instability (inflammatory myopathies, dystrophies, toxic myopathies, myotonic myopathies), whereas a lack of irritability is characteristic of long-standing myopathic disorders (muscular dystrophies with severe fibrofatty replacement, endocrine myopathies, disuse atrophy, and many of the metabolic myopathies between bouts of rhabdomyolysis). In addition, the EMG may demonstrate myotonic discharges that will narrow the differential diagnosis (Table 449-1). Another important EMG finding is the presence of short-duration, small-amplitude, polyphasic motor unit action potentials (MUAPs). In myopathies, the MUAPs fire early but at a normal rate to compensate for the loss of individual muscle fibers, whereas in neurogenic disorders, the MUAPs fire faster. An EMG is usually normal in steroid or disuse myopathy, both of which are associated with type 2 fiber atrophy; this is because the EMG preferentially assesses the physiologic function of type 1 fibers. The EMG can supplement the clinical examination in choosing an appropriately affected muscle to biopsy.

Imaging Studies Skeletal MRI and ultrasound are increasing utilized to assess the pattern of muscle involvement, which can help in narrowing the diagnosis, and are often more sensitive than the clinical examination and EMG, particularly early in a disease course. For

example, there is early predilection of the vastus lateralis and medialis muscles with relative sparing of the rectus femoris muscles on imaging of thigh muscles in patients with inclusion body myositis, and this can be appreciated on imaging prior to weakness being detected on manual muscle testing. MRI can also demonstrate fasciitis when the clinical examination and EMG are normal. Imaging can also be used to help guide what muscle to biopsy in patients with weakness on manual muscle testing and EMG abnormalities only in muscles that are not typically biopsied (e.g., paraspinal or hip girdle). We have found imaging helpful in patients with presumed muscular dystrophy when the muscle biopsy is not diagnostic and genetic testing shows only a variation of unclear significance. In this situation, the pattern of muscle involvement on imaging can support the known pattern of muscle involvement of a specific hereditary myopathy. The cost and availability of MRI preclude routine use in some settings, but ultrasound is more readily available and less expensive.

Genetic Testing This is increasingly available and is the gold standard for diagnosing patients with hereditary myopathies. Next-generation sequencing panels are increasing utilized, but clinicians need to know their limitations; large deletions and duplications can be missed, as can mutations in noncoding (intronic) regions. Furthermore, testing often reveals sequence alterations of unclear significance.

Forearm Exercise Test With exercise-induced muscle pain and myoglobinuria, there may be a defect in glycolysis. For safety, the test should not be performed under ischemic conditions to avoid an unnecessary insult to the muscle, causing rhabdomyolysis. The test is performed by placing a small indwelling catheter into an antecubital vein. A baseline blood sample is obtained for lactic acid and ammonia. The forearm muscles are exercised by asking the patient to vigorously open and close the hand for 1 min. Blood is then obtained at intervals of 1, 2, 4, 6, and 10 min for comparison with the baseline sample. A three- to fourfold rise of lactic acid is typical. The simultaneous measurement of ammonia serves as a control because it should also rise with exercise. In patients with myophosphorylase deficiency and certain other glycolytic defects, the lactic acid rise will be absent or below normal, while the rise in ammonia will reach control values. If there is lack of effort, neither lactic acid nor ammonia will rise. Patients with selective failure to increase ammonia may have myoadenylate deaminase deficiency. This condition has been reported to be a cause of myoglobinuria, but deficiency of this enzyme in asymptomatic individuals makes interpretation controversial.

Muscle Biopsy Muscle biopsy is extremely helpful in evaluation of acquired myopathies but is performed less frequently in suspected hereditary myopathies as genetic testing has become more widely available. However, muscle biopsy can be helpful in cases of suspected hereditary myopathy in which genetic testing was nondiagnostic. Almost any superficial muscle can be biopsied, but it is important to biopsy one that is affected clinically but not too severely (for example grade 4 out of 5 strength or movement against moderate resistance by manual muscle testing [Chap. 422]). A specific diagnosis can be established in many disorders.

HEREDITARY MYOPATHIES

Muscular dystrophy refers to a group of hereditary progressive diseases, each with unique phenotypic and genetic features (Tables 449-3, 449-4, and 449-5, and Fig. 449-6). The prognosis of dystrophies is slow progressive weakness, though the severity and course are variable between and even within subtypes. Some are associated with cardiac and ventilatory muscle involvement, which are the leading causes of mortality. Unfortunately, there are no specific medical therapies for most of the muscular dystrophies, and treatment is aimed at maintaining function with physical and occupational therapy. Noninvasive ventilation and tracheostomy may be warranted. Those with cardiomyopathy may require afterload reduction, antiarrhythmic agents, pacemakers or intracardiac defibrillators, and occasionally cardiac transplantation. We will focus primarily on those that manifest in adulthood.

DUCHENNE AND BECKER MUSCULAR DYSTROPHY (DMD AND BMD)

DMD and BMD are X-linked recessive muscular dystrophies caused by mutations in the *dystrophin* gene. Affecting 1 in 3000 male births, DMD is the most common mutational disease affecting boys. The incidence of BMD is ~5 per 100,000.

Clinical Features Proximal muscles, especially of the lower extremities, are prominently involved in both disorders. This becomes evident in DMD very early; boys with DMD have difficulty climbing stairs and never run well. As the disease progresses, weakness becomes more generalized. Hypertrophy of muscles, particularly in the calves, is an early and prominent finding. Most patients with BMD first experience difficulties between ages 5 and 15 years, although onset in the third or fourth decade or even later can occur. Life expectancy for DMD and BMD is reduced, but most BMD cases survive into the fourth or fifth decade. Intellectual disability may occur in both disorders but is less common in BMD. Cardiac involvement is common in both DMD and BMD and may result in heart failure; some BMD patients manifest with only heart failure. Other less common presentations of dystrophinopathy are asymptomatic hyper-CK-emia, myalgias without weakness, and myoglobinuria.

Laboratory Features Serum CK levels are usually elevated. Muscle biopsies demonstrate dystrophic features. Western blot analysis of muscle biopsy samples demonstrates absent dystrophin in DMD or reduction in levels or size of dystrophin in BMD. In both disorders, mutations can be established using DNA from peripheral blood leukocytes. In most cases, muscle biopsies are no longer performed when DMD or BMD is suspected, as genetic testing is less invasive, less costly, and routinely available. Deletions within or duplications of the *dystrophin* gene are common in both DMD and BMD; in ~95% of cases, the mutation does not alter the translational reading frame of messenger RNA. These "in-frame" mutations allow for production of some dystrophin, which accounts for the presence of altered rather than absent dystrophin on Western blot analysis and a milder clinical phenotype.

TREATMENT

Duchenne and Becker Muscular Dystrophy

Glucocorticoids slow progression in DMD, but their use has not been adequately studied in BMD. Physical and occupational therapy are important in helping maintain function. As patients often die from the associated cardiomyopathy, it is important to follow patients with a cardiologist and treat appropriately. Recent studies suggest that there is clinical benefit in selected cases of DMD from short oligonucleotides that permit skipping of mutant exons, leading to expression of a short but nonetheless functional dystrophin protein. In parallel, other studies suggest that small molecules may permit read-through of protein-truncating mutations in some DMD cases, again with clinical benefit.

LIMB-GIRDLE MUSCULAR DYSTROPHY

The limb-girdle muscular dystrophies (LGMDs) are a genetically heterogenous group of dystrophies in which males and females are affected equally, with typical onset ranging from late in the first decade to the fourth decade. The LGMDs typically manifest with progressive weakness of pelvic and shoulder girdle musculature and are often clinically indistinguishable from DMD and BMD. Respiratory insufficiency from weakness of the diaphragm may occur, as may cardiomyopathy. Serum CKs are elevated, and the EMG is myopathic. Muscle biopsy reveal dystrophic features, but the findings are not specific to differentiate subtypes from one another unless immunohistochemistry is employed (e.g., immunostaining for various sarcoglycans, dysferlin, alpha-dystroglycan, merosin) or there are features to suggest one of the myofibrillar myopathies. Nonetheless, definitive diagnosis requires genetic testing.

The traditional classification of LGMD is based on autosomal dominant (LGMD1) and autosomal recessive (LGMD2) inheritance.

TABLE 449-3 Autosomal Dominant Limb-Girdle Muscular Dystrophies (LGMDs)

TRADITIONAL CLASSIFICATION/ PROPOSED NEW CLASSIFICATION (WHEN APPLICABLE)	CLINICAL FEATURES	LABORATORY FEATURES	ABNORMAL PROTEIN
LGMD1A/myofibrillar myopathy	Onset second to eighth decade Muscle weakness affects proximal and distal limb muscles, vocal cords, and pharyngeal muscles	Serum CK 2× normal EMG myopathic and may have pseudomotonic discharges Muscle biopsy: features of MFM	Myotilin
LGMD1B/EDMD2	Onset first or second decade Proximal lower limb weakness and cardiomyopathy with conduction defects Some cases indistinguishable from Emery-Dreifuss muscular dystrophy (EDMD) with joint contractures	Serum CK 3–5× normal EMG myopathic	Lamin A/C
LGMD1C/rippling muscle disease	Onset in early childhood Proximal weakness Gower sign, calf hypertrophy, rippling muscles Exercise-related muscle cramps	Serum CK 4–25× normal EMG myopathic	Caveolin-3
LGMD1D/LGMDD1	Onset second to sixth decade Proximal and distal muscle weakness	Serum CK 2–3× normal EMG myopathic Muscle biopsy: features of MFM	DNAJB6
LGMD1E/myofibrillar myopathy	Onset first to sixth decade Proximal or distal muscle weakness Cardiomyopathy and arrhythmias	Serum CK 2–4× normal EMG myopathic and may have pseudomotonic discharges Muscle biopsy: features of MFM	Desmin
LGMD1F/LGMDD2	Onset infancy to sixth decade Proximal or distal weakness May have early contractures resembling Emery-Dreifuss syndrome	Serum CK normal to 20× normal EMG myopathic Muscle biopsy may show enlarged nuclei with central pallor, rimmed vacuoles, and filamentous inclusions	TNPO3
LGMD1G/LGMDD3	Onset teens to sixth decade Proximal weakness contractures of fingers and toes	Muscle biopsies show rimmed vacuoles CK normal to 9× normal	HNRNPDL
LGMD1I/LGMDD4	Onset teens to ninth decade Proximal weakness, scapular winging	CK normal to 50× normal EMG myopathic	Calpain-3
Bethlem myopathy/LGMD1D5	Onset in childhood to adulthood Contractures at elbows, distal fingers, knees, ankles Hyperextensible fingers proximally Keloids	CK normal to 3× normal MRI and ultrasound of muscle show a peripheral > central predilection for fibrofatty replacement in individual muscles	Collagen VI alpha 1 chain

Abbreviations: CK, creatine kinase; EMG, electromyography; HNRNPDL, heterogeneous nuclear ribonucleoprotein D-like protein; MFM, myofibrillar myopathy.

Superimposed on the backbone of LGMD1 and LGMD2, the classification uses a sequential alphabetical lettering system (LGMD1A, LGMD2A, etc.) based on genotype. However, ever-expanding discoveries of new genes have outgrown the alphabet. The European Neuromuscular Centre (ENMC) recently proposed a new nomenclature in which autosomal dominant cases are termed LGMD "D" and autosomal recessive as LGMD "R," followed by a numerical number based on genotype. Furthermore, this new classification only includes cases in which at least two unrelated families have been reported, the predominant weakness at onset was proximal, independent ambulation was achieved at some time, CK is elevated, and muscle biopsies or imaging revealed dystrophic features. Thus, mutations in the *CPN3* gene leading to a deficiency in calpain-3, which traditionally were classified as LGMD2A, are classified as LGMDR1 by this new system. In contrast, mutations in myotilin (LGMD1A) and desmin (LGMD1E and LGMD2R) and that often have more distal weakness and have biopsies features of a myofibrillar myopathy are not classified as a LGMD in this new scheme but rather as subtypes of myofibrillar myopathy. Likewise, laminopathies (LGMD1B) are considered a subtype of EDMD rather than an LGMD. This new classification of LGMD and distal muscular dystrophies is summarized in Tables 449-3 and 449-4.

The prevalence of LGMD ranges from 80 to 700 per 100,000, while estimated prevalences of individual specific subtypes of LGMDs vary. The most common types of adult-onset LGMD are calpainopathy (LGMD2A/LGMDR1), Fukutin-related protein (FKRP) deficiency (LGMD2I/LGMDR9), and anoctaminopathy (LGMD2L/LGMDR12). Calpainopathy (LGMD2A/LGMDR1), the most common cause of LGMD in those with ancestry from Spain, France, Italy, and Great Britain, is associated with marked scapular winging, lack of calf muscle hypertrophy, and lack of cardiac and lung involvement. Of note, autosomal dominant mutations in an intron of the calpain-3 gene is responsible for LGMD1I/LGMDD4. LGMD2I/LGMDR9 is more common in individuals with northern European ancestry, is associated with calf muscle hypertrophy, and can have cardiac and lung involvement out of proportion to extremity weakness. LGMD2L/LGMDR12 accounts for ~7% of LGMD in the United States, and the prevalence is higher in northern Europe; as seen in dysferlinopathies (LGMD2B/LGMDR2 and Miyoshi myopathy type 1), anoctaminopathy has an early predilection for medial calf atrophy and weakness.

Importantly, immune-mediated necrotizing myopathies can mimic LGMD clinically and histopathologically (Chap. 365). Anyone suspected of having an LGMD but without definite pathogenic mutation(s) identified on genetic testing should be screened for the presence of serum antibodies against HMGCR and SRP to assess for a treatable autoimmune cause.

EMERY-DREIFUSS MUSCULAR DYSTROPHY

There are at least five genetically distinct forms of EDMD. *Emerin* mutations are the most common cause of X-linked EDMD, although mutations in *FHL1* may also be associated with a similar phenotype, which is X-linked as well. Mutations involving the gene for Lamin A/C

TABLE 449-4 Autosomal Recessive Limb-Girdle Muscular Dystrophies (LGMDs)

DISEASE	CLINICAL FEATURES	LABORATORY FEATURES	ABNORMAL PROTEIN
LGMD2A/LGMDR1	Onset first or second decade Scapular winging; no calf hypertrophy; no cardiac or respiratory muscle weakness Proximal and distal weakness; may have contractures at elbows, wrists, and fingers	Serum CK 3–15× normal EMG myopathic Muscle biopsy may show lobulated muscle fibers	Calpain-3
LGMD2B/LGMDR2	Onset second or third decade Proximal muscle weakness at onset, later distal (calf) muscles affected Miyoshi myopathy is variant of LGMD2B with calf muscles affected at onset	Serum CK 3–100× normal EMG myopathic Inflammation on muscle biopsy may simulate polymyositis; amyloid deposition in endomysium	Dysferlin
LGMD2C–F/LGMDR3–6	Onset in childhood to teenage years Clinical condition similar to Duchenne and Becker muscular dystrophies Cognitive function normal	Serum CK 5–100× normal EMG myopathic	γ, α, β, δ sarcoglycans
LGMD2G/LGMDR7	Onset age 10–15 Proximal and distal muscle weakness	Serum CK 3–17× normal EMG myopathic Muscle biopsy may show rimmed vacuoles	Telethonin
LGMD2H/LGMDR8	Onset first to third decade Allelic to sarcotubular congenital myopathy Proximal muscle weakness	Serum CK 2–25× normal EMG myopathic Muscle biopsy reveals dilated T-tubules	Tripartite motif-containing 32
LGMD2I/LGMDR9	Onset first to third decade Clinical condition similar to Duchenne or Becker dystrophies Cardiomyopathy and respiratory failure may occur early before significant weakness Cognitive function normal	Serum CK 10–30× normal EMG myopathic	Fukutin-related protein
LGMD2J[a] /LGMDR10	Onset first to third decade Proximal lower limb weakness Mild distal weakness Progressive weakness causes loss of ambulation	Serum CK 1.5–2× normal EMG myopathic Muscle biopsy reveals rimmed vacuoles	Titin
LGMD2K/LGMDR11	Usually presents in infancy as Walker-Warburg syndrome but can present in early adult life with proximal weakness and only minor CNS abnormalities	CK 10–20× normal EMG myopathic	POMT1
LGMD2L/LGMDR12	Presents in childhood or adult life May manifest with quadriceps atrophy and myalgia Some present with early involvement of the calves in the second decade of life, resembling Miyoshi myopathy type 1 (dysferlinopathy)	CK 8–20× normal EMG myopathic	Anoctamin 5
LGMD2M/LGMDR13	Usually presents in infancy as Fukuyama congenital muscular dystrophy but can present in early adult life with proximal weakness and only minor CNS abnormalities	CK 10–50× normal EMG myopathic	Fukutin
LGMD2N/LGMDR14	Usually presents in infancy as muscle-eye-brain disease but can present in early adult life with proximal weakness and only minor CNS abnormalities	CK 5–20× normal EMG myopathic	POMGNT1
LGMD2O/LGMDR15	Usually presents in infancy as Walker-Warburg syndrome but can present in early adult life with proximal weakness and only minor CNS abnormalities	CK 5–20× normal EMG myopathic	POMT2
LGMD2P/LGMD R16	One case reported presenting in early childhood	CK >10× normal	α-Dystroglycan
LGMD2Q/LGMDR17	Onset in infancy to fourth decade; proximal weakness; may have ptosis and extraocular weakness; epidermolysis bullosa (also considered a congenital myasthenic syndrome)	CK variable, but usually only mildly elevated EMG myopathic Repetitive nerve stimulation may show decrement	Plectin 1
LGMD2R/myofibrillar myopathy	See LGMD1E (see Table 449-6)	See LGMD1E	Desmin
LGMD2S/LGMDR18	Onset in infancy to sixth decade of proximal weakness Eye abnormalities common; truncal ataxia and chorea Mild to moderate intellectual disability Hutterite descent	CK 1.5–20× normal	TRAPC11
LGMD2T/LGMDR19	Onset in early childhood to fourth decade Proximal weakness CNS abnormalities, cataracts, cardiomyopathy, and neuromuscular junction dysfunction	CK 3 to >10× normal EMG myopathic	GMPPB

(*Continued*)

TABLE 449-4 Autosomal Recessive Limb-Girdle Muscular Dystrophies (LGMDs) (Continued)

DISEASE	CLINICAL FEATURES	LABORATORY FEATURES	ABNORMAL PROTEIN
LGMD2U/LGMDR20	Onset typically in early childhood of proximal weakness May have CNS and ocular abnormalities	CK 5 to >20× normal	ISPD
LGMD2V/late-onset Pompe disease	Childhood or adult onset of proximal weakness Ventilatory muscle weakness	CK normal to mildly elevated EMG myopathic (may have myotonic discharges)	Alpha-glucosidase
LGMD2W/PINCH2-related myopathy	Reported in only one family Childhood onset of proximal weakness Macroglossia with broad-based, triangular tongue Cardiomyopathy in third decade	CK 3 to >20× normal	PINCH2
LGMD2Y/TOR1AIP1-related myopathy	Reported in only one family Childhood onset of proximal weakness Rigid spine and contractures	CK normal to 4× normal EMG myopathic	Lamina-associated polypeptide 1B
LGMD2Z/LGMDR21	Adult-onset proximal weakness Scapular winging	CK mildly elevated	POGLUT1
Bethlem myopathy (recessive)/LGMDR22	Onset in childhood to adulthood Contractures at elbows, distal fingers, knees, ankles Hyperextensible fingers proximally Keloids	CK normal to 3× normal MRI and ultrasound of muscle show a peripheral > central predilection for fibrofatty replacement in individual muscles	Collagen VI alpha 1, alpha 2, or alpha 3 chains
Laminin alpha-2 muscular dystrophy/ LGMDR23	Congenital to adult onset May have CNS abnormalities	CK 2–5× normal	Laminin alpha 2 (merosin)
POMGNT-related muscular dystrophy/ LGMDR24	Congenital to adult onset May have CNS abnormalities	CK 5 to >20× normal	POMGNT2
LGMD2X/LGMDR25	Adult onset of proximal weakness Cardiac arrhythmias	CK 3 to >20× normal	Popeye domain containing protein 1

[a]Udd-type distal myopathy is a form of titin deficiency with only distal muscle weakness (see Table 449-5).

Abbreviations: CK, creatine kinase; CNS, central nervous system; EMG, electromyography; GMPPB; guanosine diphosphate (GDP)-mannose pyrophosphorylase B; ISPD, isoprenoid synthase domain containing; PINCH2, particularly interesting new cysteine-histidine rich protein 2; POGLUT1, protein O-glucosyltransferase 1; POMGNT1, O-linked mannose beta 1,2-*N*-acetylglucosaminyltransferase; POMGNT2, protein O-mannose beta-1,4-*N*-acetylglucosaminyltransferase-2; POMT1, protein-O-mannosyltransferase 1; POMT2, protein-O-mannosyltransferase 2; TNPO3, transportin 3; TOR1AIP1, DNA sequencing of torsinA-interacting protein 1; TRAPC11, transport (trafficking) protein particle complex, subunit 11.

(*LMNA*) are the most common cause of autosomal dominant EDMD (also known as LGMD1B) and are also a common cause of hereditary cardiomyopathy. Less commonly, autosomal dominant EDMD has been reported with mutations in *SYNE1*, *SYNE2*, *TMEM43*, *SUN1*, *SUN2*, and *TTN* genes encoding nesprin-1, nesprin-2, LUMA, SUN1, SUN2, and titin, respectively.

Clinical Features Prominent contractures can be recognized in early childhood and teenage years, often preceding muscle weakness. The contractures persist throughout the course of the disease and are present at the elbows, ankles, and neck. Muscle weakness affects humeral and peroneal muscles at first and later spreads to a limb-girdle distribution (Table 449-1). The cardiomyopathy is potentially life threatening and may result in sudden death. A spectrum of atrial rhythm and conduction defects includes atrial fibrillation and paralysis and atrioventricular heart block. Some patients have a dilated cardiomyopathy. Female carriers of the X-linked variant may manifest with a cardiomyopathy.

Laboratory Features Serum CK is usually slightly elevated, and the EMG is myopathic. Muscle biopsy usually shows nonspecific dystrophic features, although cases associated with *FHL1* mutations have features of myofibrillar myopathy. Immunohistochemistry reveals absent emerin staining of myonuclei in X-linked EDMD due to *emerin* mutations. Electrocardiograms (ECGs) demonstrate atrial and atrioventricular rhythm disturbances.

X-linked EDMD usually arises from defects in the *emerin* gene encoding a nuclear envelope protein. *FHL1* mutations are also a cause of X-linked scapuloperoneal dystrophy but can also present with an X-linked form of EDMD. The autosomal dominant disease can be caused by mutations in the *LMNA* gene encoding Lamin A/C; in the synaptic nuclear envelope protein 1 (*SYNE1*) or 2 (*SYNE2*) encoding nesprin-1 and nesprin-2, respectively; and in *TMEM43* encoding LUMA. These proteins are essential components of the filamentous network underlying the inner nuclear membrane. Loss of structural integrity of the nuclear envelope from defects in emerin, Lamin A/C, nesprin-1, nesprin-2, and LUMA accounts for overlapping phenotypes.

TREATMENT

Emery-Dreifuss Muscular Dystrophy

Supportive care should be offered for neuromuscular disability, including ambulatory aids, if necessary. Stretching of contractures is difficult. Management of cardiomyopathy and arrhythmias (e.g., early use of a defibrillator or cardiac pacemaker) may be lifesaving.

MYOTONIC DYSTROPHY

There are two distinct forms of myotonic dystrophy (*dystrophia myotonica* [DM]), namely myotonic dystrophy type 1 (DM1) and myotonic dystrophy type 2 (DM2), also called *proximal myotonic myopathy* (PROMM).

Clinical Features The clinical expression of DM1 varies widely and involves many systems other than muscle. Affected patients may have a "hatchet-faced" appearance due to temporalis, masseter, and facial muscle atrophy and weakness. Frontal baldness is frequent. Weakness of wrist and fingers occurs early, as does foot drop. Proximal muscles are less affected. Palatal, pharyngeal, and tongue involvement can lead to dysarthria and dysphagia. Some patients have diaphragm and intercostal muscle weakness, resulting in ventilatory insufficiency. Myotonia is usually apparent by the age of 5 years and is best demonstrable by percussion of the thenar eminence or asking patients to close their fingers very tightly and then relax.

TABLE 449-5 Distal Myopathies

DISEASE	CLINICAL FEATURES	LABORATORY FEATURES	ABNORMAL PROTEIN
Welander distal myopathy	Onset in fifth decade Weakness begins in hands Slow progression with spread to distal lower extremities Life span normal	Serum CK 2–3× normal EMG myopathic NCS normal Muscle biopsy shows dystrophic features and rimmed vacuoles	AD TIA1
Tibial muscular dystrophy (Udd)	Onset fourth to eighth decade Distal lower extremity weakness (tibial distribution) Upper extremities usually normal Life span normal	Serum CK 2–4× normal EMG myopathic NCS normal Muscle biopsy shows dystrophic features and rimmed vacuoles Titin absent in M-line of muscle	AD Titin AR (associated with more proximal weakness—LGMD2J)
Markesbery-Griggs distal myopathy	Onset fourth to eighth decade Distal lower extremity weakness (tibial distribution) with progression to distal arms and proximal muscles	Serum CK is usually mildly elevated EMG reveals irritative myopathy Muscle biopsies demonstrate rimmed vacuoles and features of MFM	AD Z-band alternatively spliced PDX motif-containing protein (ZASP)
Laing distal myopathy	Onset childhood to third decade Distal lower extremity weakness (anterior tibial distribution) and neck flexors affected early May have cardiomyopathy	Serum CK is normal or slightly elevated Muscle biopsies do not typically show rimmed vacuoles, but may show hyaline bodies with accumulation of myosin Large deposits of myosin heavy chain are seen in type 1 muscle fibers	AD Myosin heavy chain 7
GNE myopathy (Nonaka distal myopathy and autosomal recessive hereditary inclusion body myopathy)	Onset second to third decade Distal lower extremity weakness (anterior tibial distribution) Mild distal upper limb weakness may be present early Progression to other muscles sparing quadriceps Ambulation may be lost in 10–15 years	Serum CK 3–10× normal EMG myopathic NCS normal Dystrophic features on muscle biopsy plus rimmed vacuoles and 15- to 19-nm filaments within vacuoles	AR *GNE* gene: UDP-*N*-acetylglucosamine 2-epimerase/*N*-acetylmannosamine kinase Allelic to a form of hereditary inclusion body myopathy
Miyoshi myopathy[a]	Onset second to third decade Lower extremity weakness in posterior compartment muscles Progression leads to weakness in other muscle groups Ambulation lost after 10–15 years in about one-third of cases	Serum CK 20–100× normal EMG myopathic NCS normal Muscle biopsy shows nonspecific dystrophic features often with prominent inflammatory cell infiltration; no rimmed vacuoles	AR Dysferlin (allelic to LGMD2B) ANO-5 (allelic to LGMD2L)
Williams myopathy	Distal lower extremity weakness (anterior tibial distribution)	Muscle biopsy may show rimmed vacuoles and features of MFM	AD Filamin-C
Myofibrillar myopathies	Onset from early childhood to late adult life Weakness may be distal, proximal, or generalized Cardiomyopathy and respiratory involvement are not uncommon	Serum CKs can be normal or moderately elevated EMG is myopathic and often associated with myotonic discharges Muscle biopsy demonstrates abnormal accumulation of desmin and other proteins, rimmed vacuoles, and myofibrillar degeneration	Genetically heterogeneous AD Myotilin (also known as LGMD1A) ZASP (see Markesbery-Griggs distal myopathy) Filamin-C Desmin Alpha B crystallin Bag3 Titin DNAJB6 TNPO3 AR, AD Desmin X-linked FHL1

[a]Miyoshi myopathy phenotype may also be seen with mutations in ANO-5 that encodes for anoctamin 5 (allelic to LGMD2L).

Abbreviations: AD, autosomal dominant; AR, autosomal recessive; CK, creatine kinase; EMG, electromyography; MFM, myofibrillar myopathy; NCS, nerve conduction studies.

ECG abnormalities include first-degree heart block and more extensive conduction system involvement. Complete heart block and sudden death can occur. Congestive heart failure occurs infrequently but may result from cor pulmonale secondary to respiratory failure. Other associated features include intellectual impairment, hypersomnia, posterior subcapsular cataracts, gonadal atrophy, insulin resistance, and decreased esophageal and colonic motility.

Congenital myotonic dystrophy is a more severe form of DM1 and occurs in ~25% of infants of affected mothers. It is characterized by severe facial and bulbar weakness, transient neonatal respiratory insufficiency, and intellectual disability.

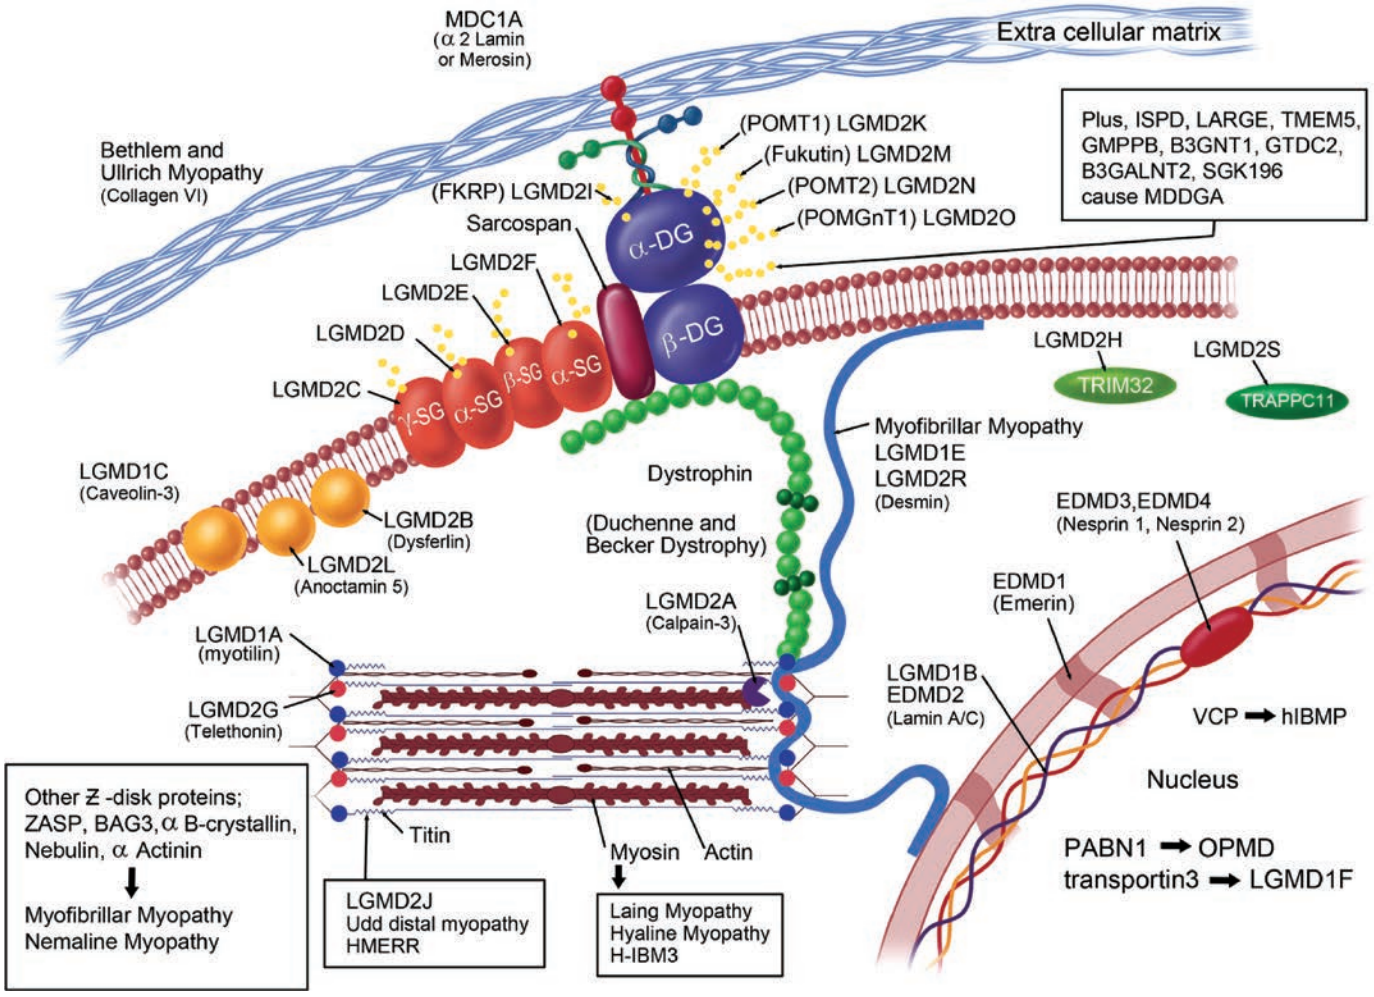

FIGURE 449-6 Proteins involved in the muscular dystrophies. This schematic shows the location of various sarcolemmal, sarcomeric, nuclear, and enzymatic proteins associated with muscular dystrophies. The diseases associated with mutations in the genes responsible for encoding these proteins are shown in boxes. Dystrophin, via its interaction with the dystroglycan complex, connects the actin cytoskeleton to the extracellular matrix. Extracellularly, the sarcoglycan complex interacts with biglycan, which connects this complex to the dystroglycan complex and the extracellular matrix collagen. Various enzymes are important in the glycosylation of the α-dystroglycan and mediate its binding to the extracellular matrix and usually cause a congenital muscular dystrophy with severe brain and eye abnormalities but may cause milder LGMD phenotype. Mutations in genes that encode for sarcomeric and Z-disk proteins cause forms of LGMD and distal myopathies (including myofibrillar myopathy, forms of hereditary inclusion body myopathy) as well as nemaline rod myopathy and other "congenital" myopathies. Mutations affecting nuclear membrane proteins are responsible for most forms of EDMD. Mutations in other nuclear genes cause other forms of dystrophy. *(From AA Amato, J Russell: Neuromuscular Disorders, 2nd ed. McGraw-Hill, 2016, Figure 27-1, p. 657; with permission.)*

DM2 or PROMM involves mainly proximal muscles. Other features of the disease overlap with DM1, including cataracts, testicular atrophy, insulin resistance, constipation, hypersomnia, and cognitive defects. Cardiac conduction defects occur but are less common. The hatchet face and frontal baldness are also less consistent features. A very striking difference is the failure to clearly identify a congenital form of DM2.

Laboratory Features The diagnosis of myotonic dystrophy can usually be made on the basis of clinical findings. Serum CK levels may be normal or mildly elevated. EMG evidence of myotonia is present in most cases of DM1 but is more patchy in DM2. Muscle biopsy is not typically performed for diagnosis but is sometimes done when the clinical features and electrophysiologic features are not recognized. The major histopathologic features in both DM1 and DM2 are numerous internalized nuclei in individual muscle fibers combined with many atrophic fibers with pyknotic nuclear clumps.

DM1 and DM2 are autosomal dominant disorders. DM1 is transmitted by an intronic mutation consisting of an unstable expansion of a CTG trinucleotide repeat in a serine-threonine protein kinase gene (named *DMPK*). An increase in the severity of the disease phenotype in successive generations (genetic anticipation) is accompanied by an increase in the number of trinucleotide repeats. The unstable triplet repeat in myotonic dystrophy can be used for prenatal diagnosis. Congenital disease occurs almost exclusively in infants born to affected mothers.

DM2 is caused by a DNA expansion mutation consisting of a CCTG repeat in intron 1 of the *CNBP* gene encoding the CCHC-type zinc finger nucleic acid binding protein. The DNA expansions in DM1 and DM2 impair muscle function by a toxic gain of function of the mutant mRNA. In both DM1 and DM2, the mutant RNA appears to form intranuclear inclusions composed of aberrant RNA. These RNA inclusions sequester RNA-binding proteins essential for proper splicing of a variety of other mRNAs. This leads to abnormal transcription of multiple proteins in a variety of tissues/organ systems, in turn causing the systemic manifestations of DM1 and DM2.

TREATMENT

Myotonic Dystrophy

The myotonia in DM1 and DM2 is usually not so bothersome to warrant treatment, but when it is, mexiletine may be helpful. A cardiac pacemaker or implantable cardioverter defibrillator should be considered for patients with significant arrhythmia. Molded ankle-foot orthoses help stabilize gait in patients with foot drop. Excessive daytime somnolence with or without sleep apnea is not

uncommon. Sleep studies, noninvasive respiratory support (biphasic positive airway pressure [BiPAP]), and treatment with modafinil may be beneficial.

FACIOSCAPULOHUMERAL (FSHD) MUSCULAR DYSTROPHY

There are two forms of FSHD that have similar pathogenesis. Most patients have FSHD type 1 (95%), whereas ~5% have FSHD2. Both forms are clinically and histopathologically identical. The prevalence FSHD is ~5 per 100,000 individuals.

Clinical Features FSHD typically presents in childhood or young adulthood. In most cases, facial weakness is the initial manifestation, appearing as an inability to smile, whistle, or fully close the eyes. Loss of scapular stabilizer muscles makes arm elevation difficult. Scapular winging (Fig. 449-3) becomes apparent with attempts at abduction and forward movement of the arms. Biceps and triceps muscles may be severely affected, with relative sparing of the deltoid muscles. Weakness is invariably worse for wrist extension than for wrist flexion, and weakness of the anterior compartment muscles of the legs may lead to foot drop. In 20% of patients, weakness progresses to involve the pelvic muscles, and severe functional impairment and possible wheelchair dependency result. The heart is not involved, but there can be ventilatory muscle weakness in 5% of affected individuals. There is an increased incidence of nerve deafness. *Coats' disease*, a disorder consisting of telangiectasia, exudation, and retinal detachment, also occurs.

Laboratory Features The serum CK level may be normal or mildly elevated. EMG and muscle biopsy show nonspecific abnormalities but on occasion can reveal a prominent inflammatory infiltrate leading to an incorrect diagnosis of myositis (Chap. 365).

FSHD1 is associated with deletions of tandem 3.3-kb repeats at 4q35. The deletion reduces the number of repeats to a fragment of <35 kb in most patients. Within these repeats lies the *DUX4* gene, which usually is not expressed after early muscle development. In patients with FSHD1, these deletions in the setting of a specific polymorphism lead to hypomethylation of the region and toxic expression of the *DUX4* gene. In cases of FSHD2, there is no deletion, but rather mutations in three different genes have been identified, each of which interestingly leads to hypomethylation of the DUX4 region and the permissive expression of the *DUX4* gene. Dominant mutations in the structural maintenance of chromosomes hinge domain 1 (*SMCHD1*) gene is the most common cause of FSHD2, but recently, heterozygous mutations in the DNA methyltransferase 3B (*DNMT3B*) gene and homozygous mutations in the ligand-dependent nuclear receptor-interacting factor 1 (*LRIF1*) gene have been reported in rare cases of autosomal recessive FSHD2. These proteins normally interact with SMCHD1, and mutations lead to hypomethylation of the DUX4 region and, as in FSHD1, to an overexpression of the *DUX4* transcript.

TREATMENT

Facioscapulohumeral Muscular Dystrophy

No specific treatment is available; ankle-foot orthoses are helpful for foot drop. Scapular stabilization procedures improve scapular winging but may not improve function.

OCULOPHARYNGEAL DYSTROPHY (OPMD)

OPMD represents one of several disorders characterized by progressive external ophthalmoplegia, which consists of slowly progressive ptosis and limitation of eye movements with sparing of pupillary reactions for light and accommodation. Patients usually do not complain of diplopia, in contrast to patients having conditions with a more acute onset of ocular muscle weakness (e.g., myasthenia gravis).

Clinical Features OPMD has a late onset; it usually presents in the fourth to sixth decade with ptosis or dysphagia. The extraocular muscle impairment is less prominent in the early phase but may become severe over time. The swallowing problem may lead to aspiration. Weakness of the neck and proximal extremities can develop but is usually mild in degree.

Laboratory Features The serum CK level may be two to three times normal. EMG can identify myopathic changes in weak muscles. Muscle biopsies are no longer necessary for diagnosis in most cases but, when performed, demonstrate muscle fibers with rimmed vacuoles. On electron microscopy, a distinctive feature of OPMD is the presence of 8.5-nm tubular filaments in some muscle cell nuclei.

OPMD is an autosomal dominant disorder that has a high incidence in certain populations (e.g., French-Canadians, individuals of Spanish ancestry, and Ashkenazi Jews). The molecular defect in OPMD is an expansion of a polyalanine repeat tract in a poly-RNA-binding protein (*PABP2*) gene.

TREATMENT

Oculopharyngeal Dystrophy

Dysphagia can lead to significant undernourishment and aspiration. Cricopharyngeal myotomy may improve swallowing. Eyelid crutches can improve vision when ptosis obstructs vision; candidates for ptosis surgery must be carefully selected—those with severe facial weakness are not suitable.

DISTAL MYOPATHIES/DYSTROPHIES

The distal myopathies are notable for their preferential distal distribution of muscle weakness in contrast to most muscle conditions associated with proximal weakness. The major distal myopathies are summarized in Tables 449-1 and 449-5.

Clinical Features *Welander, Udd*, and *Markesbery-Griggs type distal myopathies* are all late-onset, dominantly inherited disorders of distal limb muscles, usually beginning after age 40 years. Welander distal myopathy preferentially involves the wrist and finger extensors, whereas the others are associated with anterior tibial weakness leading to progressive foot drop. *Laing distal myopathy* is also a dominantly inherited disorder heralded by tibial weakness; however, it is distinguished by onset in childhood or early adult life. GNE myopathy (also known as *Nonaka distal myopathy* and autosomal recessive hereditary inclusion body myopathy) and *Miyoshi myopathy* are distinguished by autosomal recessive inheritance and onset in the late teens or twenties. GNE and Williams myopathy produce prominent anterior tibial weakness, whereas Miyoshi myopathy is unique in that gastrocnemius muscles are preferentially affected at onset. Finally, the *myofibrillar myopathies* (MFMs) are a clinically and genetically heterogeneous group of muscular dystrophies that can be associated with prominent distal weakness; they can be inherited in an autosomal dominant or recessive pattern. Of note, Markesbery-Griggs myopathy (caused by mutations in ZASP), LGMD1E and LGMD2R (caused by mutations in desmin), and LGMD1A (caused by mutations in myotilin) are subtypes of MFM.

Laboratory Features Serum CK levels are markedly elevated in Miyoshi myopathy, but in the other conditions, serum CK is only slightly increased. EMGs are myopathic and can be irritable with myotonic discharges in MFM. Muscle biopsy shows nonspecific dystrophic features and, with the exception of Laing and Miyoshi myopathies, often shows rimmed vacuoles. MFM is associated with the accumulation of dense inclusions and amorphous material best seen on Gomori trichrome staining along with myofibrillar disruption on electron microscopy. Immune staining sometimes demonstrates accumulation of desmin and other proteins in MFM, large deposits of myosin heavy chain in the subsarcolemmal region of type 1 muscle fibers in Laing myopathy, and reduced or absent dysferlin in Miyoshi myopathy type 1.

TREATMENT

Distal Myopathies

Occupational therapy is offered for loss of hand function; ankle-foot orthoses can support distal lower limb muscles. The MFMs

can be associated with cardiomyopathy (congestive heart failure or arrhythmias) and respiratory failure that may require medical management. Laing-type distal myopathy can also be associated with a cardiomyopathy.

DISORDERS OF MUSCLE ENERGY METABOLISM

There are two principal sources of energy for skeletal muscle—fatty acids and glucose. Abnormalities in either glucose or lipid utilization can be associated with distinct clinical presentations that can range from an acute, painful syndrome with rhabdomyolysis and myoglobinuria to a chronic, progressive muscle weakness simulating muscular dystrophy (Table 449-1). As with the muscular dystrophies, there are no specific medical treatments available.

GLYCOGEN STORAGE AND GLYCOLYTIC DEFECTS

Disorders of Glycolysis Causing Exercise Intolerance Several glycolytic defects are associated with recurrent myoglobinuria. The most common is *McArdle disease* caused by mutations in the *PYGM* gene leading to *myophosphorylase deficiency*. Symptoms of muscle pain and stiffness usually begin in adolescence. With severe episodes, myoglobinuria can occur.

Certain features help distinguish some enzyme defects. In McArdle disease, exercise tolerance can be enhanced by a slow induction phase (warm-up) or brief periods of rest, allowing for the start of the "second-wind" phenomenon (switching to utilization of fatty acids). Varying degrees of hemolytic anemia accompany deficiencies of both phosphofructokinase (mild) and phosphoglycerate kinase (severe). In phosphoglycerate kinase deficiency, the usual clinical presentation is a seizure disorder associated with intellectual disability; exercise intolerance is an infrequent manifestation.

In all of these conditions, the serum CK levels fluctuate widely and may be elevated even during symptom-free periods. CK levels >100 times normal are expected accompanying myoglobinuria. A forearm exercise test reveals a blunted rise in venous lactate with a normal rise in ammonia. A definitive diagnosis of glycolytic disease can be made by muscle biopsy with appropriate staining and enzyme assays, but genetic testing is now done in lieu of biopsy in most cases.

Training may enhance exercise tolerance, perhaps by increasing perfusion to muscle. Dietary intake of free glucose or fructose prior to activity may improve function, but care must be taken to avoid obesity from ingesting too many calories.

Disorders of Glycogen Storage Causing Progressive Weakness

α-GLUCOSIDASE, OR ACID MALTASE, DEFICIENCY (POMPE DISEASE) Three clinical forms of α-glucosidase, or acid maltase, deficiency (*type II glycogenosis*) can be distinguished. The infantile form is the most common, with onset of symptoms in the first 3 months of life. Infants develop severe muscle weakness, cardiomegaly, hepatomegaly, and respiratory insufficiency. Glycogen accumulation in motor neurons of the spinal cord and brainstem contributes to muscle weakness. Death usually occurs by 1.5 years of age. In the childhood form, the picture resembles DMD with delayed motor milestones resulting from proximal limb muscle weakness and involvement of respiratory muscles. The heart may be involved, but the liver and brain are unaffected. The adult form usually begins in the third or fourth decade but can present as late as the seventh decade. Ventilatory weakness can be the initial and only manifestation in 20–30% of late-onset cases.

The serum CK level is 2–10 times normal in infantile or childhood-onset Pompe disease but can be normal in adult-onset cases. EMG can demonstrate muscle membrane irritability, particularly in the paraspinal muscles. The muscle biopsy in infants typically reveals vacuoles containing glycogen and the lysosomal enzyme acid phosphatase. Electron microscopy reveals membrane-bound and free tissue glycogen. However, muscle biopsies in late-onset Pompe disease may demonstrate only nonspecific abnormalities. Enzyme analysis of dried blood spots is a sensitive technique to screen for Pompe disease. A definitive diagnosis is established by genetic testing.

Pompe disease is inherited as an autosomal recessive disorder caused by mutations of the *α-glucosidase* gene. Enzyme replacement therapy (ERT) with IV recombinant human α-glucosidase is beneficial in infantile-onset Pompe disease. In late-onset cases, ERT has a more modest benefit.

OTHER GLYCOGEN STORAGE DISEASES WITH PROGRESSIVE WEAKNESS In *debranching enzyme deficiency* (*type III glycogenosis*), a slowly progressive form of muscle weakness can develop after puberty. Rarely, myoglobinuria may be seen. Patients are usually diagnosed in infancy, however, because of hypotonia and delayed motor milestones; hepatomegaly, growth retardation, and hypoglycemia are other manifestations. *Branching enzyme deficiency* (*type IV glycogenosis*) is a rare and fatal glycogen storage disease characterized by failure to thrive and hepatomegaly. Hypotonia and muscle wasting may be present, but the skeletal muscle manifestations are minor compared to liver failure. Recently, the first autosomal dominant glycogen storage disease was reported in a family and was caused by a mutation in the *PYGM* gene that typically causes autosomal recessive McArdle disease. Affected individuals presented with progressive proximal weakness, no exercise intolerance, normal CK, and a normal lactic acid increase with exercise.

LIPID AS AN ENERGY SOURCE AND ASSOCIATED DEFECTS

Lipid is an important muscle energy source during rest and during prolonged, submaximal exercise. Oxidation of fatty acids occurs in the mitochondria. To enter the mitochondria, a fatty acid must first be converted to an "activated fatty acid," acyl-CoA. The acyl-CoA must be linked with carnitine by the enzyme CPT for transport into the mitochondria.

Carnitine Palmitoyltransferase 2 Deficiency CPT2 deficiency is the most common recognizable cause of recurrent myoglobinuria. Onset is usually in the teenage years or early twenties. Muscle pain and myoglobinuria typically occur after prolonged exercise but can also be precipitated by fasting or infections; up to 20% of patients do not exhibit myoglobinuria, however. Strength is normal between attacks. In contrast to disorders caused by defects in glycolysis, in which muscle cramps follow short, intense bursts of exercise, the muscle pain in CPT2 deficiency does not occur until the limits of utilization have been exceeded and muscle breakdown has already begun.

Serum CK levels and EMG findings are both usually normal between episodes. A normal rise of venous lactate during forearm exercise distinguishes this condition from glycolytic defects. Muscle biopsy does not show lipid accumulation and is usually normal between attacks. The diagnosis requires direct measurement of muscle CPT or genetic testing. Attempts to improve exercise tolerance with frequent meals and a low-fat, high-carbohydrate diet, or by substituting medium-chain triglycerides in the diet, have not proven to be beneficial.

MITOCHONDRIAL MYOPATHIES

Mitochondria play a key role in energy production. Oxidation of the major nutrients derived from carbohydrate, fat, and protein leads to the generation of reducing equivalents. The latter are transported through the respiratory chain in the process known as *oxidative phosphorylation*. The energy generated by the oxidation-reduction reactions of the respiratory chain is stored in an electrochemical gradient coupled to ATP synthesis.

A novel feature of mitochondria is their genetic composition. Each mitochondrion possesses a DNA genome that is distinct from that of the nuclear DNA. Human mitochondrial DNA (mtDNA) consists of a double-strand, circular molecule comprising 16,569 base pairs (bp). It codes for 22 transfer RNAs, 2 ribosomal RNAs, and 13 polypeptides of the respiratory chain enzymes. The genetics of mitochondrial diseases differ from the genetics of chromosomal disorders. The DNA of mitochondria is directly inherited from the cytoplasm of the gametes, mainly from the oocyte. The sperm contributes very little of its mitochondria to the offspring at the time of fertilization. Thus, mitochondrial genes are derived almost exclusively from the mother, accounting for maternal inheritance of some mitochondrial disorders.

Patients with mitochondrial myopathies have clinical manifestations that usually fall into three groups: chronic progressive external ophthalmoplegia (CPEO), skeletal muscle–CNS syndromes, and pure myopathy simulating muscular dystrophy or metabolic myopathy. Unfortunately, no specific medical therapies are clearly beneficial, although coenzyme Q10 supplements are often prescribed.

Kearns-Sayre Syndrome (KSS) This is a widespread multiorgan system disorder with a defined triad of clinical findings: onset before age 20, CPEO, and pigmentary retinopathy, plus one or more of the following features: complete heart block, cerebrospinal fluid (CSF) protein >1 g/L (100 mg/dL), or cerebellar ataxia. The cardiac disease includes syncopal attacks and cardiac arrest related to the abnormalities in the cardiac conduction system: prolonged intraventricular conduction time, bundle branch block, and complete atrioventricular block. Death attributed to heart block occurs in ~20% of the patients. Varying degrees of progressive limb muscle weakness and easy fatigability affect activities of daily living. Many affected individuals have intellectual disabilities. Endocrine abnormalities are also common, including gonadal dysfunction in both sexes with delayed puberty, short stature, and infertility. Diabetes mellitus occurs in ~13% of KSS patients. Other less common endocrine disorders include thyroid disease, hyperaldosteronism, Addison's disease, and hypoparathyroidism.

Serum CK and lactate levels are normal or slightly elevated. EMG is myopathic. NCS may be abnormal related to an associated neuropathy. Muscle biopsies reveal ragged red fibers and cytochrome oxidase (COX)–negative fibers. By electron microscopy, there are increased numbers of mitochondria that often appear enlarged and contain paracrystalline inclusions.

KSS is a sporadic disorder caused by single mtDNA deletions that are presumed to arise spontaneously in the ovum or zygote. The most common deletion, occurring in about one-third of patients, removes 4977 bp of contiguous mtDNA. Monitoring for cardiac conduction defects is critical. Prophylactic pacemaker implantation is indicated when ECGs demonstrate a bifascicular block.

Progressive External Ophthalmoplegia (PEO) PEO can be caused by nuclear DNA mutations affecting mtDNA and thus inherited in a Mendelian fashion or by mutations in mtDNA. Onset is usually after puberty. Fatigue, exercise intolerance, dysphagia, and complaints of muscle weakness are typical. The neurologic examination confirms the ptosis and ophthalmoplegia, usually asymmetric in distribution. Patients do not complain of diplopia. Mild facial, neck flexor, and proximal weakness is typical. Rarely, respiratory muscles may be progressively affected and may be the direct cause of death.

Serum CK and lactate can be normal or mildly elevated. The EMG can be myopathic. Ragged red and COX-negative fibers are prominently displayed in the muscle biopsy.

This autosomal dominant form of CPEO is most commonly caused by mutations in the genes encoding adenine nucleotide translocator 1 (*ANT1*), twinkle gene (*C10orf2*), and mtDNA polymerase 1 (*POLG1*). Autosomal recessive PEO can also be caused by mutations in *POLG1*. Point mutations have been identified within various mitochondrial tRNA (Leu, Ile, Asn, Trp) genes in families with maternal inheritance of PEO.

There is no specific medical treatment available; exercise may improve function, but this will depend on the patient's ability to participate.

Myoclonic Epilepsy with Ragged Red Fibers (MERRF) The onset of MERRF is variable, ranging from late childhood to middle adult life. Characteristic features include myoclonic epilepsy, cerebellar ataxia, and progressive proximal muscle weakness. The seizure disorder is an integral part of the disease and may be the initial symptom. Cerebellar ataxia precedes or accompanies epilepsy. Other more variable features include dementia, peripheral neuropathy, optic atrophy, hearing loss, and diabetes mellitus.

Serum CK levels and lactate may be normal or elevated. EMG is myopathic, and in some patients, NCS show a neuropathy. The electroencephalogram is abnormal, corroborating clinical findings of epilepsy. Typical ragged red fibers are seen on muscle biopsy. MERRF is caused by maternally inherited point mutations of mitochondrial tRNA genes. The most common mutation found in 80% of MERRF patients is an A to G substitution at nucleotide 8344 of tRNA lysine (A8344G $tRNA^{lys}$). Only supportive treatment is possible, with special attention to epilepsy.

Mitochondrial Myopathy, Encephalopathy, Lactic Acidosis, and Stroke-like Episodes (MELAS) MELAS is the most common mitochondrial encephalomyopathy. The term *stroke-like* is appropriate because the cerebral lesions do not conform to a strictly vascular distribution. The onset in the majority of patients is before age 20. Seizures, usually partial motor or generalized, are common and may represent the first clearly recognizable sign of disease. The cerebral insults that resemble strokes cause hemiparesis, hemianopia, and cortical blindness. A presumptive stroke occurring before age 40 should place this mitochondrial encephalomyopathy high in the differential diagnosis. Associated conditions include hearing loss, diabetes mellitus, hypothalamic pituitary dysfunction causing growth hormone deficiency, hypothyroidism, and absence of secondary sexual characteristics. In its full expression, MELAS leads to dementia, a bedridden state, and a fatal outcome. Serum lactic acid is typically elevated.

The CSF protein is also increased but is usually ≤1 g/L (100 mg/dL). Muscle biopsies show ragged red fibers. Neuroimaging demonstrates basal ganglia calcification in a high percentage of cases. Focal lesions that mimic infarction are present predominantly in the occipital and parietal lobes. Strict vascular territories are not respected, and cerebral angiography fails to demonstrate lesions of the major cerebral blood vessels.

MELAS is usually caused by maternally inherited point mutations of mitochondrial tRNA genes. The A3243G point mutation in $tRNA^{Leu(UUR)}$ is the most common, occurring in ~80% of MELAS cases. No specific treatment is available. Supportive treatment is essential for the stroke-like episodes, seizures, and endocrinopathies.

Mitochondrial DNA Depletion Syndromes Mitochondrial DNA depletion syndrome (MDS) is a heterogeneous group of disorders that are inherited in an autosomal recessive fashion and can present in infancy or in adults. MDS can be caused by mutations in several genes (*TK2*, *DGUOK*, *RRM2B*, *TYMP*, *SUCLA1*, and *SUCLA2*) that lead to depletion of mitochondrial deoxyribonucleotides (dNTP) necessary for mtDNA replication. The other major cause of MDS is a set of mutations in genes essential for mtDNA replication (e.g., *POLG1* and *C10orf2*). The clinical phenotypes associated with MDS vary. Patients may develop a severe encephalopathy (e.g., Leigh's syndrome), PEO, an isolated myopathy, myo-neuro-gastrointestinal encephalopathy (MNGIE), and a sensory neuropathy with ataxia.

DISORDERS OF MUSCLE MEMBRANE EXCITABILITY

Muscle membrane excitability is affected in a group of disorders referred to as *channelopathies*. These disorders usually present with episodic muscle weakness (periodic paralysis) and sometimes myotonia or paramyotonia (Table 449-1).

CALCIUM CHANNEL DISORDERS OF MUSCLE

Hypokalemic Periodic Paralysis (HypoKPP) This is an autosomal dominant disorder with onset in adolescence. Males are more often affected because of decreased penetrance in females. Episodic weakness with onset after age 25 is almost never due to periodic paralyses, with the exception of thyrotoxic periodic paralysis. Attacks are often provoked by meals high in carbohydrates or sodium and may accompany rest following prolonged exercise. Weakness usually affects proximal limb muscles more than distal. Ocular and bulbar muscles are less likely to be affected. Respiratory muscles are usually spared, but when they are involved, the condition may prove fatal. Weakness may

take as long as 24 h to resolve. Life-threatening cardiac arrhythmias related to hypokalemia may occur during attacks. As a late complication, patients commonly develop severe, disabling proximal lower extremity weakness.

Attacks of thyrotoxic periodic paralysis resemble those of primary HypoKPP. Despite a higher incidence of thyrotoxicosis in women, men, particularly those of Asian descent, are more likely to manifest this complication. Attacks abate with treatment of the underlying thyroid condition.

A low serum potassium level during an attack, excluding secondary causes, establishes the diagnosis. In the midst of an attack of weakness, motor conduction studies may demonstrate reduced amplitudes, whereas EMG may show electrical silence in severely weak muscles. In between attacks, the EMG and routine NCS are normal. However, a long exercise NCS test may demonstrate decrementing amplitudes.

HypoKPP type 1 is the most common form and is caused by mutations in the voltage-sensitive, skeletal muscle calcium channel gene, *CALCL1A3*. Approximately 10% of cases are HypoKPP type 2, arising from mutations in the voltage-sensitive sodium channel gene (*SCN4A*). In both forms, the mutations lead to an abnormal gating pore current that predisposes the muscle cell to depolarize when potassium levels are low.

TREATMENT

Hypokalemic Periodic Paralysis

Mild attacks usually do not require medical treatment. However, severe attacks of weakness can be improved by the administration of potassium. Oral KCl (0.2–0.4 mmol/kg) can be given every 30 min. Only rarely is IV therapy necessary (e.g., when swallowing problems or vomiting is present). The long-term goal of therapy is to avoid attacks. Patients should be made aware of the importance of a low-carbohydrate, low-sodium diet and consequences of intense exercise. Prophylactic administration of acetazolamide or dichlorphenamide can reduce attacks of periodic weakness. However, in patients with HypoKPP type 2, attacks of weakness can be exacerbated with these medications.

SODIUM CHANNEL DISORDERS OF MUSCLE

Hyperkalemic Periodic Paralysis (HyperKPP) The term *hyperkalemic* is misleading because patients are often normokalemic during attacks. That attacks are precipitated by potassium administration best defines the disease. The onset is usually in the first decade; males and females are affected equally. Attacks are brief and mild, usually lasting 30 min to several hours. Weakness affects proximal muscles, sparing bulbar muscles. Attacks are precipitated by rest following exercise and fasting.

Potassium may be slightly elevated or normal during an attack. As in HypoKPP, NCS in HyperKPP muscle may demonstrate reduced motor amplitudes and the EMG may be silent in very weak muscles. A long exercise NCS test can reveal diminished amplitudes as well. The EMG may demonstrate myotonic discharges. HyperKPP is caused by mutations of the voltage-gated sodium channel *SCN4A* gene. Acetazolamide or dichlorphenamide can reduce the frequency and severity of attacks. Mexiletine may be helpful in patients with significant clinical myotonia.

Paramyotonia Congenita In PC, the attacks of weakness are cold-induced or occur spontaneously and are mild. Myotonia is a prominent feature but worsens with muscle activity (paradoxical myotonia). This is in contrast to classic myotonia in which exercise alleviates the condition. Attacks of weakness are seldom severe enough to require emergency room treatment. Over time, patients develop inter-attack weakness as they do in other forms of periodic paralysis.

Serum CK is usually mildly elevated. Routine NCS are normal. Short exercise NCS tests may be abnormal, however, and cooling of the muscle often dramatically reduces the amplitude of the compound muscle action potentials. EMG reveals diffuse myotonic potentials in PC. Upon local cooling of the muscle, the myotonic discharges disappear as the patient becomes unable to activate MUAPs.

PC is inherited as an autosomal dominant condition; voltage-gated sodium channel mutations are responsible, and thus, this disorder is allelic with HyperKPP. Mexiletine is reported to be helpful in reducing the myotonia.

POTASSIUM CHANNEL DISORDERS

Andersen-Tawil Syndrome This rare disease is characterized by episodic weakness, cardiac arrhythmias, and dysmorphic features (short stature, scoliosis, clinodactyly, hypertelorism, small or prominent low-set ears, micrognathia, and broad forehead). The cardiac arrhythmias are potentially serious and life threatening. They include long QT, ventricular ectopy, bidirectional ventricular arrhythmias, and tachycardia. The disease is most commonly caused by mutations of the inwardly rectifying potassium channel (*Kir 2.1*) gene that heighten muscle cell excitability. The episodes of weakness may differ between patients because of potassium variability. Acetazolamide may decrease the attack frequency and severity.

CHLORIDE CHANNEL DISORDERS

Two forms of this disorder, autosomal dominant (*Thomsen disease*) and autosomal recessive (*Becker disease*), are both caused by mutations in the chloride channel 1 gene (*CLCN1*). Symptoms are noted in infancy and early childhood. The severity lessens in the third to fourth decade. Myotonia is worsened by cold and improved by activity. The gait may appear slow and labored at first but improves with walking. In Thomsen disease, muscle strength is normal, but in Becker disease, which is usually more severe, there may be muscle weakness. Muscle hypertrophy is usually present. Myotonic discharges are prominently displayed by EMG recordings. Serum CK is normal or mildly elevated. Mexiletine is helpful in relieving the myotonia.

ENDOCRINE AND METABOLIC MYOPATHIES

Endocrinopathies can cause weakness, but fatigue is more common than true weakness. The serum CK level is often normal (except in hypothyroidism) and the muscle histology is characterized by atrophy rather than destruction of muscle fibers. Nearly all endocrine myopathies respond to treatment.

THYROID DISORDERS

Hypothyroidism (Chap. 383) Patients with hypothyroidism have frequent muscle complaints, and about one-third have proximal muscle weakness. Muscle cramps, pain, and stiffness are common. Some patients have enlarged muscles. Features of slow muscle contraction and relaxation occur in 25% of patients; the relaxation phase of muscle stretch reflexes is characteristically prolonged and best observed at the ankle or biceps brachii reflexes. The serum CK level is often elevated (up to 10 times normal). EMG is typically normal. Muscle biopsy shows no distinctive morphologic abnormalities.

Hyperthyroidism (Chap. 384) Patients who are thyrotoxic commonly have proximal muscle weakness, but they rarely complain of myopathic symptoms. Activity of deep tendon reflexes may be enhanced. Fasciculations may be apparent and, when coupled with increased muscle stretch reflexes, may lead to an erroneous diagnosis of amyotrophic lateral sclerosis. A form of hypokalemic periodic paralysis can occur in patients who are thyrotoxic. Mutations in the *KCNJ18* gene that encodes for the inwardly rectifying potassium channel, Kir 2.6, have been discovered in up to a third of cases.

PARATHYROID DISORDERS (SEE ALSO CHAP. 410)

Hyperparathyroidism Proximal muscle weakness, muscle wasting, and brisk muscle stretch reflexes are the main features of this endocrinopathy. Some patients develop neck extensor weakness (part

of the dropped head syndrome). Serum CK levels are usually normal or slightly elevated. Serum parathyroid hormone levels are elevated, while vitamin D and calcium levels are usually reduced. Muscle biopsies show only mild type 2 fiber atrophy.

Hypoparathyroidism An overt myopathy due to hypocalcemia rarely occurs. Neuromuscular symptoms are usually related to localized or generalized tetany. Serum CK levels may be increased secondary to muscle damage from sustained tetany. Hyporeflexia or areflexia is usually present and contrasts with the hyperreflexia in hyperparathyroidism.

ADRENAL DISORDERS (SEE ALSO CHAP. 386)

Conditions associated with glucocorticoid excess cause a myopathy; steroid myopathy is the most commonly diagnosed endocrine muscle disease. Proximal muscle weakness combined with a cushingoid appearance are the key clinical features. Serum CK and EMG are normal. Muscle biopsy, not typically done for diagnostic purposes, reveals type 2b muscle fiber atrophy. In primary hyperaldosteronism (*Conn's syndrome*), neuromuscular complications are due to potassium depletion. The clinical picture is one of persistent muscle weakness. Longstanding hyperaldosteronism may lead to proximal limb weakness and wasting. Serum CK levels may be elevated, and a muscle biopsy may demonstrate necrotic fibers. These changes relate to hypokalemia and are not a direct effect of aldosterone on skeletal muscle.

PITUITARY DISORDERS (SEE ALSO CHAP. 380)

Patients with acromegaly usually have mild proximal weakness. Muscles often appear enlarged but exhibit decreased force generation. The duration of acromegaly, rather than the serum growth hormone levels, correlates with the degree of myopathy.

DIABETES MELLITUS (SEE ALSO CHAP. 405)

Neuromuscular complications of diabetes mellitus are most often related to neuropathy. The only notable myopathy is ischemic infarction of leg muscles, usually involving one of the thigh muscles but on occasion affecting the distal leg. This condition occurs in patients with poorly controlled diabetes and presents with the abrupt onset of pain, tenderness, and edema of a thigh or calf. The area of muscle infarction is hard and indurated. The muscles most often affected include the vastus lateralis, thigh adductors, and biceps femoris. Computed tomography (CT) or MRI can demonstrate focal abnormalities in the affected muscle. Diagnosis by imaging is preferable to muscle biopsy, if possible, as hemorrhage into the biopsy site can occur.

MYOPATHIES OF SYSTEMIC ILLNESS

Systemic illnesses such as chronic respiratory, cardiac, or hepatic failure are frequently associated with severe muscle wasting and complaints of weakness. Fatigue is usually a more significant problem than weakness, which is typically mild.

DRUG-INDUCED OR TOXIC MYOPATHIES

The most common toxic myopathies are caused by the cholesterol-lowering agents and glucocorticoids. Others impact practice to a lesser degree but are important to consider in specific situations. Table 449-6 provides a comprehensive list of drug-induced myopathies with their distinguishing features.

TABLE 449-6 Drug-Induced Myopathies

DRUGS	MAJOR TOXIC REACTION
Lipid-lowering agents HMG-CoA reductase inhibitors Fibric acid derivatives Niacin (nicotinic acid)	Drugs belonging to all three of the major classes of lipid-lowering agents can produce a spectrum of toxicity: asymptomatic serum creatine kinase elevation, myalgias, exercise-induced pain, rhabdomyolysis, and myoglobinuria.
Glucocorticoids	Acute, high-dose glucocorticoid treatment can cause acute quadriplegic myopathy. These high doses of steroids are often combined with nondepolarizing neuromuscular blocking agents, but the weakness can occur without their use. Chronic steroid administration produces predominantly proximal weakness.
Nondepolarizing neuromuscular blocking agents	Acute quadriplegic myopathy can occur with or without concomitant glucocorticoids.
Zidovudine	Mitochondrial myopathy with ragged red fibers
Drugs of abuse Alcohol Amphetamines Cocaine Heroin Phencyclidine Meperidine	All drugs in this group can lead to widespread muscle breakdown, rhabdomyolysis, and myoglobinuria. Local injections cause muscle necrosis, skin induration, and limb contractures.
Autoimmune myopathy Statins Check point inhibitors D-Penicillamine	Use of statins may cause an immune-mediated necrotizing myopathy associated with HMG-CoA reductase antibodies. Checkpoint inhibitors can be complicated by myositis, myasthenia gravis, and immune-mediated neuropathies. Myasthenia gravis has also been reported with penicillamine.
Amphophilic cationic drugs Amiodarone Chloroquine Hydroxychloroquine	All amphophilic drugs have the potential to produce painless, proximal weakness associated with necrosis and autophagic vacuoles in the muscle biopsy.
Antimicrotubular drugs Colchicine	This drug produces painless, proximal weakness especially in the setting of renal failure. Muscle biopsy shows necrosis and fibers with autophagic vacuoles.

MYOPATHY FROM LIPID-LOWERING AGENTS

All classes of lipid-lowering agents have been implicated in muscle toxicity, including HMG-CoA reductase inhibitors (statins) and, to a much lesser extent, fibrates, niacin, and ezetimibe. Myalgia and elevated CKs are the most common manifestations. Rarely, patients exhibit proximal weakness or myoglobinuria. Concomitant use of statins with fibrates and cyclosporine increases the risk of severe myotoxicity. EMG demonstrates irritability, and myopathic units and muscle biopsies reveal necrotic muscle fibers in weak muscles. Severe myalgia, weakness, marked elevations in serum CK (>3–5 times baseline), and myoglobinuria are indications for stopping the drug. Patients usually improve with drug cessation, although this may take several weeks. Rare cases continue to progress after the offending agent is discontinued. It is possible that in such cases the statin may have triggered an immune-mediated necrotizing myopathy, as these individuals require immunotherapy (e.g., intravenous immunoglobulin or immunosuppressive agents) to improve and often relapse when these therapies are discontinued (Chap. 365). Autoantibodies directed against HMG-CoA reductase have been identified in many of these cases.

GLUCOCORTICOID-RELATED MYOPATHIES

Glucocorticoid myopathy occurs with chronic treatment or as "acute quadriplegic" myopathy secondary to high-dose IV glucocorticoid use. Chronic administration produces proximal weakness accompanied by cushingoid manifestations, which can be quite debilitating; the chronic use of prednisone at a daily dose of ≥30 mg/d is most often associated with toxicity. Patients taking fluorinated glucocorticoids (triamcinolone, betamethasone, dexamethasone) appear to be at especially high risk for myopathy. In chronic steroid myopathy, the serum CK is usually normal. Serum potassium may be low. The muscle biopsy in chronic cases shows preferential type 2 muscle fiber atrophy; this is not reflected in the EMG, which is usually normal.

Patients receiving high-dose IV glucocorticoids for status asthmaticus, chronic obstructive pulmonary disease, organ transplantation, or other indications may develop severe generalized weakness (critical illness myopathy). This myopathy, also known as acute quadriplegic myopathy, can also occur in the setting of sepsis. Involvement of the diaphragm and intercostal muscles causes ventilatory muscle weakness and is usually appreciated when patients are unable to be weaned off a ventilatory in the intensive care unit. NCS demonstrate reduced compound muscle action potentials in the setting of relatively preserved sensory potentials. EMG can demonstrate abnormal insertional and spontaneous activity and early recruitment of myopathic appearing units in those muscles that can be activated. Muscle biopsy can show a distinctive loss of thick filaments (myosin) by electron microscopy. Treatment is withdrawal of glucocorticoids and physical therapy, but the recovery is slow. Patients require supportive care and rehabilitation.

OTHER DRUG-INDUCED MYOPATHIES

Certain drugs produce painless, largely proximal muscle weakness. These drugs include the amphophilic cationic drugs (amiodarone, chloroquine, hydroxychloroquine) and antimicrotubular drugs (colchicine) (Table 449-6). Muscle biopsy can be useful in the identification of toxicity because autophagic vacuoles are prominent pathologic features of these toxins.

GLOBAL ISSUES

As previously discussed, certain dystrophies have an increased prevalence in different parts of the world. LGMD2A/LGMDR1 is the most common LGMD in individuals from Spain, France, Italy, and Great Britain; LGMD2I/LGMDR9 is more common in those with northern European ancestry. GNE myopathy is the most common form of distal myopathy in Japan but is also prevalent in the Ashkenazi population. OPMD is most common in those with ancestry from Spain and French-Canada as well as among Ashkenazi. Epidemiologic studies are lacking regarding other forms of myopathy and their prevalence in different areas of the world.

Section 4 Myalgic Encephalomyelitis/ Chronic Fatigue Syndrome

450 Myalgic Encephalomyelitis/ Chronic Fatigue Syndrome

Elizabeth R. Unger, Jin-Mann S. Lin, Jeanne Bertolli

Myalgic encephalomyelitis/chronic fatigue syndrome (ME/CFS) is a chronic complex illness with multisystem manifestations and long-term impact on functional impairment comparable to multiple sclerosis, rheumatoid arthritis, and congestive heart failure. The hallmark of ME/CFS is persistent and unexplained fatigue resulting in significant impairment in daily functioning along with worsening symptoms following physical or mental exertion that would have been tolerated before illness (post-exertional malaise). Besides intense fatigue, many patients report concomitant symptoms such as pain, cognitive dysfunction, and unrefreshing sleep. Additional symptoms can include headache, sore throat, tender lymph nodes, muscle aches, joint aches, feverishness, difficulty sleeping, psychiatric problems, allergies, and abdominal cramps.

The condition has been known by many names and debate about the name and case definition continues. The composite name ME/CFS was adopted by the U.S. Department of Health and Human Services in recognition of the limitations of either ME (absence of definitive inflammation in brain and spinal cord) or CFS (trivializes an often devastating illness through confusion with fatigue that everyone experiences). An alternative name, systemic exertion intolerance disease (SEID), proposed by the 2015 Institute of Medicine (IOM, now the National Academy of Medicine) committee reviewing ME/CFS, has not gained acceptance.

EPIDEMIOLOGY

Determining how frequently ME/CFS occurs and characteristics of those affected has been complicated by variability in study design and application of case definitions. In the absence of a simple diagnostic test, evaluation by an experienced clinician is required for case identification. Clinic-based studies most accurately identify patients with ME/CFS but overrepresent higher socioeconomic groups with access to ME/CFS clinics. Population-based surveys that included a clinical evaluation estimated a prevalence of 0.2–0.7%, suggesting ≥1 million Americans have ME/CFS. However, these surveys found that ≥80% of those meeting criteria for ME/CFS had not been diagnosed by a health care provider. ME/CFS is three to four times more common in women than men. The highest prevalence of illness is among those 40–50 years of age, but the age range is broad and includes children and adolescents. Persons of all race and ethnicities are affected, and there is some evidence that socioeconomically disadvantaged groups are at increased risk.

RISK FACTORS AND PATHOPHYSIOLOGY

A wide variety of infectious agents have been reported to be associated with a postinfectious fatiguing illness resembling ME/CFS. These include both viral and nonviral pathogens, such as Epstein-Barr virus, Ross River virus, *Coxiella burnetti* (Q fever), Ebola virus, SARS-CoV-1, and *Giardia*. While recovery from these infections is the rule, approximately 10% of those infected remain ill for ≥6 months. Most recently, published reports suggest that SARS-CoV-2 infection is also associated

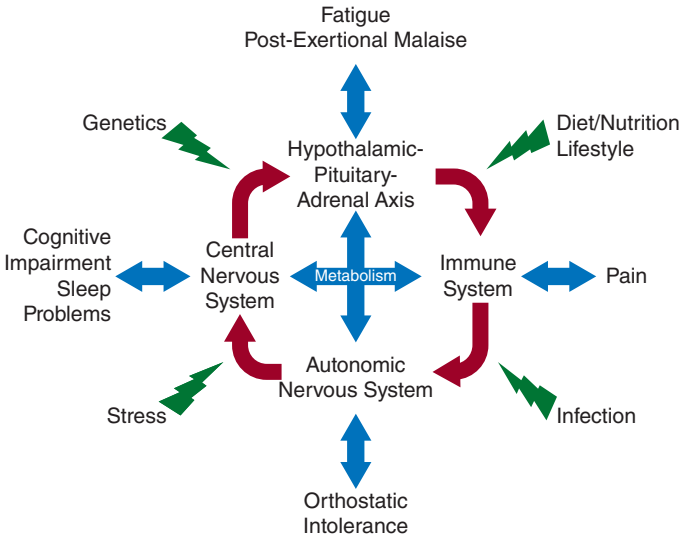

FIGURE 450-1 A multisystem model for ME/CFS. An example of a unifying model for ME/CFS demonstrating the interactions of multiple organ systems, environmental, genetic, and behavioral factors contributing to symptoms.

with prolonged fatiguing illness. Host and pathogen factors associated with recovery versus persistent disease remain elusive. In addition to infectious insults, a variety of stressors, including physical trauma, adverse events, and allostatic load (or "wear and tear" on the body) have been found to be associated with ME/CFS. Twin studies and family histories suggest a role for shared environment as well as genetic factors.

Evidence for immunologic dysfunction is inconsistent. Modest elevations in titers of antinuclear antibodies, reductions in immunoglobulin subclasses, deficiencies in mitogen-driven lymphocyte proliferation, reductions in natural killer cell activity, disturbances in cytokine production, and altered T-cell metabolism have been described. None of these immune findings has been firmly established and none of these changes appear in most patients. In theory, symptoms of ME/CFS could result from excessive production of a cytokine, such as interleukin 1 or interferon alpha, which induces fatigue and other flulike symptoms; however, compelling data in support of this hypothesis are lacking.

Other studies have reported various nonspecific changes in regional brain structures estimated by MRI; dysfunction of the autonomic nervous system; abnormalities in the hypothalamic-pituitary-adrenal (HPA) axis; altered metabolism; and dysbiosis of the intestinal microbiome. Confirmatory studies are needed and none of the findings are consistent enough to be used for diagnosis. It is clear that ME/CFS represents a complex disorder with alterations in multiple interrelated homeostatic systems. A variety of unifying models for the illness have been proposed and discoveries about the pathophysiology of ME/CFS hold promise for elucidating novel mechanisms and interactions important in other illnesses (Fig. 450-1).

APPROACH TO THE PATIENT

DIAGNOSIS

A diagnosis of ME/CFS is made based on patient-reported symptoms that fit a characteristic profile. After a careful review of the literature and symptom-based case definitions for ME, CFS, or ME/CFS, the IOM committee recommended in 2015 a straightforward clinical case definition (Table 450-1). This includes the symptoms consistently noted in prior consensus case definitions: fatigue limiting the patient's ability to participate in his/her usual pre-illness activities, sleep problems, and post-exertional malaise (PEM). PEM is a relapse in symptoms triggered by physical, emotional, or cognitive exertion that would not have been problematic for the patient before onset of ME/CFS. The relapse lasts more than a day, and sometimes weeks. In addition, either difficulty thinking and concentrating (often referred to by patients as "brain fog") or orthostatic intolerance should be present.

TABLE 450-1 2015 Institute of Medicine Clinical Case Definition for ME/CFS

Substantial reduction or impairment in the ability to engage in pre-illness levels of activity (occupational, educational, social, or personal life) that:

a. lasts for more than 6 months

b. is accompanied by fatigue that is often profound, of new or definite onset (not lifelong), not the result of ongoing excessive exertion, and is not substantially alleviated by rest

*__Post-exertional malaise (PEM)__—worsening of symptoms after physical, mental, or emotional exertion that would not have caused a problem before the illness

*__Unrefreshing sleep__

*__Cognitive impairment__ or __orthostatic intolerance__

*Frequency and severity of symptoms should be assessed; should be present at least half of the time and with at least moderate intensity

Patients with ME/CFS may experience a wide range of other symptoms not specified in the IOM clinical case definition (Table 450-2). As a result, patients meeting the case definition could have very different clinical features based on the type, frequency, and severity of their symptoms. Patients may describe a precipitating cause for their illness, such as a known or presumed infection, but frequently no initiating factor is recognized. The symptoms may occur suddenly within a day or week or may occur gradually.

While the case definition indicates illness must be present at least 6 months, the possibility of ME/CFS should be considered for patients with consistent symptoms persisting >1 month, and evaluation and supportive care can begin as early as 4–6 weeks after onset. Listening to patients' descriptions of what they are experiencing is important. Asking questions can help patients accurately describe their experience with fatigue and PEM. These include asking about current activity levels compared with before they became ill, what happens when they are as active as they were pre-illness, and how long it takes to recover after exertion. Whereas patients recognize relapses, the relation of relapse to activity level may not be apparent, and as a result PEM may not be recognized. Patients may also appear well during an office visit, only to relapse afterwards from exertion surrounding the consultation.

Although the IOM definition does not list medical or psychological conditions that exclude the diagnosis of ME/CFS, a careful clinical evaluation is required to identify and treat other illness that could explain or contribute to the patient's symptoms. The initial evaluation also requires reviewing family history; medical history (including infections, traumas/surgeries, occupational exposure to environmental toxins); a review of medications and supplements; physical examination, including lean test for postural orthostatic tachycardia syndrome (POTS; Chap. 440); mental health assessment (screen for depression and anxiety); and routine screening laboratory tests (if recent results are not on record). As routine

TABLE 450-2 Additional Symptoms Experienced by Patients with ME/CFS

Joint pain without swelling or redness
Muscle aches
New headaches
Tender lymph nodes
Sensitivity to sensory stimuli (e.g., light, noise, smells)
Sore throat
Alcohol intolerance
Difficulties with temperature regulation (feeling feverish or chilled)

TABLE 450-3 ME/CFS Comorbid Conditions

Chronic overlapping pain conditions: fibromyalgia (FM), chronic migraine, temporomandibular joint disease (TMJ), irritable bowel syndrome (IBS), endometriosis, vulvodynia, urologic chronic pelvic pain syndromes (UCPPS)
Postural orthostatic tachycardia syndrome (POTS)
Allergies
Sjögren's syndrome
Ehlers-Danlos syndrome
Mast-cell activation syndrome (MCAS)
Dysautonomia
Multiple chemical sensitivities

laboratory tests are usually within normal limits, their role is in identifying other illnesses and the specific panel of tests should be adjusted based on the patient's presentation. Typically the tests include complete blood count, erythrocyte sedimentation rate, electrolytes, fasting glucose, renal function tests (blood urea nitrogen, glomerular filtration rate), calcium, phosphate, liver function (bilirubin, alanine aminotransferase, alkaline phosphatase, aspartate aminotransferase, gamma-glutamyl transferase, total protein, albumin/globulin ratio), C-reactive protein, thyroid function (thyroid-stimulating hormone, free thyroxine), iron studies to assess both iron overload and iron deficiency (serum iron, transferrin saturation, ferritin), celiac disease screening tests, and urinalysis.

DIFFERENTIAL DIAGNOSIS AND COMORBID CONDITIONS

While the differential diagnosis for fatigue is quite broad, further workups and referrals should be chosen carefully based on the patient's history, symptoms (particularly those that are new, worsening, or unusual), and results of initial laboratory tests. Conditions reported to occur in association with ME/CFS **(Table 450-3)** should be kept in mind during the evaluation and follow-up, as management and treatment modalities for these comorbidities could contribute to an improved quality of life.

MANAGEMENT

While there are no approved drugs to treat or cure ME/CFS, patients benefit from receiving a diagnosis and an individualized plan that addresses the symptoms that are most problematic for the patient. Some symptoms, in particular, disturbed sleep **(Chap. 31)** and pain **(Chap. 13)**, may improve with nonpharmacologic therapies (such as sleep hygiene, massage, acupuncture, hot or cold packs) or medications. Any medications should be started at lower doses than usual and only slowly increased. Patients with ME/CFS have been reported to be more sensitive to medications than the general population, and benefits with fewer toxicities may be achieved at lower doses. Narcotics should be avoided, and referral to sleep centers or other specialists may be required.

Controlled therapeutic trials have not established significant benefit for patients with ME/CFS from acyclovir, fludrocortisone, galantamine, modafinil, and IV immunoglobulin, among other agents. These studies have been limited by small numbers and lack power to investigate benefit in patient subgroups. Preliminary small studies reported the possible effectiveness of the B-cell targeting anti-CD20 monoclonal antibody rituximab in ME/CFS, but a subsequent large, well-designed prospective double-blind study found no benefit. Numerous anecdotes circulate regarding other traditional and nontraditional therapies. It is important to guide patients away from therapeutic modalities that are toxic, expensive, or unreasonable.

Educating the patient and family about PEM can be helpful in avoiding the harmful cycle of overexertion during "good days" followed by relapse that can negate any functional gains. This is often referred to as "push and crash." Recognizing limits and using activity management (pacing) can help limit PEM. It is important to maintain tolerated activity levels to minimize deconditioning. Activity may be advanced very gradually as tolerated.

Counseling may help patients and their families cope with the long-term consequences of living with a chronic illness. Consultation with a physical or occupational therapist may identify energy-saving strategies for activities of daily living as well as needed accommodations, such as a wheelchair for activities that require walking longer distances or prolonged standing.

COURSE AND PROGNOSIS

The illness severity varies from mild or moderate, with patients retaining varying degrees of pre-illness function, to severe, with patients essentially homebound. Most patients experience some improvement and stabilize, although return to their prior level of function is unusual. A continued decline in function should prompt evaluation for other illnesses. Patients should be re-evaluated at scheduled intervals to adjust treatments and detect any intercurrent disease. New or changing symptoms should be worked up to identify any new illnesses. Given the social isolation and loss of hope associated with a debilitating chronic illness, serious depression and an increased risk of suicide is reported for patients with ME/CFS. Clinicians should be prepared to screen for this and refer patients as needed.

Section 5 Psychiatric and Addiction Disorders

451 Biology of Psychiatric Disorders

Robert O. Messing, Eric J. Nestler, Matthew W. State

Psychiatric disorders are central nervous system diseases characterized by disturbances in emotion, cognition, motivation, and socialization. They are highly heritable, with genetic risk comprising 20–90% of disease vulnerability. As a result of their prevalence, early onset, and persistence, they contribute substantially to the burden of illness worldwide. All psychiatric disorders are broad heterogeneous syndromes that currently lack well-defined neuropathology and bona fide biologic markers. Therefore, diagnoses continue to be made solely from clinical observations using criteria in the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition (DSM-5)*, of the American Psychiatric Association **(see Chap. 452)**.

There is increasing agreement that the classification of psychiatric illnesses in DSM does not accurately reflect the underlying biology of these disorders. Uncertainties in diagnosis complicate efforts to study the genetic basis and attendant neurobiological mechanisms underlying mental illness, though recent advances in genomic and neuroscience technologies along with the consolidation of very large patient cohorts have, for multiple disorders, led to major progress in these realms. In addition, there have been efforts to address the limitations of a categorical nosology directly through the development of an alternative diagnostic scheme, termed Research Domain Criteria (RDoC). This system classifies mental illness on the basis of core behavioral abnormalities shared across several syndromes—such as psychosis (loss of reality) or anhedonia (decreased ability to experience pleasure)—and the associated brain circuitry that controls these behavioral domains. It is anticipated that such classifications will assist in defining the biologic basis of key symptoms. Other factors that have impeded progress in understanding mental illness include the lack of access to pathologic brain tissue except upon death and the inherent limitations of animal models for disorders defined largely by behavioral abnormalities (e.g., hallucinations, delusions, guilt, suicidality) that are inaccessible in animals.

Despite these limitations, the past decade has been marked by real progress. Neuroimaging methods are beginning to provide evidence of brain pathology; genome-wide association studies and high-throughput sequencing are reliably identifying genes and genomic loci that confer risk for severe forms of mental illness; and investigations of better validated animal models, leveraging a host of new methods to study molecular, cellular, and circuit-level processes, are offering new insight into disease pathogenesis. There is also excitement in the utility of neurons, glia, and brain organoids induced in vitro from patient-derived pluripotent stem cells, providing novel ways to study disease pathophysiology and screen for new treatments. There is consequently justified optimism that the field of psychiatry will better integrate behaviorally defined syndromes with an understanding of biological substrates in a way that will drive the development of improved treatments and eventually cures and preventive measures. This chapter describes several examples of recent discoveries in basic neuroscience and genetics that have informed our current understanding of disease mechanisms in psychiatry.

NEUROGENETICS

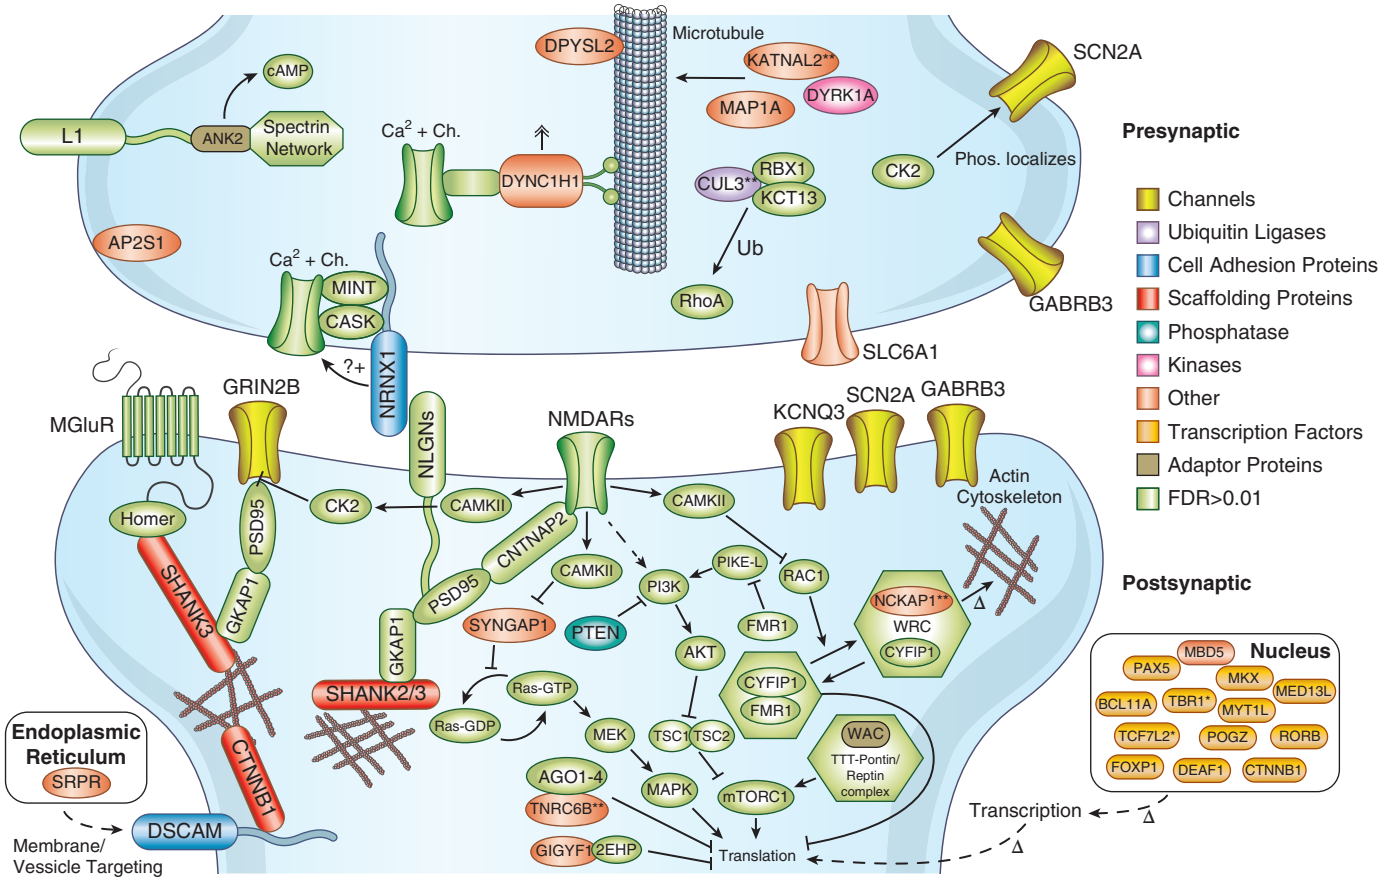
Because the human brain can only be examined indirectly during life, genome analyses have been extremely important for obtaining molecular clues about the pathogenesis of psychiatric disorders. Moreover, the identification of germline risk alleles and mutations provides potential traction on the question of cause versus effect. In other types of cross-sectional studies, it may be impossible to determine whether a phenotype or biomarker observed in affected humans or model systems reflects an etiologic factor or a compensatory response. In contrast, germline genetic risk is present before the brain develops—at least theoretically allowing for experiments to address temporal sequencing.

A wealth of new information has been made possible by recent technologic developments that have permitted affordable, large-scale genome-wide association studies and high-throughput sequencing. As an example of the latter, there has been significant progress in the genetics of autism spectrum disorders (ASDs), which are a heterogeneous group of neurodevelopmental diseases that share clinical features of impaired social communication and restricted, repetitive patterns of behavior. ASDs are highly heritable; concordance rates in monozygotic twins (~60–90%) are five- to tenfold higher than in dizygotic twins and siblings, and first-degree relatives show approximately tenfold increased risk compared with the general population. ASDs are also genetically heterogeneous. More than 100 individual risk genes, along with dozens of submicroscopic deletions and duplications often containing multiple genes, have been identified, almost exclusively through the study of rare, large-effect, new (de novo) mutations **(Fig. 451-1)**. All told, genes and genomic regions vulnerable to these types of mutations account for ~20–30% of formerly idiopathic cases that present in the clinic, although none individually accounts for >1%. In addition, ~10% of individuals with ASD have well-described intellectual disability syndromes including *fragile X syndrome, Rett syndrome,* and *tuberous sclerosis* **(Chap. 90)**. However, it appears that most of the risk for ASD in the population involves true polygenic inheritance. There is considerable evidence, for example, that >50% of the genetic liability is carried in common alleles of very small individual effect. To date, studies of tens of thousands of cases have identified five reproducible associations of loci meeting gold standard genome-wide association statistical thresholds. With continually increasing cohort sizes, and thus power, this number is certain to grow in the future.

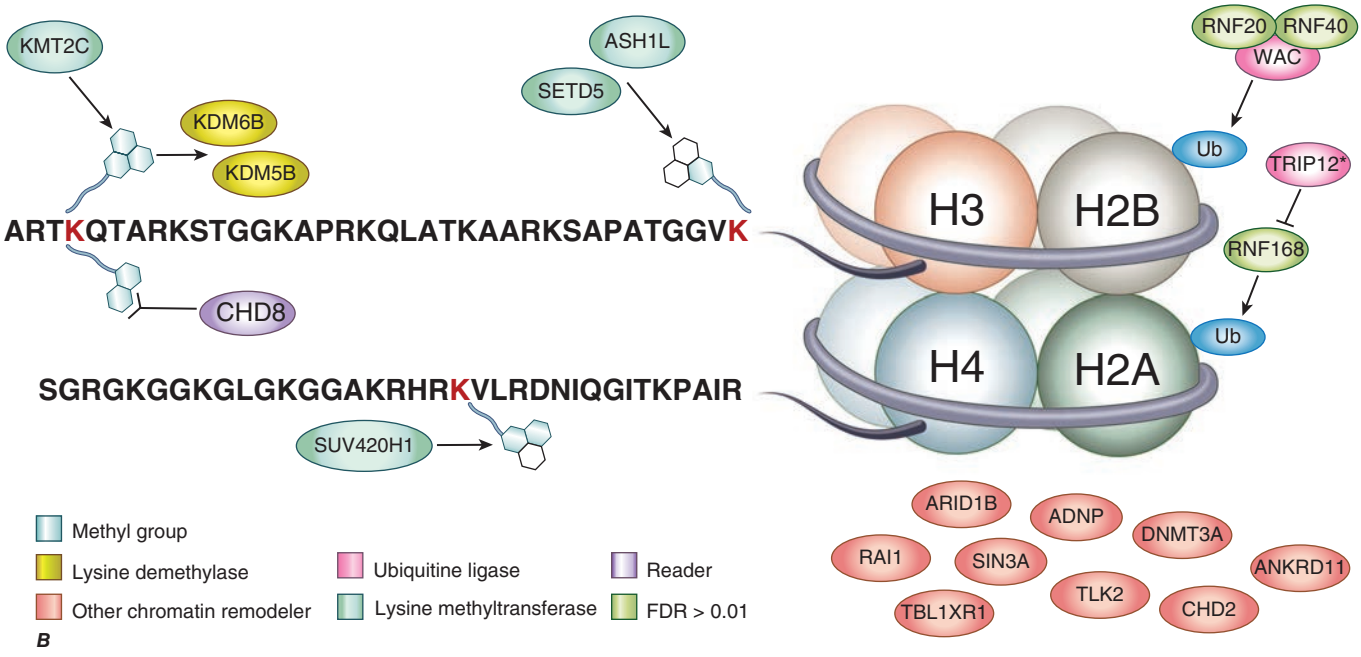
Amid the genetic heterogeneity that has so far been identified, common themes have emerged that inform pathogenesis of ASDs. For instance, many identified rare mutations are in genes that encode proteins involved in synaptic function and early transcriptional and chromatin regulation (Fig. 451-1) and have a clear relationship to activity-dependent neural responses that can affect the development of neural systems underlying cognition and social behaviors. One particularly intriguing hypothesis is that these genes may lead to ASD risk by changing the balance of excitatory versus inhibitory synaptic signaling in local and extended circuits and by altering mechanisms that control brain growth. Some mutations affect genes (e.g., *PTEN, TSC1*, and *TSC2*) that negatively regulate signaling from several types of extracellular stimuli, including those transduced by receptor tyrosine kinases. Their dysregulation can alter neuronal growth, resulting in altered brain size, as well as synaptic development and function. Finally, several recent studies have focused on the question of when and where multiple functionally diverse risk genes converge with respect to human brain development. Interestingly, these studies have thus far tended to overlap with expression patterns of glutamatergic neurons in mid-fetal cortex (Fig. 451-1). Given the pleiotropic biological effects of the ASD genes identified to date, an understanding of the developmental or "spatiotemporal" dimensions of risk is likely to serve as a useful complement to studies of the function of individual genes. In short, it may turn out that when and where genetic variation has its impact in the developing brain may be as important as the key processes that are identified.

With further understanding of pathogenesis and the definition of specific ASD subtypes, there is reason to believe that effective therapies will be identified. Work in mouse models has already demonstrated that some autism-like behaviors can be reversed, even in fully developed adult animals, by modifying the underlying genetic or functional pathology. These results suggest that key phenotypes arising from some ASD-related large-effect mutations may well reflect ongoing functional derangements, offering hope that interventions can be successful well after the initial developmental insult and the emergence of symptoms. Treatments that target excitation-inhibition imbalance or altered mRNA translation are one area of early promise. For example, the genes *TSC1, TSC2*, and *PTEN* are negative regulators of signaling through the target of rapamycin complex 1 (TORC1), which regulates protein synthesis. Rapamycin, a selective inhibitor of TORC1, can reverse several behavioral and synaptic defects in mice carrying null mutations in these genes.

Increasingly, attention has turned to the strategy of targeting the genetic "lesion" early in development to treat or prevent ASD and related phenotypes in those cases in which a single, highly penetrant coding mutation is present. However, even with the relatively large number of risk genes (>100) that have been identified carrying de novo putative loss-of-function coding mutations, there is a much smaller number of potential targets that carry sufficiently high and predictable risks for severe outcomes to consider directly targeting nucleic acids, for example, with CRISPR-based therapies or the use of antisense oligonucleotides (ASOs). Clearly, however, recent successes with very early intervention in spinal muscular atrophy, using both strategies, are driving increased interest in their utility in a range of brain-based disorders. Currently, with regard to neurodevelopmental conditions, these approaches are being most actively pursued for well-known intellectual disability syndromes that may also carry elevated risk for ASD, such as Angelman syndrome, Rett and *MECP2* duplication syndrome, and fragile X syndrome. Such efforts could be transformational



A



B

FIGURE 451-1 Functional characteristics and developmental convergence of autism spectrum disorder (ASD) associated genes: genes associated with ASD based on recurrent de novo and transmitted coding mutations are shown in ***A*** and ***B***. Those genes encoding proteins with a false discovery rate (FDR) <0.01 in Sanders et al, *Neuron* 2015, and Satterstrom et al, *Cell* 2020, are highlighted with respect to their putative functions. Genes meeting the highest confidence criteria in Sanders et al 2015 and showing either an FDR >0.01 or an FDR >0.3 in Satterstrom are noted (* and **, respectively). Additional interacting and functionally related molecules that do not meet the above criteria are shown in *green*. *FMR1*, *TSC1*, and *TSC2* are syndromic ASD genes included in the figure (***A***). Multiple gene ontology analyses of ASD genes have highlighted both pre- and postsynaptic molecules (***A***) and chromatin modifiers (***B***) as points of enrichment. In ***C***, an alternative strategy for grouping ASD risk genes is highlighted (Willsey et al, *Cell* 2013), based on their spatiotemporal expression patterns as opposed to putative functions. One analytic strategy, illustrated in ***C***, leveraged only high-confidence ASD genes and examined their developmental expression patterns using the BrainSpan data set. Convergence for ASD risk was identified in deep layer (V and VI) excitatory neurons in mid-fetal human cortex. Multiple analyses have similarly found glutamatergic neurons in mid-fetal prefrontal cortex as one point of convergence, with somewhat less agreement on layer specificity and potential additional spatiotemporal points of convergence.

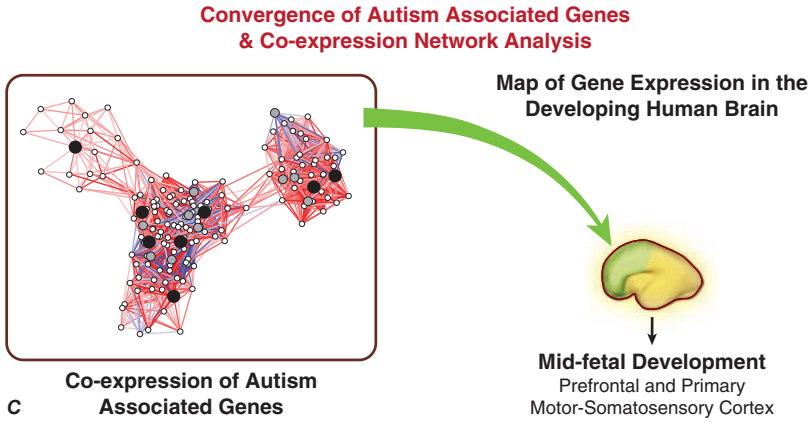


FIGURE 451-1 (*Continued*)

for very small numbers of individuals and may well yield important insights into biology that have impact beyond those carrying rare very highly penetrant mutations. They will undoubtedly raise significant practical as well as ethical challenges as treatments for more common forms of ASD.

The ability to catalog common genetic variants and assay them on array-based platforms and, more recently, to carry out whole exome sequencing has allowed investigators to leverage very large patient cohorts to detect risk loci for schizophrenia and bipolar disorder with genome-wide significance. In contrast to ASD, where the lion's share of early success in gene identification has resulted from the study of rare, large-effect, de novo mutations, much of gene discovery to date for these syndromes has resulted from genome-wide association studies of common inherited polymorphisms. It is noteworthy that there is also striking overlap among the submicroscopic deletions and duplications, called copy number variants (CNVs), that have been found to carry large risks for ASD, schizophrenia, and bipolar disorder, as well as epilepsy and intellectual disability.

To date, >200 distinct genomic regions, marked by associated single nucleotide polymorphisms, have been identified in schizophrenia, some of which show risk as well for bipolar disorder. Several of the identified genes are parts of molecular complexes, such as voltage-gated calcium channels (in particular, *CACNA1C* and *CACNB2*) and the postsynaptic density of excitatory synapses. Genes that promote risk for addiction and depression have also begun to emerge from large studies. The best-established susceptibility locus for addiction is the *CHRNA5-A3-B4* nicotinic acetylcholine receptor gene cluster on chromosome 15 associated with nicotine and alcohol addiction. Recent genome-wide association studies of depression have required hundreds of thousands of cases and controls to identify the first statistically significant loci using state-of-the-art approaches. These findings collectively point to the tremendous heterogeneity of depressive disorders as well as the very small biologic effects conferred by any individual common allele.

A recurrent theme that has emerged from genetic studies of psychiatric disorders is phenotypic pleiotropy, namely, that many genes are associated with multiple psychiatric syndromes. For example, mutations in *MECP2, FMR1*, and *TSC1* and *TSC2* can cause intellectual disability without ASD, others in *MECP2* can cause obsessive-compulsive and attention-deficit/hyperactivity disorders, some alleles of *NRXN1* are associated with symptoms of both ASD and schizophrenia, and common polymorphisms in *CACNA1C* are strongly associated with both schizophrenia and bipolar disorder. Likewise, duplication of chromosome 16p is associated with both schizophrenia and autism, whereas deletions in the DiGeorge's (velocardiofacial) syndrome region are associated with schizophrenia, autism, and bipolar disorder. The association of genes and genomic regions with multiple syndromes attests to the complexity of psychiatric disorders, the very large gap between molecular mechanisms and the current categorical diagnostic schemes, and the influence of additional factors that combine to specify the ultimate phenotype. The latter might include polygenic "background," variations in regulatory regions of the genome that determine cell-type specificity and timing of gene expression, protective variants, stochastic events, and epigenetic effects. This pleiotropy of consequences for a given genetic mutation in psychiatry is akin to the pleiotropy seen for many cancer-causing mutations, where the same mutation can lead to many different types of cancers across the population.

SIGNAL TRANSDUCTION

Studies of signal transduction have revealed numerous intracellular signaling pathways that are perturbed in psychiatric disorders, and such research has provided insight into development of new therapeutic agents. For example, lithium is a highly effective drug for bipolar disorder and competes with magnesium to inhibit numerous magnesium-dependent enzymes, including the enzyme GSK3β and several enzymes involved in phosphoinositide signaling that lead to activation of protein kinase C. These findings have led to discovery programs focused on developing GSK3β or protein kinase C inhibitors as potential novel treatments for mood disorders, although none have demonstrated clinical efficacy to date.

The observations that tricyclic antidepressants (e.g., imipramine) inhibit serotonin and/or norepinephrine reuptake and that monoamine oxidase inhibitors (e.g., tranylcypromine) are effective antidepressants initially led to the view that depression is caused by a deficiency of these monoamines. However, this hypothesis has not been substantiated. A cardinal feature of these drugs is that long-term (weeks to months) administration is needed for their antidepressant effects. This means that their short-term actions, namely promotion of serotonin or norepinephrine function, are not per se antidepressant but rather induce a cascade of adaptations in the brain that underlie their slowly developing clinical effects. The nature of these therapeutic drug-induced adaptations has not been identified with certainty. One hypothesis holds that, in a subset of depressed patients who display upregulation of the hypothalamic-pituitary-adrenal (HPA) axis characterized by increased secretion of corticotropin-releasing factor (CRF) and glucocorticoids, excessive glucocorticoids cause atrophy of hippocampal neurons, which is associated with reduced hippocampal volumes seen clinically. Chronic antidepressant administration might reverse this atrophy by increasing brain-derived neurotrophic factor (BDNF) or a host of other neurotrophic factors in the hippocampus. A role for stress-induced decreases in the generation of newly born hippocampal granule cell neurons, and its reversal by antidepressants through BDNF or other growth factors, has also been suggested.

A major advance in recent years has been the identification of several rapidly acting antidepressants with non–monoamine-based mechanisms of action. The best established is ketamine, a non-competitive antagonist of *N*-methyl-D-aspartate (NMDA) glutamate receptors among other actions, which exerts rapid (hours) and robust antidepressant effects in severely depressed patients who have not responded to other treatments. Ketamine, which at higher doses is psychotomimetic and anesthetic, exerts these antidepressant effects

at lower doses with minimal side effects. However, the response to ketamine is transient, which has led to several approaches to maintain treatment response, such as repeated ketamine delivery. The mechanism underlying ketamine's antidepressant action is not known, and its action as an NMDA receptor antagonist has recently been called into question. Nevertheless, ketamine's striking clinical efficacy has stimulated animal research on the role of glutamate neurotransmission and synaptic plasticity in key limbic regions. Recent evidence supports a role for TORC1 or BDNF activation, as blockade of either blocks the antidepressant-like effects of ketamine in animal models. Mechanisms by which ketamine activates these signaling cascades are currently an active area of investigation.

A major goal in the field of substance use disorders has been to identify neuroadaptive mechanisms that lead from recreational use to addiction. Such research has determined that repeated intake of abused drugs induces specific changes in cellular signal transduction, leading to changes in synaptic strength (long-term potentiation or depression) and neuronal structure (altered dendritic branching or cell soma size) within the brain's reward circuitry. These drug-induced modifications are mediated in part by changes in gene expression, achieved by regulation of transcription factors (e.g., CREB [cAMP response element-binding protein] and ΔFosB [a Fos family protein]) and their target genes. Such alterations in gene expression are associated with lasting alterations in epigenetic modifications, including histone acetylation and methylation and DNA methylation. These adaptations provide opportunities for developing treatments targeted to drug-addicted individuals. The fact that the spectrum of these adaptations differs in part depending on the particular addictive substance used raises hope that treatments could be developed that are specific for different classes of addictive drugs and less likely to disturb basic mechanisms that govern normal motivation and reward.

Increasingly, causal relationships are being established between individual molecular and cellular adaptations and specific behavioral abnormalities that characterize the addicted state. For example, acute activation of μ-opioid receptors by morphine or other opiates activates $G_{i/o}$ proteins, leading to inhibition of adenylyl cyclase (AC), resulting in reduced cyclic AMP (cAMP) production, protein kinase A (PKA) activation, and activation of the transcription factor CREB. Repeated administration of these drugs **(Fig. 451-2)** evokes a homeostatic response involving upregulation of ACs and PKA and increased activation of CREB. Such upregulation of cAMP-CREB signaling has been identified in the locus coeruleus (LC), periaqueductal gray, ventral tegmental area (VTA), nucleus accumbens (NAc), and several other central nervous system (CNS) regions and contributes to opiate craving and signs of opiate withdrawal. The fact that endogenous opioid peptides do not produce tolerance and dependence, while morphine and heroin do, may relate to the observation that, unlike endogenous opioids, morphine and heroin are weak inducers of μ-opioid receptor desensitization and endocytosis. Therefore, these drugs cause prolonged receptor activation and inhibition of ACs, which provides a powerful stimulus for the upregulation of cAMP-CREB signaling that characterizes the opiate-dependent state.

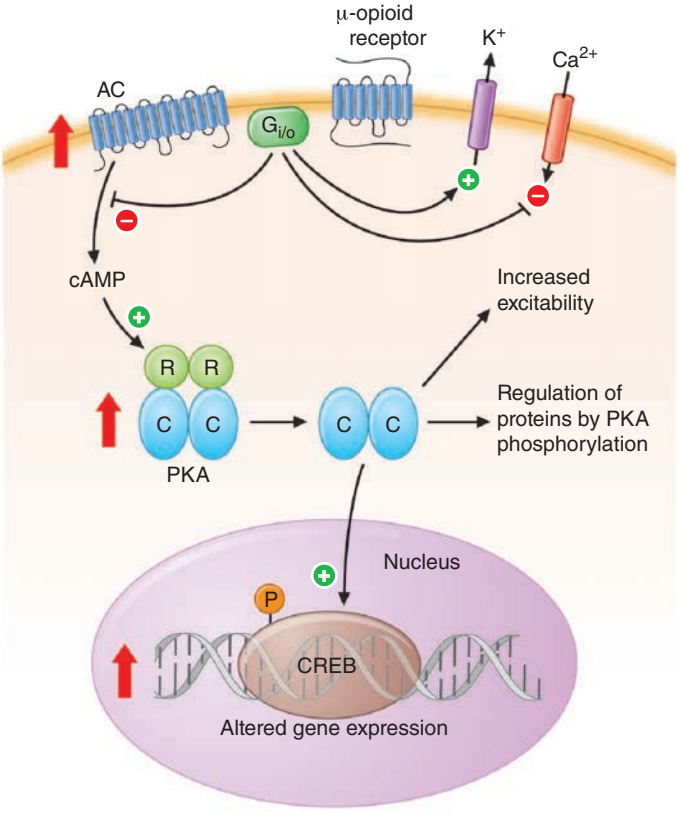

FIGURE 451-2 Opiate action in the locus coeruleus (LC). Binding of opiate agonists to μ-opioid receptors on LC neurons catalyzes nucleotide exchange on G_i and G_o proteins, leading to inhibition of adenylyl cyclase (AC), neuronal hyperpolarization via activation of K^+ channels and perhaps inhibition of Ca^{2+} channels. Inhibition of AC reduces protein kinase A (PKA) activity and phosphorylation of several PKA substrate proteins, thereby altering their function. For example, opiates reduce phosphorylation of the cAMP response element-binding protein (CREB), which initiates longer term changes in neuronal function. Chronic administration of opiates increases levels of AC isoforms, PKA catalytic (C) and regulatory (R) subunits, and the phosphorylation of several proteins, including CREB (indicated by *red arrows*). These changes contribute to the altered phenotype of the drug-addicted state. For example, the excitability of LC neurons is increased by enhanced cAMP signaling. Activation of CREB causes upregulation of AC isoforms and tyrosine hydroxylase, the rate-limiting enzyme in catecholamine biosynthesis.

SYSTEMS NEUROSCIENCE

The study of interconnected brain circuits that drive behavior has been greatly advanced through newer methods in brain imaging that have documented abnormalities in neural function and connectivity in psychiatric disorders. Electroceutical devices, which use electrical or magnetic stimulation to control neuronal activity, have had some success in depression, obsessive-compulsive disorder, pain, and addiction. The past decade has also witnessed the development of revolutionary new techniques—optogenetics, designer receptors, and ligands—that provide unprecedented temporal and spatial control of neural circuits. The development of genetically encoded calcium detectors and electrode arrays has allowed in vivo monitoring of thousands of neurons in multiple brain regions simultaneously. Advances in histology and microscopy now permit three-dimensional imaging of specific proteins in the intact brain, while advances in endoscopic microscopy allow imaging of hundreds of neurons within deep brain structures in awake, freely moving animals. These new methods are revolutionizing our ability to understand the circuit basis of brain function.

Positron emission tomography (PET), diffusion tensor imaging (DTI), and functional magnetic resonance imaging (fMRI) have identified neural circuits that contribute to psychiatric disorders, for example, defining the neural circuitry of mood within the brain's limbic system **(Fig. 451-3)**. Integral to this system are the NAc (important also for brain reward—see below), amygdala, hippocampus, and regions of prefrontal cortex. Recent optogenetic research in animals, where the activity of specific types of neurons in defined circuits can be controlled with light, has confirmed the importance of this limbic circuitry in controlling depression-related behavioral abnormalities. Given that many symptoms of depression (so-called neurovegetative symptoms) involve physiologic functions, a key role for the hypothalamus is presumed as well. A subset of depressed individuals shows a small reduction in hippocampal size, as noted above. In addition, brain imaging investigations have revealed increased activation of the amygdala by negative stimuli and reduced activation of the NAc by rewarding stimuli. There is also evidence for altered activity in prefrontal cortex, such as hyperactivity of subgenual area 25 in anterior cingulate cortex. Such findings have led to trials of deep brain stimulation (DBS) of either the NAc or subgenual area 25 **(see Fig. 30-1)**, which appears to be therapeutic in some severely depressed individuals.

In schizophrenia, structural and functional imaging studies have confirmed earlier pathologic studies that show enlargement of the ventricular system and reduction of cortical and subcortical gray matter

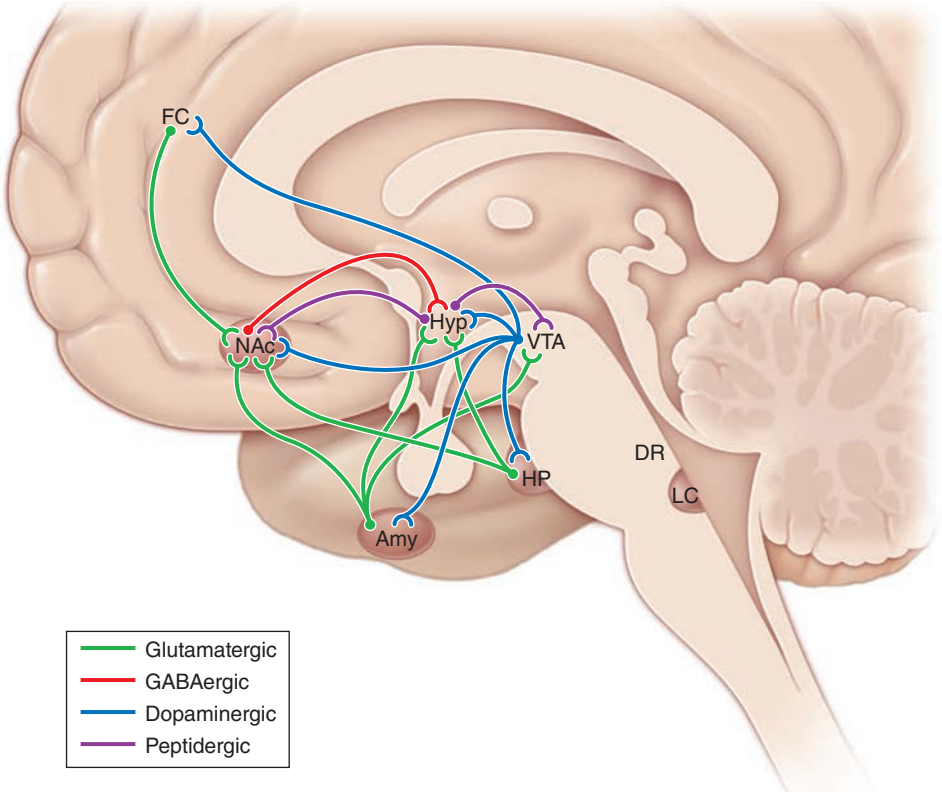

FIGURE 451-3 Neural circuitry of depression and addiction. The figure shows a simplified summary of a series of limbic circuits in brain that regulate mood and motivation and are implicated in depression and addiction. Shown in the figure are the hippocampus (HP) and amygdala (Amy) in the temporal lobe, regions of prefrontal cortex, nucleus accumbens (NAc), and hypothalamus (Hyp). Only a subset of the known interconnections among these brain regions is shown. Also shown is the innervation of several of these brain regions by monoaminergic neurons. The ventral tegmental area (VTA) provides dopaminergic input to each of the limbic structures. Norepinephrine (from the locus coeruleus [LC]) and serotonin (from the dorsal raphe [DR] and other raphe nuclei) innervate all of the regions shown. In addition, there are strong connections between the hypothalamus and the VTA-NAc pathway. Important peptidergic projections from the hypothalamus include those from the arcuate nucleus that release β-endorphin and melanocortin and from the lateral hypothalamus that release orexin.

in frontal and temporal lobes and in the limbic system. Functional imaging studies show reduced metabolic (presumably neural) activity in the dorsolateral prefrontal cortex at rest and when performing tests of executive function, including working memory. There is also evidence for impaired structural and task-related functional connectivity, mainly in frontal and temporal lobes. The reduction in cortical thickness seen in schizophrenia is associated with increased cell packing density and reduced neuropil (defined as axons, dendrites, and glial cell processes) without an apparent change in neuronal cell number. Specific classes of interneurons in prefrontal cortex consistently show reduced expression of the gene encoding the enzyme glutamic acid decarboxylase 1 (*GAD1*), which synthesizes γ-aminobutyric acid (GABA), the principal inhibitory neurotransmitter in the brain. Recently, results from well-powered genome-wide association studies point to synaptic pruning, including the involvement of microglia, as a potential contributing mechanism. In the region of the genome most strongly associated with schizophrenia risk, variations in the relative expression of two isotypes of complement component 4, C4A and C4B, have been found to account for a significant proportion of this genetic signal. Studies of loss of C4 in mice show deficient synaptic pruning, leading to the hypothesis that increased expression of C4A in humans may result in excessive synaptic pruning. Such results point to the potential for a gene-driven understanding of pathophysiology; however, the findings also leave some important questions unanswered. The strongest effect haplotype in humans still only accounts for a very small increase in risk, with an odds ratio of <1.3. In contrast, having a sibling with schizophrenia increases risk approximately tenfold. In short, whether this allele reflects a driving pathophysiologic mechanism remains to be determined. Moreover, humans have diverged at the C4 locus compared with rodents such that only a single C4 isotype is present in the mouse, preventing any analysis of the putative effects of changing the ratio of C4A to C4B—the phenomenon associated with disease risk in humans. Nonetheless, all the aforementioned findings support the notion that schizophrenia is a developmental neurodegenerative disorder with some evidence pointing to loss of cortical interneurons in frontal and temporal lobes.

Work in rodent and nonhuman primate models of addiction has established the brain's reward regions as key neural substrates for the acute actions of drugs of abuse and for addiction induced in vulnerable individuals by repeated drug administration (Fig. 451-3). Midbrain dopamine neurons in the VTA function normally as rheostats of reward: they are activated by natural rewards (food, sex, social interaction) or even by the expectation of such rewards, and many are suppressed by the absence of an expected reward or by aversive stimuli. These neurons thereby transmit crucial survival signals to the rest of the limbic brain to promote reward-related behavior, including motor responses to seek and obtain the rewards (NAc), memories of reward-related cues and contexts (amygdala, hippocampus), and executive control of obtaining rewards (prefrontal cortex).

Drugs of abuse alter neurotransmission through initial actions at different classes of ion channels, neurotransmitter receptors, or neurotransmitter transporters (Table 451-1). Studies in animal models have demonstrated that although the initial targets differ, the actions of these drugs converge on the brain's reward circuitry by promoting dopamine neurotransmission in the NAc and other limbic targets of the VTA. In addition, some drugs promote activation of opioid and cannabinoid receptors, which modulate this reward circuitry. By these mechanisms, drugs of abuse produce powerful rewarding signals, which, after repeated drug administration, corrupt a vulnerable brain's reward circuitry in ways that promote addiction. Three major pathologic adaptations have been described. First, drugs produce tolerance in reward circuits and increased activity in stress circuits, which promote escalating drug intake and a negative emotional state during drug withdrawal that promotes relapse. Second, sensitization to the rewarding effects of the drugs and associated cues is seen during prolonged abstinence and also triggers relapse. Third, executive function is impaired in such a way as to increase impulsivity and compulsivity, both of which promote relapse.

Imaging studies in humans confirm that addictive drugs, as well as craving for them, activate the brain's reward circuitry. In addition, patients who abuse alcohol or psychostimulants show reduced gray matter in the prefrontal cortex as well as reduced activity in anterior cingulate and orbitofrontal cortex during tasks of attention and inhibitory control. It is thought that damage to these cortical areas contributes to addiction by impairing decision-making and increasing impulsivity.

NEUROINFLAMMATION

There is increasing evidence for the involvement of inflammatory mechanisms in a wide range of psychiatric syndromes. For example, a subset of depressed patients displays elevated blood levels of interleukin 6 (IL-6), tumor necrosis factor α (TNF-α), and other proinflammatory cytokines. Moreover, rodents exposed to chronic stress exhibit

TABLE 451-1 Initial Actions of Drugs of Abuse

DRUG	NEUROTRANSMITTER AFFECTED	DRUG TARGET (ACTION)
Opiates	Endorphins, enkephalins	μ- and δ-opioid receptors (agonist)
Psychostimulants (cocaine, amphetamine, methamphetamine)	Dopamine	Dopamine transporter (antagonist—cocaine; reverse transport—amphetamine, methamphetamine)
Nicotine	Acetylcholine	Nicotinic cholinergic receptors (agonist)
Ethanol	GABA	$GABA_A$ receptors (positive allosteric modulator)
	Glutamate	NMDA glutamate receptors (antagonist)
	Acetylcholine	Nicotinic cholinergic receptors (allosteric modulator)
	Serotonin	5-HT_3 receptor (positive allosteric modulator)
	Others	Calcium-activated K^+ channel (activator)
Marijuana	Endocannabinoids (anandamide, 2-arachidonoylglycerol)	CB_1 receptor (agonist)
Phencyclidine	Glutamate	NMDA glutamate receptor (antagonist)

Abbreviations: GABA, γ-aminobutyric acid; NMDA, *N*-methyl-D-aspartate

similar increases in peripheral levels of these cytokines, and peripheral or central delivery of those cytokines to normal rodents increases their susceptibility to chronic stress. These findings have led to the novel idea of using peripheral cytokines as biomarkers of a subtype of depression and the potential utility of developing new antidepressants that oppose the actions of specific cytokines.

Recent evidence has also linked proinflammatory signaling in the brain to addiction, particularly to alcohol. Human alcoholism is associated with impaired innate immunity, increases in circulating proinflammatory cytokines, and increases in brain expression of several immune-related genes. Many of these genes are expressed by astrocytes and microglia, and by neurons under certain pathologic conditions, where they play important roles in modifying neuronal function and plasticity. For example, cytokine monocyte chemotactic protein-1 (MCP-1) modulates the release of certain neurotransmitters and, when administered into the VTA, increases neuronal excitability, promotes dopamine release, and increases locomotor activity. Gene expression studies of alcohol drinking in mice have identified a network of regulated neuroimmune proteins in brain, and a role in regulation of alcohol consumption has been validated for several, including chemokines MCP-1 and chemokine (C-C motif) ligand 3 (CCL3), beta-2 microglobulin, CD14, IL-1 receptor antagonist, and cathepsins S and F. This work has led to discovery of anti-inflammatory medications that reduce alcohol intake in animals, such as antagonists of phosphodiesterase 4, which regulates cAMP availability, or agonists of peroxisome proliferator-activated receptors (PPARs), which are transcription factors that repress key inflammatory signaling molecules such as nuclear factor-κB (NF-κB) and nuclear factor of activated T cells (NFAT). A major focus of current research is to define the sites and mechanisms by which proinflammatory cytokines impair brain function to elicit a depressive episode or promote drug abuse.

CONCLUSIONS

This brief narrative illustrates the substantial progress that is being made in understanding the genetic and neurobiological basis of mental illness. It is anticipated that biologic measures will be used increasingly to more accurately diagnose and subtype psychiatric disorders and that targeted therapeutics will become available for these complex conditions.

452 Psychiatric Disorders

Victor I. Reus

Psychiatric disorders are common in medical practice and may present either as a primary disorder or as a comorbid condition. The prevalence of mental or substance use disorders in the United States is ~30%, but only one-third of affected individuals are currently receiving treatment. Global burden of disease statistics indicates that 4 of the 10 most important causes of morbidity and attendant health care costs worldwide are psychiatric in origin.

Changes in health care delivery underscore the need for primary care physicians to assume responsibility for the initial diagnosis and treatment of the most common mental disorders. Prompt diagnosis is essential to ensure that patients have access to appropriate medical services and to maximize the clinical outcome. Validated patient-based questionnaires have been developed that systematically probe for signs and symptoms associated with the most prevalent psychiatric diagnoses and guide the clinician into targeted assessment. The Primary Care Evaluation of Mental Disorders (PRIME-MD; and a self-report form, the Patient Health Questionnaire) and the Symptom-Driven Diagnostic System for Primary Care (SDDS-PC) are inventories that require only 10 min to complete and link patient responses to the formal diagnostic criteria of anxiety, mood, somatoform, and eating disorders and to alcohol abuse or dependence. A variety of smart phone apps for assessment and monitoring of psychiatric conditions and for psychological and pharmacologic treatment interventions are also available.

A physician who refers patients to a psychiatrist should know not only when doing so is appropriate but also how to refer because societal misconceptions and the stigma of mental illness impede the process. Primary care physicians should base referrals to a psychiatrist on the presence of signs and symptoms of a mental disorder and not simply on the absence of a physical explanation for a patient's complaint. The physician should discuss with the patient the reasons for requesting the referral or consultation and provide reassurance that he or she will continue to provide medical care and work collaboratively with the mental health professional. Consultation with a psychiatrist or transfer of care is appropriate when physicians encounter evidence of psychotic symptoms, mania, severe depression, or anxiety; symptoms of posttraumatic stress disorder (PTSD); suicidal or homicidal preoccupation; or a failure to respond to first-order treatment. This chapter reviews the clinical assessment and treatment of some of the most common mental disorders presenting in primary care and is based on

the *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition (DSM-5), the framework for categorizing psychiatric illness used in the United States. **Eating disorders are discussed later in this chapter, and the biology of psychiatric and addictive disorders is discussed in Chap. 451.**

GLOBAL CONSIDERATIONS

The DSM-5 and the tenth revision of the International Classification of Diseases (ICD-10), which is used more commonly worldwide, have taken somewhat differing approaches to the diagnosis of mental illness, but considerable effort has been expended to provide an operational translation between the two nosologies. Both systems are in essence purely descriptive and emphasize clinical pragmatism, in distinction to the Research Domain Criteria (RDOC) proposed by the National Institute of Mental Health, which aspires to provide a causal framework for classification of behavioral disturbance. None of these diagnostic systems has as yet achieved adequate validation. The Global Burden of Disease Study (2019), using available epidemiologic data, nevertheless has reinforced the conclusion that, regardless of nosologic differences, mental and substance abuse disorders are the major cause of life-years lost to disability among all medical illnesses, affecting >300 million individuals worldwide. There is general agreement that high-income countries will need to build capacity in professional training in low- and middle-income countries in order to provide an adequate balanced care model for the delivery of evidence-based therapies for mental disorders. Recent surveys that indicate a dramatic increase in mental disorder prevalence in rapidly developing countries, such as China, may reflect both an increased recognition of the issue, but also the consequence of social turmoil, stigma, and historically inadequate resources. A salient example of the ways in which societal disruption and isolation may contribute to exacerbating already unmet mental health needs can be seen in the COVID-19 pandemic, which has resulted in an increased incidence of diagnosed psychiatric disorders in both affected and unaffected individuals, as well as caregivers. The need for improved prevention strategies and for more definitive and effective interventional treatments remains a global concern.

ANXIETY DISORDERS

Anxiety disorders, the most prevalent psychiatric illnesses in the general community, are present in 15–20% of medical clinic patients. Anxiety, defined as a subjective sense of unease, dread, or foreboding, can indicate a primary psychiatric condition or can be a component of, or reaction to, a primary medical disease. The primary anxiety disorders are classified according to their duration and course and the existence and nature of precipitants.

When evaluating the anxious patient, the clinician must first determine whether the anxiety antedates or postdates a medical illness or is due to a medication side effect. Approximately one-third of patients presenting with anxiety have a medical etiology for their psychiatric symptoms, but an anxiety disorder can also present with somatic symptoms in the absence of a diagnosable medical condition.

PANIC DISORDER

Clinical Manifestations Panic disorder is defined by the presence of recurrent and unpredictable panic attacks, which are distinct episodes of intense fear and discomfort associated with a variety of physical symptoms, including palpitations, sweating, trembling, shortness of breath, chest pain, dizziness, and a fear of impending doom or death. Paresthesias, gastrointestinal distress, and feelings of unreality are also common. Diagnostic criteria require at least 1 month of concern or worry about the attacks or a change in behavior related to them. The lifetime prevalence of panic disorder is 2–3%. Panic attacks have a sudden onset, developing within 10 min and usually resolving over the course of an hour, and they occur in an unexpected fashion. Some may occur when waking from sleep. The frequency and severity of panic attacks vary, ranging from once a week to clusters of attacks separated by months of well-being. The first attack is usually outside the home, and onset is typically in late adolescence to early adulthood. In some individuals, anticipatory anxiety develops over time and results in a generalized fear and a progressive avoidance of places or situations in which a panic attack might recur. *Agoraphobia*, which occurs commonly in patients with panic disorder, is an acquired irrational fear of being in places where one might feel trapped or unable to escape. It may, however, be diagnosed even if panic disorder is not present. Typically, it leads the patient into a progressive restriction in lifestyle and, in a literal sense, in geography. Frequently, patients are embarrassed that they are housebound and dependent on the company of others to go out into the world and do not volunteer this information; thus, physicians will fail to recognize the syndrome if direct questioning is not pursued.

Differential Diagnosis A diagnosis of panic disorder is made after a medical etiology for the panic attacks has been ruled out. A variety of cardiovascular, respiratory, endocrine, and neurologic conditions can present with anxiety as the chief complaint. Patients with true panic disorder will often focus on one specific feature to the exclusion of others. For example, 20% of patients who present with syncope as a primary medical complaint have a primary diagnosis of a mood, anxiety, or substance abuse disorder, the most common being panic disorder. The differential diagnosis of panic disorder is complicated by a high rate of comorbidity with other psychiatric conditions, especially alcohol and benzodiazepine abuse, which patients initially use in an attempt at self-medication. Some 75% of panic disorder patients will also satisfy criteria for major depression at some point in their illness.

When the history is nonspecific, physical examination and focused laboratory testing must be used to rule out anxiety states resulting from medical disorders such as pheochromocytoma, thyrotoxicosis, or hypoglycemia. Electrocardiogram (ECG) and echocardiogram may detect some cardiovascular conditions associated with panic such as paroxysmal atrial tachycardia and mitral valve prolapse. In two studies, panic disorder was the primary diagnosis in 43% of patients with chest pain who had normal coronary angiograms and was present in 9% of all outpatients referred for cardiac evaluation. Panic disorder has also been diagnosed in many patients referred for pulmonary function testing or with symptoms of irritable bowel syndrome.

Etiology and Pathophysiology The etiology of panic disorder is unknown but appears to involve a genetic predisposition, altered autonomic responsivity, and social learning. Panic disorder shows familial aggregation; the disorder is concordant in 30–45% of monozygotic twins, and genome-wide screens have identified suggestive risk loci. Acute panic attacks appear to be associated with increased noradrenergic discharges in the locus coeruleus. Intravenous infusion of sodium lactate evokes an attack in two-thirds of panic disorder patients, as do the α_2-adrenergic antagonist yohimbine, cholecystokinin tetrapeptide (CCK-4), and carbon dioxide inhalation. It is hypothesized that each of these stimuli activates a pathway involving noradrenergic neurons in the locus coeruleus and serotonergic neurons in the dorsal raphe. Resting-state fMRI has identified abnormalities in the default mode network involving the medial temporal lobe, with greater activation in the sensorimotor cortex in panic disorder and in amygdala-frontal connectivity in social anxiety disorder. Agents that block serotonin reuptake can prevent attacks. Patients with panic disorder have a heightened sensitivity to somatic symptoms, which triggers increasing arousal, setting off the panic attack; accordingly, therapeutic intervention involves altering the patient's cognitive interpretation of anxiety-producing experiences as well as preventing the attack itself.

TREATMENT

Panic Disorder

Achievable goals of treatment are to decrease the frequency of panic attacks and to reduce their intensity. The cornerstone of drug therapy is antidepressant medication **(Tables 452-1 through 452-3)**. Selective serotonin reuptake inhibitors (SSRIs) benefit the majority of panic disorder patients and do not have the adverse effects of tricyclic antidepressants (TCAs). Fluoxetine, paroxetine, sertraline, and the selective serotonin-norepinephrine reuptake inhibitor

TABLE 452-1 Antidepressants

NAME	USUAL DAILY DOSE (mg)	SIDE EFFECTS	COMMENTS
SSRIs			
Fluoxetine (Prozac)	10–80	Headache; nausea and other GI effects; jitteriness; insomnia; sexual dysfunction; can affect plasma levels of other medicines (except sertraline); akathisia rare	Once-daily dosing, usually in the morning; fluoxetine has very long half-life; must not be combined with MAOIs
Sertraline (Zoloft)	50–200		
Paroxetine (Paxil)	20–60		
Fluvoxamine (Luvox)	100–300		
Citalopram (Celexa)	20–60		
Escitalopram (Lexapro)	10–30		
TCAs and Tetracyclics			
Amitriptyline (Elavil)	150–300	Anticholinergic (dry mouth, tachycardia, constipation, urinary retention, blurred vision); sweating; tremor; postural hypotension; cardiac conduction delay; sedation; weight gain	Once-daily dosing, usually qhs; blood levels of most TCAs available; can be lethal in overdose (lethal dose = 2 g); nortriptyline best tolerated, especially by elderly
Nortriptyline (Pamelor)	50–200		
Imipramine (Tofranil)	150–300		
Desipramine (Norpramin)	150–300		
Doxepin (Sinequan)	150–300	Nausea, anxiety, dry mouth	FDA-approved for OCD
Clomipramine (Anafranil)	150–300		
Maprotiline (Ludiomil)	25–150		
Protriptyline (Vivactil)	15–40	Drowsiness, constipation, dry mouth	TID or QID dosing required
Trimipramine (Surmontil)	75–200		
Amoxapine (Asendin)	100–300		Lethality in OD, EPS possible
Mixed Norepinephrine/Serotonin Reuptake Inhibitors (SNRI) and Receptor Blockers			
Venlafaxine (Effexor), XR	75–375	Nausea; dizziness; dry mouth; headaches; increased blood pressure; anxiety and insomnia	Bid–tid dosing (extended-release available); lower potential for drug interactions than SSRIs; contraindicated with MAOIs
Desvenlafaxine (Pristiq)	50–400	Nausea, dizziness, insomnia	Primary metabolite of venlafaxine; no increased efficacy with higher dosing
Duloxetine (Cymbalta)	40–60	Nausea, dizziness, headache, insomnia, constipation	May have utility in treatment of neuropathic pain and stress incontinence
Mirtazapine (Remeron)	15–45	Somnolence, weight gain; neutropenia rare	Once-a-day dosing; 5HT3 antagonist
Vilazodone (Viibryd)	40	Nausea, diarrhea, headache; dosage adjustment if given with CYP3A4 inhibitor/stimulator	Also 5-HT_{1a} receptor partial agonist
Vortioxetine (Trintellix)	5–20	Nausea, diarrhea, sweating, headache; low incidence of sedation or weight gain	No specific p450 effects; 5-HT_{3a} and 5-HT_{7} receptor antagonist, 5-HT_{1b} partial agonist, and 5-HT_{1a} agonist
Levomilnacipran (Fetzima)	40–120	Nausea, constipation, sweating; rare increase in blood pressure/pulse	Most noradrenergic of SNRIs
Mixed-Action Drugs			
Bupropion (Wellbutrin), CR, XR	250–450	Jitteriness; flushing; seizures in at-risk patients; anorexia; tachycardia; psychosis	Tid dosing, but sustained-release also available; fewer sexual side effects than SSRIs or TCAs; may be useful for adult ADD
Trazodone (Desyrel)	200–600	Sedation; dry mouth; ventricular irritability; postural hypotension; priapism rare	Useful in low doses for sleep because of sedating effects with no anticholinergic side effects
Trazodone extended-release (Oleptro)	150–375	Daytime somnolence, dizziness, nausea	
Nefazodone	300–600	Headache, nausea, dizziness	Rare risk of liver failure, priapism
MAOIs			
Phenelzine (Nardil)	45–90	Insomnia; hypotension; edema; anorgasmia; weight gain; neuropathy; hypertensive crisis; toxic reactions with SSRIs; narcotics	May be more effective in patients with atypical features or treatment-refractory depression
Tranylcypromine (Parnate)	20–50		
Isocarboxazid (Marplan)	20–60		Less weight gain and hypotension than phenelzine
Transdermal selegiline (Emsam)	6–12	Local skin reaction, hypertension	No dietary restrictions with 6-mg dose

Abbreviations: ADD, attention deficit disorder; EPS, extrapyramidal symptoms; FDA, U.S. Food and Drug Administration; GI, gastrointestinal; MAOIs, monoamine oxidase inhibitors; OCD, obsessive-compulsive disorder; SSRIs, selective serotonin reuptake inhibitors; TCAs, tricyclic antidepressants.

(SNRI) venlafaxine have received approval from the U.S. Food and Drug Administration (FDA) for this indication. These drugs should be started at one-third to one-half of their usual antidepressant dose (e.g., 5–10 mg fluoxetine, 25–50 mg sertraline, 10 mg paroxetine, venlafaxine 37.5 mg). Monoamine oxidase inhibitors (MAOIs) are also effective and may specifically benefit patients who have comorbid features of atypical depression (i.e., hypersomnia and weight gain). Insomnia, orthostatic hypotension, and the need to maintain a low-tyramine diet (avoidance of cheese and wine) have limited their use, however. Antidepressants typically take 2–6 weeks to become effective, and doses may need to be adjusted based on the clinical response.

Because of anticipatory anxiety and the need for immediate relief of panic symptoms, benzodiazepines are useful early in the course of treatment and sporadically thereafter (Table 452-4). FDA-approved agents include alprazolam and clonazepam. A recent Cochrane review found no difference between antidepressants and benzodiazepines in response rate, although benzodiazepines were somewhat better tolerated by patients. In treatment-resistant cases, short-term augmentation with aripiprazole,

TABLE 452-2 Management of Antidepressant Side Effects

SYMPTOMS	COMMENTS AND MANAGEMENT STRATEGIES
Gastrointestinal	
Nausea, loss of appetite	Usually short-lived and dose-related; consider temporary dose reduction or administration with food and antacids
Diarrhea	Famotidine, 20–40 mg/d
Constipation	Wait for tolerance; try diet change, stool softener, exercise; avoid laxatives
Sexual dysfunction	Consider dose reduction; drug holiday
Anorgasmia/impotence; impaired ejaculation	Bethanechol, 10–20 mg, 2 h before activity, or cyproheptadine, 4–8 mg, 2 h before activity, or bupropion, 100 mg bid, or amantadine, 100 mg bid/tid
Orthostasis	Tolerance unlikely; increase fluid intake, use calf exercises/support hose; fludrocortisone, 0.025 mg/d
Anticholinergic	Wait for tolerance
Dry mouth, eyes	Maintain good oral hygiene; use artificial tears, sugar-free gum
Tremor/jitteriness	Antiparkinsonian drugs not effective; use dose reduction/slow increase; lorazepam, 0.5 mg bid, or propranolol, 10–20 mg bid
Insomnia	Schedule all doses for the morning; trazodone, 50–100 mg qhs
Sedation	Caffeine; schedule all dosing for bedtime; bupropion, 75–100 mg in afternoon
Headache	Evaluate diet, stress, other drugs; try dose reduction; amitriptyline, 50 mg/d
Weight gain	Decrease carbohydrates; exercise; consider fluoxetine
Loss of therapeutic benefit over time	Related to tolerance? Increase dose or drug holiday; add amantadine, 100 mg bid, buspirone, 10 mg tid, or pindolol, 2.5 mg bid

divalproex sodium, or pindolol has some evidence for efficacy. There also is no clear difference in short-term efficacy between psychological therapies and antidepressant or benzodiazepine treatment, alone or in combination.

Early psychotherapeutic intervention and education aimed at symptom control enhance the effectiveness of drug treatment. Patients can be taught breathing techniques, be educated about physiologic changes that occur with panic, and learn to expose themselves voluntarily to precipitating events in a treatment program spanning 12–15 sessions. Homework assignments and monitored compliance are important components of successful treatment. Once patients have achieved a satisfactory response, drug treatment should be maintained for 1–2 years to prevent relapse. Controlled trials indicate a success rate of 75–85%, although the likelihood of complete remission is somewhat lower.

TABLE 452-3 Possible Drug Interactions with Selective Serotonin Reuptake Inhibitors

AGENT	EFFECT
Monoamine oxidase inhibitors	Serotonin syndrome—absolute contraindication
Serotonergic agonists, e.g., tryptophan, fenfluramine, triptans	Potential serotonin syndrome
Drugs that are metabolized by P450 isoenzymes: tricyclics, other SSRIs, antipsychotics, beta blockers, codeine, triazolobenzodiazepines, calcium channel blockers	Delayed metabolism resulting in increased blood levels and potential toxicity
Drugs that are bound tightly to plasma proteins, e.g., warfarin	Increased bleeding secondary to displacement
Drugs that inhibit the metabolism of SSRIs by P450 isoenzymes, e.g., quinidine	Increased SSRI side effects

Abbreviation: SSRIs, selective serotonin reuptake inhibitors.

GENERALIZED ANXIETY DISORDER

Clinical Manifestations Patients with generalized anxiety disorder (GAD) have persistent, excessive, and/or unrealistic worry associated with muscle tension, impaired concentration, autonomic arousal, feeling "on edge" or restless, and insomnia (Table 452-5). Onset is usually before age 20 years, and a history of childhood fears and social inhibition may be present. The lifetime prevalence of GAD is 5–6%; the risk is higher in first-degree relatives of patients with the diagnosis. Interestingly, family studies indicate that GAD and panic disorder segregate independently. More than 80% of patients with GAD also suffer from major depression, dysthymia, or social phobia. Comorbid substance abuse is common in these patients, particularly alcohol and/or sedative/hypnotic abuse. Patients with GAD worry excessively over minor matters, with life-disrupting effects; unlike in panic disorder, complaints of shortness of breath, palpitations, and tachycardia are relatively rare.

Etiology and Pathophysiology Most anxiogenic and anxiolytic agents act on the γ-aminobutyric acid $(GABA)_A$ receptor/chloride ion channel complex, implicating this neurotransmitter system in the pathogenesis of anxiety and panic attacks. Benzodiazepines are thought to bind two separate $GABA_A$ receptor sites: type I, which has a broad neuroanatomic distribution, and type II, which is concentrated in the hippocampus, striatum, and neocortex. The antianxiety effects of the various benzodiazepines are influenced by their relative binding to alpha 2 and 3 subunits of the $GABA_A$ receptor, and sedation and memory impairment to the alpha 1 subunit. Serotonin (5-hydroxytryptamine [5-HT]), and 3α-reduced neuroactive steroids (allosteric modulators of $GABA_A$) also appear to have a role in anxiety, and buspirone, a partial $5\text{-}HT_{1A}$ receptor agonist, and certain $5\text{-}HT_{2A}$ and $5\text{-}HT_{2C}$ receptor antagonists (e.g., mirtazapine and nefazodone) may have beneficial effects.

TREATMENT

Generalized Anxiety Disorder

A combination of pharmacologic and psychotherapeutic interventions is most effective in GAD, but complete symptomatic relief is rare. A short course of a benzodiazepine is usually indicated, preferably lorazepam, oxazepam, clonazepam or, alprazolam, although only the last two are FDA approved. (The first two of these agents are metabolized via conjugation rather than oxidation and thus do not accumulate if hepatic function is impaired; the latter also has limited active metabolites.) Treatment should be initiated at the lowest dose possible and prescribed on an as-needed basis as symptoms warrant. Benzodiazepines differ in their milligram per kilogram potency, half-life, lipid solubility, metabolic pathways, and presence of active metabolites. Agents that are absorbed rapidly and are lipid soluble, such as diazepam, have a rapid onset of action and a higher abuse potential. Benzodiazepines should generally not be prescribed for >4–6 weeks because of the development of tolerance and the serious risk of abuse and dependence. Withdrawal must be closely monitored as relapses can occur. It is important to warn patients that concomitant use of alcohol or other sedating drugs may exacerbate side effects and impair their ability to function. An optimistic approach that encourages the patient to clarify environmental precipitants, anticipate his or her reactions, and plan effective response strategies is an essential element of therapy.

Adverse effects of benzodiazepines generally parallel their relative half-lives. Longer-acting agents, such as diazepam, chlordiazepoxide, flurazepam, and clonazepam, tend to accumulate active metabolites, with resultant sedation, impairment of cognition, and poor psychomotor performance. Shorter-acting compounds, such as alprazolam, lorazepam, and oxazepam, can produce daytime anxiety, early-morning insomnia, and, with discontinuation,

TABLE 452-4 Anxiolytics

NAME	EQUIVALENT PO DOSE (mg)	ONSET OF ACTION	HALF-LIFE (h)	COMMENTS
Benzodiazepines				
Diazepam (Valium)	5	Fast	20–70	Active metabolites; quite sedating
Flurazepam (Dalmane)	15	Fast	30–100	Flurazepam is a prodrug; metabolites are active; quite sedating
Triazolam (Halcion)	0.25	Intermediate	1.5–5	No active metabolites; can induce confusion and delirium, especially in elderly
Lorazepam (Ativan)	1	Intermediate	10–20	No active metabolites; direct hepatic glucuronide conjugation; quite sedating; FDA-approved for anxiety with depression
Alprazolam (Xanax)	0.5	Intermediate	12–15	Active metabolites; not too sedating; FDA-approved for panic disorder and anxiety with depression; tolerance and dependence develop easily; difficult to withdraw
Chlordiazepoxide (Librium)	10	Intermediate	5–30	Active metabolites; moderately sedating
Oxazepam (Serax)	15	Slow	5–15	No active metabolites; direct glucuronide conjugation; not too sedating
Temazepam (Restoril)	15	Slow	9–12	No active metabolites; moderately sedating
Clonazepam (Klonopin)	0.5	Slow	18–50	No active metabolites; moderately sedating; FDA-approved for panic disorder
Clorazepate (Tranxene)	15	Fast	40–200	Low sedation; unreliable absorption
Nonbenzodiazepines				
Buspirone (BuSpar)	7.5	2 weeks	2–3	Active metabolites; tid dosing—usual daily dose 10–20 mg tid; nonsedating; no additive effects with alcohol; useful for controlling agitation in demented or brain-injured patients

Abbreviation: FDA, U.S. Food and Drug Administration.

rebound anxiety and insomnia. Although patients develop tolerance to the sedative effects of benzodiazepines, they are less likely to habituate to the adverse psychomotor effects. Withdrawal from the longer half-life benzodiazepines can be accomplished through gradual, stepwise dose reduction (by 10% every 1–2 weeks) over 6–12 weeks. It is usually more difficult to taper patients off shorter-acting benzodiazepines. Physicians may need to switch the patient to a benzodiazepine with a longer half-life or use an adjunctive medication such as a beta blocker or carbamazepine, before attempting to discontinue the benzodiazepine. Withdrawal reactions vary in severity and duration; they can include depression, anxiety, lethargy, diaphoresis, autonomic arousal, and, rarely, seizures.

Buspirone is a nonbenzodiazepine anxiolytic agent. It is nonsedating, does not produce tolerance or dependence, does not interact with benzodiazepine receptors or alcohol, and has no abuse or disinhibition potential. However, it requires several weeks to take effect and requires thrice-daily dosing. Patients who were previously responsive to a benzodiazepine are unlikely to rate buspirone as equally effective, but patients with head injury or dementia who have symptoms of anxiety and/or agitation may do well with this agent. Escitalopram, paroxetine, duloxetine, and venlafaxine are FDA approved for the treatment of GAD, usually at doses that are comparable to their efficacy in major depression, and may be preferable to usage of benzodiazepines in the treatment of chronic anxiety. Benzodiazepines are contraindicated during pregnancy and breast-feeding.

Anticonvulsants with GABAergic properties may also be effective against anxiety. Gabapentin, oxcarbazepine, tiagabine, pregabalin, and divalproex have all shown some degree of benefit in a variety of anxiety-related syndromes in off-label usage.

TABLE 452-5 Diagnostic Criteria for Generalized Anxiety Disorder

A. Excessive anxiety and worry (apprehensive expectation), occurring more days than not for at least 6 months, about a number of events or activities (such as work or school performance).

B. The individual finds it difficult to control the worry.

C. The anxiety and worry are associated with three (or more) of the following six symptoms (with at least some symptoms present for more days than not for the past 6 months): (1) restlessness or feeling keyed up or on edge; (2) being easily fatigued; (3) difficulty concentrating or mind going blank; (4) irritability; (5) muscle tension; (6) sleep disturbance (difficulty falling or staying asleep, or restless, unsatisfying sleep).

D. The anxiety, worry, or physical symptoms cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.

E. The disturbance is not attributable to the physiologic effects of a substance (e.g., a drug of abuse, a medication) or another medical condition (e.g., hyperthyroidism).

F. The disturbance is not better explained by another mental disorder (e.g., anxiety or worry about having panic attacks in panic disorder, negative evaluation in social anxiety disorder [social phobia], contamination or other obsessions in obsessive-compulsive disorder, separation from attachment figures in separation anxiety disorder, reminders of traumatic events in posttraumatic stress disorder, gaining weight in anorexia nervosa, physical complaints in somatic symptom disorder, perceived appearance flaws in body dysmorphic disorder, having a serious illness in illness anxiety disorder, or the content of delusional beliefs in schizophrenia or delusional disorder).

PHOBIC DISORDERS

Clinical Manifestations The cardinal feature of phobic disorders is a marked and persistent fear of objects or situations, exposure to which results in an immediate anxiety reaction. The patient avoids the phobic stimulus, and this avoidance usually impairs occupational or social functioning. Panic attacks may be triggered by the phobic stimulus or may occur spontaneously. Unlike patients with other anxiety disorders, individuals with phobias usually experience anxiety only in specific situations. Common phobias include fear of closed spaces (claustrophobia), fear of blood, and fear of flying. Social phobia is distinguished by a specific fear of social or performance situations in which the individual is exposed to unfamiliar individuals or to possible examination and evaluation by others. Examples include having to converse at a party, use public restrooms, and meet strangers. In each case, the affected individual is aware that the experienced fear is excessive and unreasonable given the circumstance. The specific content of a phobia may vary across gender, ethnic, and cultural boundaries.

Phobic disorders are common, affecting ~7–9% of the population. Twice as many females are affected than males. Full criteria for diagnosis are usually satisfied first in early adulthood, but behavioral avoidance of unfamiliar people, situations, or objects dating from early childhood is common.

In one study of female twins, concordance rates for agoraphobia, social phobia, and animal phobia were found to be 23% for monozygotic twins and 15% for dizygotic twins. A twin study of fear conditioning, a model for the acquisition of phobias, demonstrated a heritability of 35–45%. Animal studies of fear conditioning have indicated that

processing of the fear stimulus occurs through the lateral nucleus of the amygdala, extending through the central nucleus and projecting to the periaqueductal gray region, lateral hypothalamus, and paraventricular hypothalamus.

TREATMENT

Phobic Disorders

Beta blockers (e.g., propranolol, 20–40 mg orally 2 h before the event) are particularly effective in the treatment of "performance anxiety" (but not general social phobia) and appear to work by blocking the peripheral manifestations of anxiety such as perspiration, tachycardia, palpitations, and tremor. MAOIs alleviate social phobia independently of their antidepressant activity, and paroxetine, sertraline, fluvoxamine CR, and venlafaxine XR have received FDA approval for treatment of social anxiety. Benzodiazepines can be helpful in reducing fearful avoidance, but the chronic nature of phobic disorders limits their usefulness.

Behaviorally focused psychotherapy is an important component of treatment because relapse rates are high when medication is used as the sole treatment. Cognitive-behavioral strategies are based on the finding that distorted perceptions and interpretations of fear-producing stimuli play a major role in perpetuation of phobias. Individual and group therapy sessions teach the patient to identify specific negative thoughts associated with the anxiety-producing situation and help to reduce the patient's fear of loss of control. In desensitization therapy, hierarchies of feared situations are constructed, and the patient is encouraged to pursue and master gradual exposure to the anxiety-producing stimuli.

Patients with social phobia, in particular, have a high rate of comorbid alcohol abuse, as well as of other psychiatric conditions (e.g., eating disorders), necessitating the need for parallel management of each disorder if anxiety reduction is to be achieved.

STRESS DISORDERS

Clinical Manifestations Patients may develop anxiety after exposure to extreme traumatic events such as the threat of personal death or injury or the death of a loved one. The reaction may occur shortly after the trauma (*acute stress disorder*) or be delayed and subject to recurrence (PTSD) **(Table 452-6)**. In both syndromes, individuals experience associated symptoms of detachment and loss of emotional responsivity. The patient may feel depersonalized and unable to recall

TABLE 452-6 Diagnostic Criteria for Posttraumatic Stress Disorder

A. Exposure to actual or threatened death, serious injury, or sexual violence in one (or more) of the following ways:
   1. Directly experiencing the traumatic event(s).
   2. Witnessing, in person, the event(s) as it occurred to others.
   3. Learning that the traumatic event(s) occurred to a close family member or close friend. In cases of actual or threatened death of a family member or friend, the event(s) must have been violent or accidental.
   4. Experiencing repeated or extreme exposure to aversive details of the traumatic event(s) (e.g., first responders collecting human remains; police officers repeatedly exposed to details of child abuse).

B. Presence of one (or more) of the following intrusion symptoms associated with the traumatic event(s), beginning after the traumatic event(s) occurred:
   1. Recurrent, involuntary, and intrusive distressing memories of the traumatic event(s).
   2. Recurrent distressing dreams in which the content and/or affect of the dream are related to the traumatic event(s).
   3. Dissociative reactions (e.g., flashbacks) in which the individual feels or acts as if the traumatic event(s) were recurring. (Such reactions may occur on a continuum, with the most extreme expression being a complete loss of awareness of present surroundings.)
   4. Intense or prolonged psychological distress at exposure to internal or external cues that symbolize or resemble an aspect of the traumatic event(s).
   5. Marked physiologic reactions to internal or external cues that symbolize or resemble an aspect of the traumatic event(s).

C. Persistent avoidance of stimuli associated with the traumatic event(s), beginning after the traumatic event(s) occurred, as evidenced by one or both of the following:
   1. Avoidance of or efforts to avoid distressing memories, thoughts, or feelings about or closely associated with the traumatic event(s).
   2. Avoidance of or efforts to avoid external reminders (people, places, conversations, activities, objects, situations) that arouse distressing memories, thoughts, or feelings about or closely associated with the traumatic event(s).

D. Negative alterations in cognitions and mood associated with the traumatic event(s), beginning or worsening after the traumatic event(s) occurred as evidenced by two (or more) of the following:
   1. Inability to remember an important aspect of the traumatic event(s) (typically due to dissociative amnesia and not to other factors such as head injury, alcohol, or drugs).
   2. Persistent and exaggerated negative beliefs or expectations about oneself, others, or the world (e.g., "I am bad," "No one can be trusted," "The world is completely dangerous," "My whole nervous system is permanently ruined").
   3. Persistent, distorted cognitions about the cause or consequences of the traumatic event(s) that lead the individual to blame himself/herself or others.
   4. Persistent negative emotional state (e.g., fear, horror, anger, guilt, or shame).
   5. Markedly diminished interest or participation in significant activities.
   6. Feelings of detachment or estrangement from others.
   7. Persistent inability to experience positive emotions (e.g., inability to experience happiness, satisfaction, or loving feelings).

E. Marked alterations in arousal and reactivity associated with the traumatic event(s), beginning or worsening after the traumatic event(s) occurred, as evidenced by two (or more) of the following:
   1. Irritable behavior and angry outbursts (with little or no provocation) typically expressed as verbal or physical aggression toward people or objects.
   2. Reckless or self-destructive behavior.
   3. Hypervigilance.
   4. Exaggerated startle response.
   5. Problems with concentration.
   6. Sleep disturbance (e.g., difficulty falling or staying asleep or restless sleep).

F. Duration of the disturbance (criteria B, C, D, and E) is >1 month.

G. The disturbance causes clinically significant distress or impairment in social, occupational, or other important areas of functioning.

H. The disturbance is not attributable to the physiologic effects of a substance (e.g., medication, alcohol) or another medical condition.

Source: Reprinted with permission from the *Diagnostic and Statistical Manual of Mental Disorders*, 5th ed. (Copyright © 2013). American Psychiatric Association. All Rights Reserved.

specific aspects of the trauma, although typically it is reexperienced through intrusions in thought, dreams, or flashbacks, particularly when cues of the original event are present. Patients often actively avoid stimuli that precipitate recollections of the trauma and demonstrate a resulting increase in vigilance, arousal, and startle response. Patients with stress disorders are at risk for the development of other disorders related to anxiety, mood, and substance abuse (especially alcohol). Between 5 and 10% of Americans will at some time in their life satisfy criteria for PTSD, with women more likely to be affected than men. A validated four-item screen for PTSD (PC-PTSD) is available.

Risk factors for the development of PTSD include a past psychiatric history and personality characteristics of high neuroticism and extroversion. Twin studies show a substantial genetic influence on all symptoms associated with PTSD, with less evidence for an environmental effect.

Etiology and Pathophysiology It is hypothesized that in PTSD there is excessive release of norepinephrine from the locus coeruleus in response to stress and increased noradrenergic activity at projection sites in the hippocampus and amygdala. These changes theoretically facilitate the encoding of fear-based memories. Greater sympathetic responses to cues associated with the traumatic event occur in PTSD, although pituitary adrenal responses are blunted. In addition to fear learning, changes in threat detection (insula overactivity), executive function, emotional regulation, and contextual learning have been documented. Predictive biomarkers include increased heart rate and serum lactate, decreased coagulation, insulin resistance, and alterations in glycolysis and fatty acid uptake.

TREATMENT

Stress Disorders

Acute stress reactions are usually self-limited, and treatment typically involves the short-term use of benzodiazepines and supportive/expressive psychotherapy. The chronic and recurrent nature of PTSD, however, requires a more complex approach using drug and behavioral treatments. PTSD is highly correlated with peritraumatic dissociative symptoms and the development of an acute stress disorder at the time of the trauma. The SSRIs (paroxetine and sertraline are FDA approved for PTSD), venlafaxine, fluoxetine, and topiramate can all reduce anxiety, symptoms of intrusion, and avoidance behaviors. Recently, the psychedelic agent MDMA demonstrated efficacy as an adjunct to intensive psychotherapeutic intervention, as did stellate ganglion block. Low-dose trazodone and mirtazapine, sedating antidepressants, are frequently used at night to help with insomnia. Benzodiazepines and SSRIs, however, should not be given in the early aftermath of trauma. Psychotherapeutic strategies for PTSD help the patient overcome avoidance behaviors and demoralization and master fear of recurrence of the trauma; therapies that encourage the patient to dismantle avoidance behaviors through stepwise focusing on the experience of the traumatic event, such as trauma-focused cognitive-behavioral and processing therapy and prolonged exposure therapy utilizing augmented or virtual reality are the most effective. Debriefing after the traumatic event does not prevent PTSD and may exacerbate symptoms.

OBSESSIVE-COMPULSIVE DISORDER

Clinical Manifestations Obsessive-compulsive disorder (OCD) is characterized by obsessive thoughts and compulsive behaviors that impair everyday functioning. Fears of contamination and germs are common, as are handwashing, counting behaviors, and having to check and recheck such actions as whether a door is locked. The degree to which the disorder is disruptive for the individual varies, but in all cases, obsessive-compulsive activities take up >1 h per day and are undertaken to relieve the anxiety triggered by the core fear. Patients often conceal their symptoms, usually because they are embarrassed by the content of their thoughts or the nature of their actions. Physicians must ask specific questions regarding recurrent thoughts and behaviors, particularly if physical clues such as chafed and reddened hands or patchy hair loss (from repetitive hair pulling, or trichotillomania) are present. Comorbid conditions are common, the most frequent being depression, other anxiety disorders, eating disorders, and tics. OCD has a lifetime prevalence of 2–3% worldwide. Onset is usually gradual, beginning in early adulthood, but childhood onset is not rare. The disorder usually has a waxing and waning course, but some cases may show a steady deterioration in psychosocial functioning.

Etiology and Pathophysiology A genetic contribution to OCD is suggested by twin studies, but no susceptibility gene for OCD has been identified to date. Insulin signaling has been implicated in some recent reports. Family studies show an aggregation of OCD with Tourette's disorder, and both are more common in males and in firstborn children.

The anatomy of obsessive-compulsive behavior is thought to include the orbital frontal cortex, caudate nucleus, and globus pallidus. The caudate nucleus appears to be involved in the acquisition and maintenance of habit and skill learning, and interventions that are successful in reducing obsessive-compulsive behaviors also decrease metabolic activity measured in the caudate.

TREATMENT

Obsessive-Compulsive Disorder

Clomipramine, fluoxetine, fluvoxamine, paroxetine, and sertraline are approved for the treatment of OCD in adults (and all but paroxetine are also approved for children). Clomipramine is a TCA that is often tolerated poorly owing to anticholinergic and sedative side effects at the doses required to treat the illness (25–250 mg/d); its efficacy in OCD is unrelated to its antidepressant activity. Fluoxetine (5–60 mg/d), fluvoxamine (25–300 mg/d), paroxetine (40–60 mg/d), and sertraline (50–150 mg/d) are as effective as clomipramine and have a more benign side-effect profile. Venlafaxine and duloxetine also have shown efficacy but are not FDA approved. Only 50–60% of patients with OCD show adequate improvement with pharmacotherapy alone. In treatment-resistant cases, augmentation with other serotonergic agents such as buspirone, or with a neuroleptic or benzodiazepine, may be beneficial, and in severe cases, deep-brain stimulation has been found to be effective. When a therapeutic response is achieved, long-duration maintenance therapy is usually indicated.

For many individuals, particularly those with time-consuming compulsions, behavior therapy and exposure response prevention will result in as much improvement as that afforded by medication. Effective techniques include the gradual increase in exposure to stressful situations, maintenance of a diary to clarify stressors, and homework assignments that substitute new activities for compulsive behaviors.

MOOD DISORDERS

Mood disorders are characterized by a disturbance in the regulation of mood, behavior, and affect. Mood disorders are subdivided into (1) depressive disorders, (2) bipolar disorders, and (3) depression in association with medical illness or alcohol and substance abuse **(Chaps. 453 through 457)**. Major depressive disorder (MDD) is differentiated from bipolar disorder by the absence of a manic or hypomanic episode. The relationship between pure depressive syndromes and bipolar disorders is not well understood; MDD is more frequent in families of bipolar individuals, but the reverse is not true. In the most recent Global Burden of Disease Study conducted by the World Health Organization (2019), depression was the single largest factor contributing to disability, which had increased 61% as measured by disability-adjusted life-years (DALYs) since 1990. Moreover, the COVID pandemic has been associated with a major increase in reported symptoms of depression and anxiety worldwide. In the United States, lost productivity directly related to mood disorders has been estimated at $55.1 billion per year.

DEPRESSION IN ASSOCIATION WITH MEDICAL ILLNESS

Depression occurring in the context of medical illness is difficult to evaluate. Depressive symptomatology may reflect the psychological stress of coping with the disease, may be caused by the disease process itself or by the medications used to treat it, or may simply coexist in time with the medical diagnosis.

Virtually every class of *medication* includes some agent that can induce depression. Antihypertensive drugs, anticholesterolemic agents, and antiarrhythmic agents are common triggers of depressive symptoms. Iatrogenic depression should also be considered in patients receiving glucocorticoids, antimicrobials, systemic analgesics, antiparkinsonian medications, and anticonvulsants. To decide whether a causal relationship exists between pharmacologic therapy and a patient's change in mood, it may sometimes be necessary to undertake an empirical trial of an alternative medication.

Between 20–30% of *cardiac* patients manifest a depressive disorder; an even higher percentage experience depressive symptomatology when self-reporting scales are used. Depressive symptoms following unstable angina, myocardial infarction, cardiac bypass surgery, or heart transplant impair rehabilitation and are associated with higher rates of mortality and medical morbidity. Depressed patients often show decreased variability in heart rate (an index of reduced parasympathetic nervous system activity), which may predispose individuals to ventricular arrhythmia and increased morbidity. Depression also appears to increase the risk of coronary heart disease, possibly through increased platelet aggregation. TCAs are contraindicated in patients with bundle branch block, and TCA-induced tachycardia is an additional concern in patients with congestive heart failure. SSRIs appear not to induce ECG changes or adverse cardiac events and thus are reasonable first-line drugs for patients at risk for TCA-related complications. SSRIs may interfere with hepatic metabolism of anticoagulants, however, causing increased anticoagulation.

In patients with *cancer*, the mean prevalence of depression is 25%, but depression occurs in 40–50% of patients with cancers of the pancreas or oropharynx. This association is not due to the effect of cachexia alone, as the higher prevalence of depression in patients with pancreatic cancer persists when compared to those with advanced gastric cancer. Initiation of antidepressant medication in cancer patients has been shown to improve quality of life as well as mood. Psychotherapeutic approaches, particularly group therapy, may have some effect on short-term depression, anxiety, and pain symptoms.

Depression occurs frequently in patients with *neurologic disorders*, particularly cerebrovascular disorders, Parkinson's disease, dementia, multiple sclerosis, and traumatic brain injury. One in five patients with left-hemisphere stroke involving the dorsolateral frontal cortex experiences major depression. Late-onset depression in otherwise cognitively normal individuals increases the risk of a subsequent diagnosis of Alzheimer's disease. All classes of antidepressant agents are effective against these depressions, as are, in some cases, stimulant compounds. SNRIs such as duloxetine or levomilnacipran may be more effective in depression associated with chronic pain.

The reported prevalence of depression in patients with *diabetes mellitus* varies from 8–27%, with the severity of the mood state correlating with the level of hyperglycemia and the presence of diabetic complications. Treatment of depression may be complicated by effects of antidepressive agents on glycemic control. MAOIs can induce hypoglycemia and weight gain, whereas TCAs can produce hyperglycemia and carbohydrate craving. SSRIs and SNRIs, like MAOIs, may reduce fasting plasma glucose, but are easier to use and may also improve dietary and medication compliance.

Hypothyroidism is frequently associated with features of depression, most commonly depressed mood and memory impairment. Hyperthyroid states may also present in a similar fashion, usually in geriatric populations. Improvement in mood usually follows normalization of thyroid function, but adjunctive antidepressant medication is sometimes required. Patients with subclinical hypothyroidism can also experience symptoms of depression and cognitive difficulty that respond to thyroid replacement.

The lifetime prevalence of depression in *HIV-positive* individuals has been estimated at 22–45%. The relationship between depression and disease progression is multifactorial and likely to involve psychological and social factors, alterations in immune function, and central nervous system (CNS) disease. Chronic hepatitis C infection is also associated with depression, which may worsen with interferon-α treatment.

Some chronic disorders of uncertain etiology, such as chronic fatigue syndrome **(Chap. 450)** and fibromyalgia **(Chap. 373)**, are strongly associated with depression and anxiety; patients may benefit from antidepressant treatment or anticonvulsant agents such as pregabalin.

DEPRESSIVE DISORDERS

Clinical Manifestations Major depression is defined as depressed mood on a daily basis for a minimum duration of 2 weeks **(Table 452-7)**. An episode may be characterized by sadness, indifference, apathy, or irritability and is usually associated with changes in sleep patterns, appetite, and weight; motor agitation or retardation; fatigue; impaired concentration and decision-making; feelings of shame or guilt; and thoughts of death or dying. Patients with depression have a profound loss of pleasure in all enjoyable activities, exhibit early-morning awakening, feel that the dysphoric mood state is qualitatively different from sadness, and often notice a diurnal variation in mood (worse in morning hours). Patients experiencing bereavement or grief may exhibit many of the same signs and symptoms of major depression, although the emphasis is usually on feelings of emptiness and loss, rather than anhedonia and loss of self-esteem, and the duration is usually limited. In certain cases, however, the diagnosis of major depression may be warranted even in the context of a significant loss.

TABLE 452-7 Criteria for a Major Depressive Episode

A. Five (or more) of the following symptoms have been present during the same 2-week period and represent a change from previous functioning; at least one of the symptoms is either (1) depressed mood or (2) loss of interest or pleasure. (*Note:* Do not include symptoms that are clearly attributable to another medical condition.)
   1. Depressed mood most of the day, nearly every day, as indicated by either subjective report (e.g., feels sad, empty, hopeless) or observation made by others (e.g., appears tearful).
   2. Markedly diminished interest or pleasure in all, or almost all, activities most of the day, nearly every day (as indicated by either subjective account or observation).
   3. Significant weight loss when not dieting or weight gain (e.g., a change of >5% of body weight in a month), or decrease or increase in appetite nearly every day.
   4. Insomnia or hypersomnia nearly every day.
   5. Psychomotor agitation or retardation nearly every day (observable by others, not merely subjective feelings of restlessness or being slowed down).
   6. Fatigue or loss of energy nearly every day.
   7. Feelings of worthlessness or excessive or inappropriate guilt (which may be delusional) nearly every day (not merely self-reproach or guilt about being sick).
   8. Diminished ability to think or concentrate, or indecisiveness, nearly every day (either by subjective account or as observed by others).
   9. Recurrent thoughts of death (not just fear of dying), recurrent suicidal ideation without a specific plan, or a suicide attempt or a specific plan for committing suicide.

B. The symptoms cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.

C. The episode is not attributable to the physiologic effects of a substance or to another medical condition.

D. The occurrence of the major depressive episode is not better explained by seasonal affective disorder, schizophrenia, schizophreniform disorder, delusional disorder, or other specified and unspecified schizophrenia spectrum and other psychotic disorders.

E. There has never been a manic episode or a hypomanic episode.

Source: Reprinted with permission from the *Diagnostic and Statistical Manual of Mental Disorders*, 5th ed. (Copyright © 2013). American Psychiatric Association. All Rights Reserved.

Approximately 15% of the population experiences a major depressive episode at some point in life, and 6–8% of all outpatients in primary care settings satisfy diagnostic criteria for the disorder. Depression is often undiagnosed, and even more frequently, it is treated inadequately. If a physician suspects the presence of a major depressive episode, the initial task is to determine whether it represents unipolar or bipolar depression or is one of the 10–15% of cases that are secondary to general medical illness or substance abuse. Physicians should also assess the risk of suicide by direct questioning, as patients are often reluctant to verbalize such thoughts without prompting. If specific plans are uncovered or if significant risk factors exist (e.g., a past history of suicide attempts, profound hopelessness, concurrent medical illness, substance abuse, or social isolation), the patient must be referred to a mental health specialist for immediate care. The physician should specifically probe each of these areas in an empathic and hopeful manner, being sensitive to denial and possible minimization of distress. The presence of anxiety, panic, or agitation significantly increases near-term suicidal risk. Approximately 4–5% of all depressed patients will commit suicide; most will have sought help from physicians within 1 month of their deaths.

In some depressed patients, the mood disorder does not appear to be episodic and is not clearly associated with either psychosocial dysfunction or change from the individual's usual experience in life. Persistent depressive disorder (*dysthymic disorder*) consists of a pattern of chronic (at least 2 years), ongoing depressive symptoms that are usually less severe and/or less numerous than those found in major depression, but the functional consequences may be equivalent to or even greater; the two conditions are sometimes difficult to separate and can occur together ("double depression"). Many patients who exhibit a profile of pessimism, disinterest, and low self-esteem respond to antidepressant treatment. Persistent and chronic depressive disorders occur in ~2% of the general population.

Depression is approximately twice as common in women as in men, and the incidence increases with age in both sexes. Twin studies indicate that the liability to major depression of early onset (before age 25 years) is largely genetic in origin. Negative life events can precipitate and contribute to depression, but genetic factors influence the sensitivity of individuals to these stressful events. In most cases, both biologic and psychosocial factors are involved in the precipitation and unfolding of depressive episodes. The most potent stressors appear to involve death of a relative, assault, or severe marital or relationship problems.

Unipolar depressive disorders usually begin in early adulthood and recur episodically over the course of a lifetime. The best predictor of future risk is the number of past episodes; 50–60% of patients who have a first episode have at least one or two recurrences. Some patients experience multiple episodes that become more severe and frequent over time. The duration of an untreated episode varies greatly, ranging from a few months to ≥1 year. The pattern of recurrence and clinical progression in a developing episode are also variable. Within an individual, the nature of episodes (e.g., specific presenting symptoms, frequency, and duration) may be similar over time. In a minority of patients, a severe depressive episode may progress to a psychotic state and in elderly patients, depressive symptoms can be associated with cognitive deficits mimicking dementia ("pseudodementia"). A seasonal pattern of depression, called *seasonal affective disorder*, may manifest with onset and remission of episodes at predictable times of the year. This disorder is more common in women, with symptoms of anergy, fatigue, weight gain, hypersomnia, and episodic carbohydrate craving. The prevalence increases with distance from the equator, and improvement may occur by altering light exposure.

Etiology and Pathophysiology Although evidence for genetic transmission of unipolar depression is not as strong as in bipolar disorder, monozygotic twins have a higher concordance rate (46%) than dizygotic siblings (20%), with little support for any effect of a shared family environment. Large-scale genome-wide association studies (GWAS) involving hundreds of thousands of cases and controls have identified several hundred loci across the genome, some of which are unique to major depression, but others of which overlap with findings from disparate psychiatric disorders, indicating possible pleiotropy. Epigenetic changes are also likely to contribute to risk.

Neuroendocrine abnormalities that reflect the neurovegetative signs and symptoms of depression include increased cortisol and corticotropin-releasing hormone (CRH) secretion, a decreased inhibitory response of glucocorticoids to dexamethasone, and a blunted response of thyroid-stimulating hormone (TSH) level to infusion of thyroid-releasing hormone (TRH). Antidepressant treatment leads to normalization of these abnormalities. Major depression is also associated with changes in levels of proinflammatory cytokines and neurotrophins, an increase in measures of oxidative stress and cellular aging, telomere shortening, epigenetic changes, and mitochondrial dysfunction. Alterations in the gut microbiome may also be involved.

Diurnal variations in symptom severity and alterations in circadian rhythmicity of a number of neurochemical and neurohumoral factors suggest that a primary defect may be present in regulation of biologic rhythms. Patients with major depression show consistent findings of a decrease in rapid eye movement (REM)–sleep onset (REM latency), an increase in REM density, and, in some subjects, a decrease in stage IV delta slow-wave sleep.

Although antidepressant drugs inhibit neurotransmitter uptake within hours, their therapeutic effects typically emerge over several weeks, implicating adaptive changes in second messenger systems and neurotrophic and transcription factors as possible mechanisms of action.

TREATMENT

Depressive Disorders

Treatment planning requires coordination of short-term strategies to induce remission combined with longer-term maintenance designed to prevent recurrence. The most effective intervention for achieving remission and preventing relapse is medication, but combined treatments, incorporating psychotherapy to help the patient cope with decreased self-esteem and demoralization, improve outcomes, as do self-help strategies such as exercise **(Fig. 452-1)**. Approximately 40% of primary care patients with depression drop out of treatment and discontinue medication if symptomatic improvement is not noted within a month, unless additional support is provided. Outcome improves with (1) increased intensity and frequency of visits during the first 4–6 weeks of treatment, (2) supplemental educational materials, and (3) psychiatric consultation as indicated. Despite the widespread use of SSRIs and other second-generation antidepressant drugs, there is no convincing evidence that these classes of antidepressants are more efficacious than TCAs. Between 60–70% of all depressed patients respond to any drug chosen, if it is given in a sufficient dose for 6–8 weeks.

A rational approach to selecting which antidepressant to use (Table 452-1) involves matching the patient's preference and medical history with the metabolic and side-effect profile of the drug (Tables 452-2 and 452-3). A previous response, or a family history of a positive response, to a specific antidepressant often suggests that drug should be tried first. Before initiating antidepressant therapy, the physician should evaluate the possible contribution of comorbid illnesses and consider their specific treatment. In individuals with suicidal ideation, particular attention should be paid to choosing a drug with low toxicity if taken in overdose. Newer antidepressant drugs are distinctly safer in this regard; nevertheless, the advantages of TCAs have not been completely superseded. The existence of generic equivalents makes TCAs relatively cheap, and for secondary tricyclics, particularly nortriptyline and desipramine, well-defined relationships among dose, plasma level, and therapeutic response exist. The steady-state plasma level achieved for a given drug dose can vary more than tenfold between individuals, and plasma levels may help in interpreting apparent resistance to treatment and/or unexpected drug toxicity. The principal side effects of TCAs are antihistaminergic (sedation) and anticholinergic

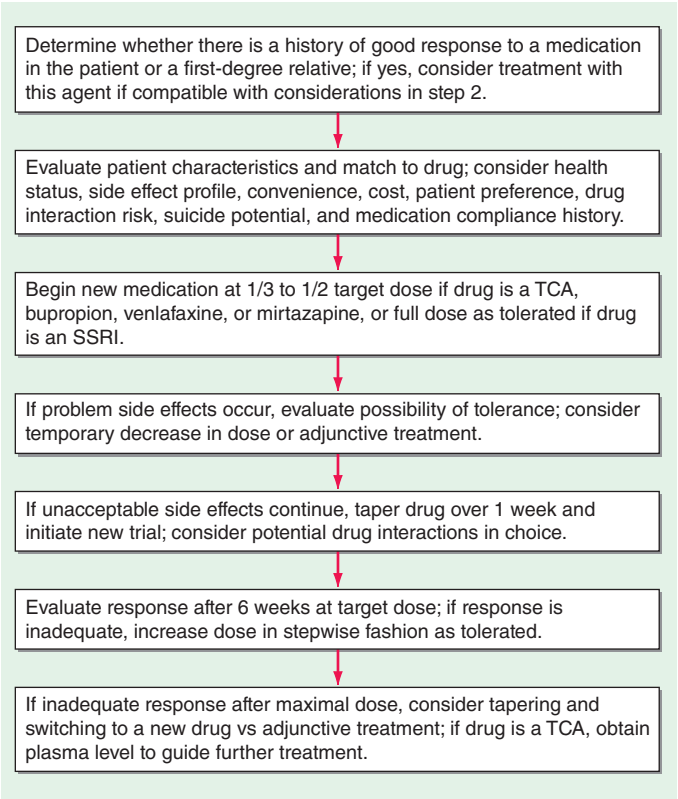

FIGURE 452-1 A guideline for the medical management of major depressive disorder. SSRI, selective serotonin reuptake inhibitor; TCA, tricyclic antidepressant.

(constipation, dry mouth, urinary hesitancy, blurred vision). TCAs are contraindicated in patients with serious cardiovascular risk factors, and overdoses of tricyclic agents can be lethal, with desipramine carrying the greatest risk. It is judicious to prescribe only a 10-day supply when suicide is a risk. Most patients require a daily dose of 150–200 mg of imipramine or amitriptyline or its equivalent to achieve a therapeutic blood level of 150–300 ng/mL and a satisfactory remission; some patients show a partial effect at lower doses. Geriatric patients may require a low starting dose and slow escalation. Ethnic differences in drug metabolism are significant, with Hispanic, Asian, and black patients generally requiring lower doses to achieve a comparable blood level.

Second-generation antidepressants are similar to tricyclics in their effect on neurotransmitter reuptake, although some also have specific actions on catecholamine and indolamine receptors as well. Amoxapine is a dibenzoxazepine derivative that blocks norepinephrine and serotonin reuptake and has a metabolite that shows a degree of dopamine blockade. Long-term use of this drug carries a risk of tardive dyskinesia. Maprotiline is a potent noradrenergic reuptake blocker that has little anticholinergic effect but may produce seizures. Bupropion is a novel antidepressant whose mechanism of action is thought to involve enhancement of noradrenergic function. It has no anticholinergic, sedating, or orthostatic side effects and has a low incidence of sexual side effects. It may, however, be associated with stimulant-like side effects, may lower seizure threshold, and has an exceptionally short half-life, requiring frequent dosing. An extended-release preparation is available.

SSRIs such as fluoxetine, sertraline, paroxetine, citalopram, and escitalopram cause a lower frequency of anticholinergic, sedating, and cardiovascular side effects but a possibly greater incidence of gastrointestinal complaints, sleep impairment, and sexual dysfunction than do TCAs. Akathisia, involving an inner sense of restlessness and anxiety in addition to increased motor activity, may also be more common, particularly during the first week of treatment. One concern is the risk of "serotonin syndrome," which is thought to result from hyperstimulation of brainstem 5-HT_{1A} receptors and is characterized by myoclonus, agitation, abdominal cramping, hyperpyrexia, hypertension, and potentially death. Serotonergic agonists taken in combination should be monitored closely for this reason. Considerations such as half-life, compliance, toxicity, and drug-drug interactions may guide the choice of a particular SSRI. Fluoxetine and its principal active metabolite, norfluoxetine, for example, have a combined half-life of almost 7 days, resulting in a delay of 5 weeks before steady-state levels are achieved and a similar delay for complete drug excretion once their use is discontinued; paroxetine appears to incur a greater risk of withdrawal symptoms with abrupt discontinuation. All the SSRIs may impair sexual function, resulting in diminished libido, impotence, or difficulty in achieving orgasm. Sexual dysfunction frequently results in noncompliance and should be asked about specifically. Sexual dysfunction can sometimes be ameliorated by lowering the dose, by instituting weekend drug holidays (two or three times a month), or by treatment with amantadine (100 mg tid), bethanechol (25 mg tid), buspirone (10 mg tid), or bupropion (100–150 mg/d). Paroxetine appears to be more anticholinergic than either fluoxetine or sertraline, and sertraline carries a lower risk of producing an adverse drug interaction than the other two. Rare side effects of SSRIs include angina due to vasospasm and prolongation of the prothrombin time. Escitalopram is the most specific of currently available SSRIs and appears to have no significant inhibitory effects on the P450 system.

Venlafaxine, desvenlafaxine, duloxetine, and levomilnacipran block the reuptake of both norepinephrine and serotonin but produce relatively little in the way of traditional tricyclic side effects. Vortioxetine, also a 5HT1a agonist, and vilazodone block reuptake of serotonin but have negligible effects on norepinephrine reuptake, although vortioxetine may increase norepinephrine levels through wide effects on serotonergic receptors, as a 5HT1a agonist, 5HT1b partial agonist, and a 5HT1d, 5HT3, and 5HT7 antagonist. Unlike the SSRIs, venlafaxine and vortioxetine have relatively linear dose-response curves. Patients on immediate-release venlafaxine should be monitored for a possible increase in diastolic blood pressure, and multiple daily dosing is required because of the drug's short half-life. An extended-release form is available and has a somewhat lower incidence of gastrointestinal side effects. Mirtazapine is a tetracyclic that has a unique spectrum of activity, as it increases noradrenergic and serotonergic neurotransmission through a blockade of central α_2-adrenergic receptors and postsynaptic 5-HT_2 and 5-HT_3 receptors. It is also strongly antihistaminic and, as such, may produce sedation. Levomilnacipran is the most noradrenergic of the SNRIs and theoretically may be appropriate for patients with more severe fatigue and anergia.

With the exception of citalopram and escitalopram, each of the SSRIs may inhibit one or more cytochrome P450 enzymes. Depending on the specific isoenzyme involved, the metabolism of a number of concomitantly administered medications can be dramatically affected. Fluoxetine and paroxetine, for example, by inhibiting 2D6, can cause dramatic increases in the blood level of type 1C antiarrhythmics, whereas sertraline, by acting on 3A4, may alter blood levels of carbamazepine or digoxin. Depending on drug specificity for a particular CYP enzyme for its own metabolism, concomitant medications or dietary factors, such as grapefruit juice, may in turn affect the efficacy or toxicity of the SSRI.

The MAOIs are highly effective, particularly in atypical depression, but the risk of hypertensive crisis following intake of tyramine-containing food or sympathomimetic drugs makes them inappropriate as first-line agents. Transdermal selegiline may avert this risk at low dose. Common side effects include orthostatic hypotension, weight gain, insomnia, and sexual dysfunction. MAOIs should not be used concomitantly with SSRIs, because of the risk of serotonin syndrome, or with TCAs, because of possible hyperadrenergic effects.

Electroconvulsive therapy is at least as effective as medication, but its use is reserved for treatment-resistant cases and delusional

depressions. Repetitive transcranial magnetic stimulation (rTMS) is approved for treatment-resistant depression and has been shown to have efficacy in several controlled trials. Vagus nerve stimulation (VNS) has also recently been approved for treatment-resistant depression, but its degree of efficacy is controversial. Some meta-analyses of low-intensity transcranial current stimulation (tCS) have shown a positive benefit over sham treatment, but whether this is comparable to or synergistic with antidepressant treatment is unclear. In off-label usage, intravenous ketamine, a dissociative anesthetic, and intranasal esketamine (an isomer that has FDA approval in treatment-resistant cases) have been shown to have short-term antidepressant efficacy, often after a single administration, suggesting a possible utility in addressing suicidality. Questions remain, however, about the risk/benefit ratio over the longer term. Psilocybin, a hallucinogen, has also shown some potential benefit in controlled administration. Lastly, deep brain stimulation of the ventral anterior limb of the internal capsule and of the subcallosal cingulate region have demonstrable efficacy in randomized experimental trials of treatment-resistant depression.

Postpartum depression may respond to any of the above interventions, but the FDA has recently approved the specific usage of brexanolone (Zulresso), administered in a continuous intravenous infusion over 60 h and found to result in symptomatic relief for at least 30 days. Sedation and loss of consciousness are possible adverse effects.

Regardless of the treatment undertaken, the response should be evaluated after ~2 months. Three-quarters of patients show improvement by this time, but if remission is inadequate, the patient should be questioned about compliance, and an increase in medication dose should be considered if side effects are not troublesome. If this approach is unsuccessful, referral to a mental health specialist is advised. Strategies for treatment resistance include selection of an alternative drug, combinations of antidepressants, and/or adjunctive treatment with other classes of drugs, including lithium, thyroid hormone, l-methylfolate, s-adenosylmethionine, n-acetyl cysteine, atypical antipsychotic agents, and dopamine agonists. In switching to a different monotherapy, other drugs from the same class appear to be as likely to be efficacious as choosing a drug from a different class. A large randomized trial (STAR-D) was unable to show preferential efficacy, but the addition of certain atypical antipsychotic drugs (quetiapine extended-release; aripiprazole; brexpiprazole) has received FDA approval, as has usage of a combined medication, olanzapine and fluoxetine (Symbyax). Patients whose response to an SSRI wanes over time may benefit from the addition of buspirone (10 mg tid) or pindolol (2–5 mg tid) or small amounts of a TCA such as nortriptyline (25 mg bid or tid). Most patients will show some degree of response, but aggressive treatment should be pursued until remission is achieved, and drug treatment should be continued for at least 6–9 months to prevent relapse. In patients who have had two or more episodes of depression, indefinite maintenance treatment should be considered. Pharmacogenomic testing focusing on cytochrome p450 allelic variation may sometimes be helpful in identifying individuals who are poor or rapid metabolizers, but assessing pharmacodynamic gene variants has not been shown to be cost-effective or affect clinical outcomes.

It is essential to educate patients both about depression and the benefits and side effects of medications they are receiving. Advice about stress reduction and cautions that alcohol may exacerbate depressive symptoms and impair drug response are helpful. Patients should be given time to describe their experience, their outlook, and the impact of the depression on them and their families. Occasional empathic silence may be as helpful for the treatment alliance as verbal reassurance. Controlled trials have shown that cognitive-behavioral and interpersonal therapies are effective in improving psychological and social adjustment and that a combined treatment approach is more successful than medication alone for many patients.

BIPOLAR DISORDER

Clinical Manifestations Bipolar disorder is characterized by unpredictable swings in mood from mania (or hypomania) to depression. Some patients suffer only from recurrent attacks of *mania*, which in its pure form is associated with increased psychomotor activity; excessive social extroversion; decreased need for sleep; impulsivity and impaired judgment; and expansive, elated, grandiose, and sometimes irritable mood **(Table 452-8)**. In severe mania, patients may experience delusions and paranoid thinking indistinguishable from schizophrenia. One-half of patients with bipolar disorder present not with euphoria but with a mixture of psychomotor agitation and activation, accompanied by dysphoria, anxiety, and irritability. It may be difficult to distinguish such a mixed state from agitated depression. In some bipolar patients (*bipolar II disorder*), the full criteria for mania are lacking, and the requisite recurrent depressions are separated by periods of mild activation and increased energy (hypomania). In *cyclothymic disorder*, there are numerous hypomanic periods, usually of relatively short duration, alternating with clusters of depressive symptoms that fail, either in severity or duration, to meet the criteria of major depression. The mood fluctuations are chronic and should be present for at least 2 years before the diagnosis is made.

Manic episodes typically emerge over a period of days to weeks, but onset within hours is possible, usually in the early-morning hours. An untreated episode of either depression or mania can be as short as several weeks or last as long as 8–12 months, and rare patients have an unremitting chronic course. The term *rapid cycling* is used for patients who have four or more episodes of either depression or mania in a given year. This pattern occurs in 15% of all patients, most of whom are women. In some cases, rapid cycling is linked to an underlying thyroid dysfunction, and in others, it is iatrogenically triggered by prolonged antidepressant treatment. Approximately one-half of patients have sustained difficulties in work performance and psychosocial functioning, with depressive phases being more responsible for impairment than mania.

Bipolar disorder is common, affecting ~1.5% of the population in the United States. Onset is typically between 20–30 years of age, but many individuals report premorbid symptoms in late childhood or early adolescence. The prevalence is similar for men and women; women are likely to have more depressive and men more manic

TABLE 452-8 Criteria for a Manic Episode

A. A distinct period of abnormally and persistently elevated, expansive, or irritable mood and abnormally and persistently increased goal-directed activity or energy, lasting at least 1 week and present most of the day, nearly every day (or any duration if hospitalization is necessary).

B. During the period of the mood disturbance and increased energy or activity, three (or more) of the following symptoms (four if the mood is only irritable) are present to a significant degree and represent a noticeable change from usual behavior:
   1. Inflated self-esteem or grandiosity.
   2. Decreased need for sleep (e.g., feels rested after only 3 h of sleep).
   3. More talkative than usual or pressure to keep talking.
   4. Flight of ideas or subjective experience that thoughts are racing.
   5. Distractibility (i.e., attention too easily drawn to unimportant or irrelevant external stimuli), as reported or observed.
   6. Increase in goal-directed activity (either socially, at work or school, or sexually) or psychomotor agitation (i.e., purposeless non-goal-directed activity).
   7. Excessive involvement in activities that have a high potential for painful consequences (e.g., engaging in unrestrained buying sprees, sexual indiscretions, or foolish business investments).

C. The mood disturbance is sufficiently severe to cause marked impairment in social or occupational functioning or to necessitate hospitalization to prevent harm to self or others, or there are psychotic features.

D. The episode is not attributable to the physiologic effects of a substance (e.g., a drug of abuse, a medication, or other treatment) or another medical condition.

episodes over a lifetime. Recognizing a bipolar diathesis in an individual who presents with a depressive episode but no history of mania is difficult but essential in optimizing treatment planning, because antidepressants may be contraindicated and result in symptom worsening and cycle acceleration. Suggestive features of bipolarity include a childhood onset, a history of antidepressant treatment failure, atypical features of hypersomnolence and weight gain, and marked irritability or impulsivity.

Differential Diagnosis The differential diagnosis of mania includes secondary mania induced by stimulant or sympathomimetic drugs, hyperthyroidism, AIDS, neurologic disorders such as Huntington's or Wilson's disease, frontotemporal dementia, and cerebrovascular accidents. Comorbidity with alcohol and substance abuse is common, either because of poor judgment and increased impulsivity or because of an attempt to self-treat the underlying mood symptoms and sleep disturbances.

Etiology and Pathophysiology Genetic predisposition to bipolar disorder is evident from family studies; the concordance rate for monozygotic twins approaches 80%. A number of risk genes that have been identified to date overlap with those conveying risk for other psychiatric disorders, such as schizophrenia and autism, implying some degree of shared pathophysiology. Replicated loci include the alpha subunit of the L-type calcium channel (*CACNA1C*), teneurin transmembrane protein 4 (*ODZ4*), ankyrin 3 (*ANK3*), neurocan (NCAN), and tetratricopeptide repeat and ankyrin repeat containing 1 (*TRANK1*). Common variants convey little individual risk, but collectively account for 25% of heritability. A few rarer, more penetrant variants have also been reported, but no causative mutations have as yet been confirmed. Similarly, no clear biomarkers have been identified, but there is evidence for circadian rhythm dysregulation and oxidative stress, mitochondrial, and endoplasmic reticulum abnormalities. Reported MRI findings include grey matter thinning in frontal, temporal, and parietal cortex.

TABLE 452-9 Clinical Pharmacology of Mood Stabilizers

AGENT AND DOSING	SIDE EFFECTS AND OTHER EFFECTS
Lithium	**Common Side Effects**
Starting dose: 300 mg bid or tid Therapeutic blood level: 0.8–1.2 meq/L	Nausea/anorexia/diarrhea, fine tremor, thirst, polyuria, fatigue, weight gain, acne, folliculitis, neutrophilia, hypothyroidism Blood level is increased by thiazides, tetracyclines, and NSAIDs Blood level is decreased by bronchodilators, verapamil, and carbonic anhydrase inhibitors *Rare side effects:* Neurotoxicity, renal toxicity, hypercalcemia, ECG changes
Valproic Acid	**Common Side Effects**
Starting dose: 250 mg tid Therapeutic blood level: 50–125 μg/mL	Nausea/anorexia, weight gain, sedation, tremor, rash, alopecia Inhibits hepatic metabolism of other medications *Rare side effects:* Pancreatitis, hepatotoxicity, Stevens-Johnson syndrome
Carbamazepine/Oxcarbazepine	**Common Side Effects**
Starting dose: 200 mg bid for carbamazepine, 150 mg bid for oxcarbazepine Therapeutic blood level: 4–12 μg/mL for carbamazepine	Nausea/anorexia, sedation, rash, dizziness/ataxia Carbamazepine, but not oxcarbazepine, induces hepatic metabolism of other medications *Rare side effects:* Hyponatremia, agranulocytosis, Stevens-Johnson syndrome
Lamotrigine	**Common Side Effects**
Starting dose: 25 mg/d	Rash, dizziness, headache, tremor, sedation, nausea *Rare side effect*: Stevens-Johnson syndrome

Abbreviations: ECG, electrocardiogram; NSAIDs, nonsteroidal anti-inflammatory drugs.

TREATMENT

Bipolar Disorder

(Table 452-9) Lithium carbonate is the mainstay of treatment in bipolar disorder, although sodium valproate and carbamazepine, as well as a number of second-generation antipsychotic agents (aripiprazole, asenapine, cariprazine, olanzapine, quetiapine, risperidone, ziprasidone), also have FDA approval for the treatment of acute mania. Oxcarbazepine is not FDA approved, but appears to enjoy carbamazepine's spectrum of efficacy. The response rate to lithium carbonate is 70–80% in acute mania, with beneficial effects appearing in 1–2 weeks. Lithium also has a prophylactic effect in prevention of recurrent mania and, to a lesser extent, in the prevention of recurrent depression, which is more difficult to treat than unipolar depression. A simple cation, lithium is rapidly absorbed from the gastrointestinal tract and remains unbound to plasma or tissue proteins. Some 95% of a given dose is excreted unchanged through the kidneys within 24 h.

Serious side effects from lithium are rare, but minor complaints such as gastrointestinal discomfort, nausea, diarrhea, polyuria, weight gain, skin eruptions, alopecia, and edema are common. Over time, urine-concentrating ability may be decreased, but significant nephrotoxicity is relatively rare. Lithium exerts an antithyroid effect by interfering with the synthesis and release of thyroid hormones. More serious side effects include tremor, poor concentration and memory, ataxia, dysarthria, and incoordination.

In the treatment of acute mania, lithium is initiated at 300 mg bid or tid, and the dose is then increased by 300 mg every 2–3 days to achieve blood levels of 0.8–1.2 meq/L. Because the therapeutic effect of lithium may not appear until after 7–10 days of treatment, adjunctive usage of lorazepam (1–2 mg every 4 h) or clonazepam (0.5–1 mg every 4 h) may be beneficial to control agitation. Antipsychotics are indicated in patients with severe agitation who respond only partially to benzodiazepines. Patients using lithium should be monitored closely, because the blood levels required to achieve a therapeutic benefit are close to those associated with toxicity.

Valproic acid may be more effective than lithium for patients who experience rapid cycling (i.e., more than four episodes a year) or who present with a mixed or dysphoric mania. Tremor and weight gain are the most common side effects; hepatotoxicity and pancreatitis are rare toxicities.

The recurrent nature of bipolar mood disorder necessitates maintenance treatment. A sustained blood lithium level of at least 0.8 meq/L is important for optimal prophylaxis and has been shown to reduce the risk of suicide, a finding not yet apparent for other mood stabilizers. Combinations of mood stabilizers together or with atypical antipsychotic drugs are sometimes required to maintain mood stability. Quetiapine extended release, olanzapine, risperidone, and lamotrigine have been approved for maintenance treatment as sole agents, in combination with lithium and with aripiprazole and ziprasidone as adjunctive drugs. Lurasidone, olanzapine/fluoxetine, and quetiapine are also approved to treat acute depressive episodes in bipolar disorder. Compliance is frequently an issue and often requires enlistment and education of concerned family members. Efforts to identify and modify psychosocial factors that may trigger episodes are important, as is an emphasis on lifestyle regularity (social rhythm therapy). Mobile apps for smartphones that alert the individual and clinician to changes in activity and speech are proving useful in early detection of behavioral change and in delivering clinical interventions and education. Antidepressant medications are sometimes required for the treatment of severe breakthrough depressions, but their use should generally be avoided during maintenance treatment because of the risk of precipitating mania or accelerating the cycle frequency. Alternative off-label agents for bipolar depression include pramipexole, modafinil, omega-3 fatty acids, and *N*-acetyl cysteine; interventions such as ECT, light therapy,

and rTMS may also be effective. Loss of efficacy over time may be observed with any of the mood-stabilizing agents. In such situations, an alternative agent or combination therapy is usually helpful.

SOMATIC SYMPTOM DISORDER

Many patients presenting in general medical practice, perhaps as many as 5–7%, will experience a somatic symptom(s) as particularly distressing and preoccupying, to the point that it comes to dominate their thoughts, feelings, and beliefs and interferes to a varying degree with everyday functioning. Although the absence of a medical explanation for these complaints was historically emphasized as a diagnostic element, it has been recognized that the patient's interpretation and elaboration of the experience is the critical defining factor and that patients with well-established medical causation may qualify for the diagnosis. Multiple complaints are typical, but severe single symptoms can occur as well. Comorbidity with depressive and anxiety disorders is common and may affect the severity of the experience and its functional consequences. Personality factors may be a significant risk factor, as may a low level of educational or socioeconomic status or a history of recent stressful life events. Cultural factors are relevant as well and should be incorporated into the evaluation. Individuals who have persistent preoccupations about having or acquiring a serious illness, but who do not have a specific somatic complaint, may qualify for a related diagnosis—illness anxiety disorder. The diagnosis of conversion disorder (functional neurologic symptom disorder) is used to specifically identify those individuals whose somatic complaints involve one or more symptoms of altered voluntary motor or sensory function that cannot be medically explained and that cause significant distress or impairment or require medical evaluation.

In *factitious illnesses*, the patient consciously and voluntarily produces physical symptoms of illness. The term *Munchausen's syndrome* is reserved for individuals with particularly dramatic, chronic, or severe factitious illness. In true factitious illness, the sick role itself is gratifying. A variety of signs, symptoms, and diseases have been either simulated or caused by factitious behavior, the most common including chronic diarrhea, fever of unknown origin, intestinal bleeding or hematuria, seizures, and hypoglycemia. Factitious disorder is usually not diagnosed until 5–10 years after its onset, and it can produce significant social and medical costs. In *malingering*, the fabrication derives from a desire for some external reward such as a narcotic medication or disability reimbursement.

TREATMENT

Somatic Symptom Disorder and Related Disorders

Patients with somatic symptom disorder are frequently subjected to many diagnostic tests and exploratory surgeries in an attempt to find their "real" illness. Such an approach is doomed to failure and does not address the core issue. Successful treatment is best achieved through behavior modification, in which access to the physician is tightly regulated and adjusted to provide a sustained and predictable level of support that is less clearly contingent on the patient's level of presenting distress. Visits can be brief and should not be associated with a need for a diagnostic or treatment action. Although the literature is limited, some patients may benefit from antidepressant treatment.

Any attempt to confront the patient usually creates a sense of humiliation and causes the patient to abandon treatment from that caregiver. A better strategy is to introduce psychological causation as one of a number of possible explanations in the differential diagnoses that are discussed. Without directly linking psychotherapeutic intervention to the diagnosis, the patient can be offered a face-saving means by which the pathologic relationship with the health care system can be examined and alternative approaches to life stressors developed. Specific medical treatments also may be indicated and effective in treating some of the functional consequences of conversion disorder.

FEEDING AND EATING DISORDERS

CLINICAL MANIFESTATIONS

Feeding and eating disorders constitute a group of conditions in which there is a persistent disturbance of eating or associated behaviors that significantly impair an individual's physical health or psychosocial functioning. In DSM-5 the described categories (with the exception of pica) are defined to be mutually exclusive in a given episode, based on the understanding that although they are phenotypically similar in some ways, they differ in course, prognosis, and effective treatment interventions. Compared with DSM-IV-TR, three disorders (i.e., avoidant/restrictive food intake disorder, rumination disorder, pica) that were previously classified as disorders of infancy or childhood have been grouped together with the disorders of anorexia and bulimia nervosa. Binge-eating disorder is also now included as a formal diagnosis; the intent of each of these modifications is to encourage clinicians to be more specific in their codification of eating and feeding pathology.

PICA

Pica is diagnosed when the individual, aged >2 years, eats one or more nonnutritive, nonfood substances for a month or more and requires medical attention as a result. There is usually no specific aversion to food in general but a preferential choice to ingest substances such as clay, starch, soap, paper, or ash. The diagnosis requires the exclusion of specific culturally approved practices and has not been commonly found to be caused by a specific nutritional deficiency. Onset is most common in childhood, but the disorder can occur in association with other major psychiatric conditions in adults. An association with pregnancy has been observed, but the condition is only diagnosed when medical risks are increased by the behavior.

RUMINATION DISORDER

In this condition, individuals who have no demonstrable associated gastrointestinal or other medical condition repeatedly regurgitate their food after eating and then either rechew or swallow it or spit it out. The behavior typically occurs on a daily basis and must persist for at least 1 month. Weight loss and malnutrition are common sequelae, and individuals may attempt to conceal their behavior, either by covering their mouth or through social avoidance while eating. In infancy, the onset is typically between 3 and 12 months of age, and the behavior may remit spontaneously, although in some it appears to be recurrent.

AVOIDANT/RESTRICTIVE FOOD INTAKE DISORDER

The cardinal feature of this disorder is avoidance or restriction of food intake, usually stemming from a lack of interest in or distaste of food and associated with weight loss, nutritional deficiency, dependency on nutritional supplementation, or marked impairment in psychosocial functioning, either alone or in combination. Culturally approved practices, such as fasting or a lack of available food, must be excluded as possible causes. The disorder is distinguished from anorexia nervosa by the presence of emotional factors, such as a fear of gaining weight and distortion of body image in the latter condition. Onset is usually in infancy or early childhood, but avoidant behaviors may persist into adulthood. The disorder is equally prevalent in males and females and is frequently comorbid with anxiety and cognitive and attention-deficit disorders and situations of familial stress. Developmental delay and functional deficits may be significant if the disorder is long-standing and unrecognized.

ANOREXIA NERVOSA

Individuals are diagnosed with anorexia nervosa if they restrict their caloric intake to a degree that their body weight deviates significantly from age, gender, health, and developmental norms and if they also exhibit a fear of gaining weight and an associated disturbance in body image. The condition is further characterized by differentiating those who achieve their weight loss predominantly through restricting intake or by excessive exercise (restricting type) from those who engage in recurrent binge eating and/or subsequent purging, self-induced vomiting, and usage of enemas, laxatives, or diuretics (binge-eating/purging

type). Such subtyping is more state- than trait-specific, as individuals may transition from one profile to the other over time. Determination of whether an individual satisfies the primary criterion of significant low weight is complex and must be individualized, using all available historical information and comparison of body habitus to international body-mass norms and guidelines.

Individuals with anorexia nervosa frequently lack insight into their condition and are in denial about possible medical consequences; they often are not comforted by their achieved weight loss and persist in their behaviors despite having met previously self-designated weight goals. Alterations in the circuitry of reward sensitivity and executive function have been reported in anorexia, implicating disturbances in frontal cortex and anterior insula regulation of interoceptive awareness of satiety and hunger. Neurochemical findings, including the role of ghrelin, remain controversial.

Onset is most common in adolescence, although onset in later life can occur. Many more females than males are affected, with a lifetime prevalence in women of up to 4%. The disorder appears most prevalent in post-industrialized and urbanized countries and is frequently comorbid with preexisting anxiety disorders. The medical consequences of prolonged anorexia nervosa are multisystemic and can be life-threatening in severe presentations. Changes in laboratory values may be present, including leukopenia with lymphocytosis, elevations in blood urea nitrogen, and metabolic alkalosis and hypokalemia when purging is present. History and physical examination may reveal amenorrhea in females, skin abnormalities (petechiae, lanugo hair, dryness), and signs of hypometabolic function, including hypotension, hypothermia, and sinus bradycardia. Endocrine effects include hypogonadism, growth hormone resistance, and hypercortisolemia. Osteoporosis is a longer-term concern.

The course of the disorder is variable, with some individuals recovering after a single episode, while others exhibit recurrent episodes or a chronic course. Untreated anorexia has a mortality of 5.1/1000, the highest among psychiatric conditions. Maudsley Anorexia Nervosa Treatment for Adults (MANTRA) and eating disorder–focused cognitive behavior therapy have proven to be effective therapies, with strict behavioral contingencies used when weight loss becomes critical. No pharmacologic intervention has proven to be specifically beneficial, but comorbid depression and anxiety should be treated. Weight gain should be undertaken gradually with a goal of 0.5–1 pound per week to prevent refeeding syndrome. Most individuals are able to achieve remission within 5 years of the original diagnosis.

BULIMIA NERVOSA

Bulimia nervosa describes individuals who engage in recurrent and frequent (at least once a week for 3 months) periods of binge eating and who then resort to compensatory behaviors, such as self-induced purging, enemas, use of laxatives, or excessive exercise, to avoid weight gain. Binge eating itself is defined as excessive food intake in a prescribed period of time, usually <2 h. As in anorexia nervosa, disturbances in body image occur and promote the behavior, but unlike in anorexia, individuals are of normal weight or even somewhat overweight. Subjects typically describe a loss of control and express shame about their actions, and often relate that their episodes are triggered by feelings of negative self-esteem or social stresses. The lifetime prevalence in women is ~2%, with a 10:1 female-to-male ratio. The disorder typically begins in adolescence and may be persistent over a number of years. Transition to anorexia occurs in only 10–15% of cases. Many of the medical risks associated with bulimia nervosa parallel those of anorexia nervosa and are a direct consequence of purging, including fluid and electrolyte disturbances and cardiac conduction abnormalities. Physical examination often results in no specific findings, but dental erosion and parotid gland enlargement may be present. Effective treatment approaches include SSRI antidepressants, usually in combination with cognitive-behavioral, emotion regulation, or interpersonal-based psychotherapies.

BINGE-EATING DISORDER

Binge-eating disorder is distinguished from bulimia nervosa by the absence of compensatory behaviors to prevent weight gain after an episode and by a lack of effort to restrict weight gain between episodes. Other features are similar, including distress over the behavior and the experience of loss of control, resulting in eating more rapidly or in greater amounts than intended or eating when not hungry. The 12-month prevalence in females is 1.6%, with a much lower female-to-male ratio than bulimia nervosa. Little is known about the course of the disorder, given its recent categorization, but its prognosis is markedly better than for other eating disorders, both in terms of its natural course and response to treatment. Transition to other eating disorder conditions is thought to be rare.

PERSONALITY DISORDERS

CLINICAL MANIFESTATIONS

Personality disorders are characteristic patterns of thinking, feeling, and interpersonal behavior that are relatively inflexible and cause significant functional impairment or subjective distress for the individual. The observed behaviors are not secondary to another mental disorder, nor are they precipitated by substance abuse or a general medical condition. This distinction is often difficult to make in clinical practice, because personality change may be the first sign of serious neurologic, endocrine, or other medical illness. Patients with frontal-lobe tumors, for example, can present with changes in motivation and personality while the results of the neurologic examination remain within normal limits. Individuals with personality disorders are often regarded as "difficult patients" in clinical medical practice because they are seen as excessively demanding and/or unwilling to follow recommended treatment plans. Although DSM-5 portrays personality disorders as qualitatively distinct categories, there is an alternative and emerging perspective that personality characteristics vary as a continuum between normal functioning and formal mental disorder, the essential features being moderate or greater impairment in self/interpersonal functioning and one or more pathological personality traits.

Personality disorders have been grouped into three overlapping clusters. *Cluster A* includes paranoid, schizoid, and schizotypal personality disorders. It includes individuals who are odd and eccentric and who maintain an emotional distance from others. Individuals have a restricted emotional range and remain socially isolated. Patients with schizotypal personality disorder frequently have unusual perceptual experiences and express magical beliefs about the external world. The essential feature of paranoid personality disorder is a pervasive mistrust and suspiciousness of others to an extent that is unjustified by available evidence. *Cluster B* disorders include antisocial, borderline, histrionic, and narcissistic types and describe individuals whose behavior is impulsive, excessively emotional, and erratic. *Cluster C* incorporates avoidant, dependent, and obsessive-compulsive personality types; enduring traits are anxiety and fear. The boundaries between cluster types are to some extent artificial, and many patients who meet criteria for one personality disorder also meet criteria for aspects of another. The risk of a comorbid major mental disorder is increased in patients who qualify for a diagnosis of personality disorder.

ETIOLOGY AND PATHOPHYSIOLOGY

Genetic studies have increasingly suggested a genetic contribution to the development of personality disorders. One study of 106,000 subjects identified nine loci significantly linked to aspects of neuroticism.

TREATMENT

Personality Disorders

Dialectical behavior therapy (DBT) is a cognitive-behavioral approach that focuses on behavioral change while providing acceptance, compassion, and validation of the patient. Several randomized trials have demonstrated the efficacy of DBT in the treatment of personality disorders. Antidepressant medications and low-dose

antipsychotic drugs have some efficacy in cluster A personality disorders, whereas anticonvulsant mood-stabilizing agents and MAOIs may be considered for patients with cluster B diagnoses who show marked mood reactivity, behavioral dyscontrol, and/or rejection hypersensitivity. Anxious or fearful cluster C patients often respond to medications used for axis I anxiety disorders (see above). It is important that the physician and the patient have reasonable expectations vis-à-vis the possible benefit of any medication used and its side effects. Improvement may be subtle and observable only over time.

SCHIZOPHRENIA

CLINICAL MANIFESTATIONS

Schizophrenia is a heterogeneous syndrome characterized by perturbations of language, perception, thinking, social activity, affect, and volition. There are no pathognomonic features. The syndrome commonly begins in late adolescence, has an insidious (and less commonly, acute) onset, and, often, a poor outcome, progressing from social withdrawal and perceptual distortions to recurrent delusions and hallucinations. Patients may present with positive symptoms (such as conceptual disorganization, delusions, or hallucinations) or negative symptoms (loss of function, anhedonia, decreased emotional expression, impaired concentration, and diminished social engagement) and must have at least two of these for a 1-month period and continuous signs for at least 6 months to meet formal diagnostic criteria. Disorganized thinking or speech and grossly disorganized motor behavior, including catatonia, may also be present. As individuals age, positive psychotic symptoms tend to attenuate, and some measure of social and occupational function may be regained. "Negative" symptoms predominate in one-third of the schizophrenic population and are associated with a poor long-term outcome and a poor response to drug treatment. However, marked variability in the course and individual character of symptoms is typical.

The term *schizophreniform disorder* describes patients who meet the symptom requirements but not the duration requirements for schizophrenia, and *schizoaffective disorder* is used for those who manifest symptoms of schizophrenia and independent periods of mood disturbance. The terms *schizotypal* and *schizoid* refer to specific personality disorders and are discussed in that section. The diagnosis of delusional disorder is used for individuals who have delusions of various content for at least 1 month but who otherwise do not meet criteria for schizophrenia. Patients who experience a sudden onset of a brief (<1 month) alteration in thought processing, characterized by delusions, hallucinations, disorganized speech, or gross motor behavior, are most appropriately designated as having a brief psychotic disorder. Catatonia is recognized as a nonspecific syndrome that can occur as a consequence of other severe psychiatric/medical disorders and is diagnosed by the documentation of three or more of a cluster of motor and behavioral symptoms, including stupor, cataplexy, mutism, waxy flexibility, and stereotypy, among others. Prognosis depends not on symptom severity but on the response to antipsychotic medication. A permanent remission without recurrence does occasionally occur. About 10% of schizophrenic patients commit suicide.

Schizophrenia is present in 0.85% of individuals worldwide, with a lifetime prevalence of ~1–1.5%. An estimated 300,000 episodes of acute schizophrenia occur annually in the United States, resulting in direct and indirect costs of $155.7 billion.

DIFFERENTIAL DIAGNOSIS

The diagnosis is principally one of exclusion, requiring the absence of significant associated mood symptoms, any relevant medical condition, and substance abuse. Drug reactions that cause hallucinations, paranoia, confusion, or bizarre behavior may be dose-related or idiosyncratic; parkinsonian medications, clonidine, quinacrine, and procaine derivatives are the most common prescription medications associated with these symptoms. Drug causes should be ruled out in any case of newly emergent psychosis. The general neurologic examination in patients with schizophrenia is usually normal, but motor rigidity, tremor, and dyskinesias are noted in one-quarter of untreated patients.

EPIDEMIOLOGY AND PATHOPHYSIOLOGY

Epidemiologic surveys identify several risk factors for schizophrenia, including genetic susceptibility, early developmental insults, winter birth, and increasing parental age. Genetic factors are involved in at least a subset of individuals who develop schizophrenia. Schizophrenia is observed in ~6.6% of all first-degree relatives of an affected proband. If both parents are affected, the risk for offspring is 40%. The concordance rate for monozygotic twins is 50%, compared to 10% for dizygotic twins. Schizophrenia-prone families are also at risk for other psychiatric disorders, including schizoaffective disorder and *schizotypal* and *schizoid personality disorders*, the latter terms designating individuals who show a lifetime pattern of social and interpersonal deficits characterized by an inability to form close interpersonal relationships, eccentric behavior, and mild perceptual distortions. Large-scale genomewide association studies have identified >100 small effect risk loci and a few larger effect copy number variants, along with epigenetic effects and have led to initial exploration in the clinical use of polygenic risk scores in diagnosis and prognosis. Pathways identified include ones involved in immunity, inflammation, and cell signaling.

TREATMENT

Schizophrenia

Antipsychotic agents **(Table 452-10)** are the cornerstone of acute and maintenance treatment of schizophrenia and are effective in the treatment of hallucinations, delusions, and thought disorders, regardless of etiology. The mechanism of action involves, at least in part, binding to dopamine D_2/D_3 receptors in the ventral striatum; the clinical potencies of traditional antipsychotic drugs parallel their affinities for the D_2 receptor, and even the newer "atypical" agents exert some degree of D_2 receptor blockade. All neuroleptics induce expression of the immediate-early gene c-*fos* in the nucleus accumbens, a dopaminergic site connecting prefrontal and limbic cortices. The clinical efficacy of newer atypical neuroleptics, however, may involve *N*-methyl-D-aspartate (NMDA) receptor blockade, α_1- and α_2-noradrenergic activity, altering the relationship between 5-HT_2 and D_2 receptor activity, and faster dissociation of D_2 binding and effects on neuroplasticity.

Conventional neuroleptics differ in their potency and side-effect profile. Older agents, such as chlorpromazine and thioridazine, are more sedating and anticholinergic and more likely to cause orthostatic hypotension, whereas higher-potency antipsychotics, such as haloperidol, perphenazine, and thiothixene, are more likely to induce extrapyramidal side effects. The model "atypical" antipsychotic agent is clozapine, a dibenzodiazepine that has a greater potency in blocking the 5-HT_2 than the D_2 receptor and a much higher affinity for the D_4 than the D_2 receptor. Its principal disadvantage is a risk of blood dyscrasias. Paliperidone is a metabolite of risperidone and shares many of its properties. Unlike other antipsychotics, clozapine does not cause a rise in prolactin levels. Approximately 30% of patients who do not benefit from conventional antipsychotic agents will have a better response to this drug, which also has a demonstrated superiority to other antipsychotic agents in preventing suicide; however, its side-effect profile makes it most appropriate for treatment-resistant cases. Risperidone, a benzisoxazole derivative, is more potent at 5-HT_2 than D_2 receptor sites, like clozapine, but it also exerts significant α_2 antagonism, a property that may contribute to its perceived ability to improve mood and increase motor activity. Risperidone is not as effective as clozapine in treatment-resistant cases but does not carry a risk of blood dyscrasias. Olanzapine is similar neurochemically to clozapine but has a significant risk of inducing weight gain. Quetiapine is distinct in having a weak D_2 effect but potent α_1 and histamine blockade. Ziprasidone causes minimal weight gain and is unlikely to increase prolactin but may increase QT prolongation. Aripiprazole also has little risk of weight gain or prolactin increase but may increase anxiety, nausea, and insomnia as a result of its partial

TABLE 452-10 Antipsychotic Agents

NAME	USUAL PO DAILY DOSE (mg)	SIDE EFFECTS	SEDATION	COMMENTS
First-Generation Antipsychotics				
Low potency				
Chlorpromazine (Thorazine)	100–1000	Anticholinergic effects; orthostasis; photosensitivity; cholestasis; QT prolongation	+++	EPSEs usually not prominent; can cause anticholinergic delirium in elderly patients
Thioridazine (Mellaril)	100–600			
Midpotency				
Trifluoperazine (Stelazine)	2–50	Fewer anticholinergic side effects	++	Well tolerated by most patients
Perphenazine (Trilafon)	4–64	Fewer EPSEs than with higher-potency agents	++	
Loxapine (Loxitane)	30–100	Frequent EPSEs	++	
Molindone (Moban)	30–100	Frequent EPSEs	0	Little weight gain
High potency				
Haloperidol (Haldol)	5–20	No anticholinergic side effects; EPSEs often prominent	0/+	Often prescribed in doses that are too high; long-acting injectable forms of haloperidol and fluphenazine available
Fluphenazine (Prolixin)	1–20	Frequent EPSEs	0/+	
Thiothixene (Navane)	2–50	Frequent EPSEs	0/+	
Second-Generation Antipsychotics				
Clozapine (Clozaril)	150–600	Agranulocytosis (1%); weight gain; seizures; drooling; hyperthermia	+ +	Requires weekly WBC count for first 6 months, then biweekly if stable
Risperidone (Risperdal)	2–8	Orthostasis	+	Requires slow titration; EPSEs observed with doses >6 mg qd
Olanzapine (Zyprexa)	10–30	Weight gain	++	Mild prolactin elevation
Quetiapine (Seroquel)	350–800	Sedation; weight gain; anxiety	+++	Bid dosing
Ziprasidone (Geodon)	120–200	Orthostatic hypotension	+/++	Minimal weight gain; increases QT interval
Aripiprazole (Abilify)	10–30	Nausea, anxiety, insomnia	0/+	Mixed agonist/antagonist; ER available
Paliperidone (Invega)	3–12	Restlessness, EPSEs, increased prolactin, headache	+	Active metabolite of risperidone
Iloperidone (Fanapt)	12–24	Dizziness, hypotension	0/+	Requires dose titration; long-acting injectable available
Asenapine (Saphris)	10–20	Dizziness, anxiety, EPSEs, minimal weight gain	++	Sublingual tablets; bid dosing
Lurasidone (Latuda)	40–80	Nausea, EPSEs	++	Uses CYP3A4
Brexpiprazole (Rexulti)	1–4	Anxiety, dizziness, fatigue	++	CYP3A4 and 2D6 interactions
Pimavanserin (Nuplazid)	34	Edema, confusion, sedation	++	Approved for Parkinson's disease psychosis
Cariprazine (Vraylar)	1.5–6	EPSEs, vomiting	++	Preferential D3 receptor affinity
Lumateperone (Caplyta)	42	Fatigue, dry mouth; no apparent metabolic/motor effects	++	5HTa>D2 receptor affinity

Abbreviations: EPSEs, extrapyramidal side effects; WBC, white blood cell.

agonist properties. Asenapine is associated with minimal weight gain and anticholinergic effect but may have a higher than expected risk of extrapyramidal symptoms (EPSs). Cariprazine, a D2/D3 partial agonist, has no QT or prolactin elevation risk, but can result in EPS as well.

Antipsychotic agents are effective in 70% of patients presenting with a first episode. Improvement may be observed within hours or days, but full remission usually requires 6–8 weeks. The choice of agent depends principally on the side-effect profile and cost of treatment or on a past personal or family history of a favorable response to the drug in question. Atypical agents appear to be more effective in treating negative symptoms and improving cognitive function. An equivalent treatment response can usually be achieved with relatively low doses of any drug selected (i.e., 4–6 mg/d of haloperidol, 10–15 mg of olanzapine, or 4–6 mg/d of risperidone). Doses in this range result in >80% D_2 receptor blockade, and there is little evidence that higher doses increase either the rapidity or degree of response. Maintenance treatment requires careful attention to the possibility of relapse and monitoring for the development of a movement disorder. Intermittent drug treatment is less effective than regular dosing, but gradual dose reduction is likely to improve social functioning in many schizophrenic patients who have been maintained at high doses. If medications are completely discontinued, however, the relapse rate is 60% within 6 months. Long-acting injectable preparations (risperidone, paliperidone, olanzapine, aripiprazole) are considered when noncompliance with oral therapy leads to relapses but should not be considered interchangeable, because the agents differ in their indications, injection intervals and sites/volumes, and possible adverse reactions, among other factors. In treatment-resistant patients, a transition to clozapine usually results in rapid improvement, but a prolonged delay in response in some cases necessitates a 6- to 9-month trial for maximal benefit to occur.

Antipsychotic medications can cause a broad range of side effects, including lethargy, weight gain, postural hypotension, constipation, and dry mouth. Extrapyramidal symptoms such as dystonia, akathisia, and akinesia are also frequent with first-generation agents and may contribute to poor adherence if not specifically addressed. Anticholinergic and parkinsonian symptoms respond well to trihexyphenidyl, 2 mg bid, or benztropine mesylate, 1–2 mg bid. Akathisia may respond to beta blockers. In rare cases, more serious and occasionally life-threatening side effects may emerge,

including hyperprolactinemia, ventricular arrhythmias, gastrointestinal obstruction, retinal pigmentation, obstructive jaundice, and neuroleptic malignant syndrome (characterized by hyperthermia, autonomic dysfunction, muscular rigidity, and elevated creatine phosphokinase levels). The most serious adverse effects of clozapine are agranulocytosis, which has an incidence of 1%, and induction of seizures, which has an incidence of 10%. Weekly white blood cell counts are required, particularly during the first 3 months of treatment.

The risk of type 2 diabetes mellitus appears to be increased in schizophrenia, and second-generation agents as a group, with the exception of lumateperone, produce greater adverse effects on glucose regulation, independent of effects on obesity, than traditional agents. Clozapine, olanzapine, and quetiapine seem more likely to cause hyperglycemia, weight gain, and hypertriglyceridemia than other atypical antipsychotic drugs. Close monitoring of plasma glucose and lipid levels is indicated with the use of these agents.

A serious side effect of long-term use of first-generation and, to a lesser extent, second-generation antipsychotic agents is tardive dyskinesia, characterized by repetitive, involuntary, and potentially irreversible movements of the tongue and lips (bucco-linguo-masticatory triad) and, in approximately half of cases, choreoathetosis. Tardive dyskinesia has an incidence of 2–4% per year of exposure and a prevalence of 20% in chronically treated patients. The prevalence increases with age, total dose, and duration of drug administration and may involve formation of free radicals and perhaps mitochondrial energy failure. Valbenazine, a vesicular monoamine transporter 2 inhibitor that depletes presynaptic dopamine, has recently received FDA approval for treatment of tardive dyskinesia.

The CATIE study, a large-scale investigation of the effectiveness of antipsychotic agents in "real-world" patients, revealed a high rate of discontinuation of treatment >18 months. Olanzapine showed greater effectiveness than quetiapine, risperidone, perphenazine, or ziprasidone but also a higher discontinuation rate due to weight gain and metabolic effects. Surprisingly, perphenazine, a first-generation agent, showed little evidence of inferiority to newer drugs.

Drug treatment of schizophrenia is by itself insufficient. Educational efforts directed toward families and relevant community resources have proved to be necessary to maintain stability and optimize outcome. A treatment model using social cognition interventions and involving a multidisciplinary case-management team that seeks out and closely follows the patient in the community has proved particularly effective. Attempts to prevent schizophrenia through early identification and treatment (both psychosocial and psychopharmacologic) of high-risk children and adolescents are currently being evaluated.

ASSESSMENT AND EVALUATION OF VIOLENCE

Primary care physicians may encounter situations in which family, domestic, or societal violence is discovered or suspected. Such an awareness can carry legal and moral obligations; many state laws mandate reporting of child, spousal, and elder abuse. Physicians are frequently the first point of contact for both victim and abuser. Approximately 2 million older Americans and 1.5 million U.S. children are thought to experience some form of physical maltreatment each year. Spousal abuse is thought to be even more prevalent. An interview study of 24,000 women in 10 countries found a lifetime prevalence of physical or sexual violence that ranged from 15–71%; these individuals are more likely to suffer from depression, anxiety, and substance abuse and to have attempted suicide. In addition, abused individuals frequently express low self-esteem, vague somatic symptomatology, social isolation, and a passive feeling of loss of control. Although it is essential to treat these elements in the victim, the first obligation is to ensure that the perpetrator has taken responsibility for preventing any further violence. Substance abuse and/or dependence and serious mental illness in the abuser may contribute to the risk of harm and require direct intervention. Depending on the situation, law enforcement agencies, community resources such as support groups and shelters, and individual and family counseling can be appropriate components of a treatment plan. A safety plan should be formulated with the victim, in addition to providing information about abuse, its likelihood of recurrence, and its tendency to increase in severity and frequency. Antianxiety and antidepressant medications may sometimes be useful in treating the acute symptoms, but only if independent evidence for an appropriate psychiatric diagnosis exists.

453 Alcohol and Alcohol Use Disorders

Marc A. Schuckit

Alcohol (beverage ethanol) has diverse and widespread effects on the body and impacts directly or indirectly on almost every neurochemical system in the brain. A large majority of patients in most clinical settings consume alcohol, with the highest proportions of drinkers of at least modest levels of alcohol seen in more educated and affluent patient groups. At even relatively low doses, this drug can exacerbate most medical problems and affect medications metabolized in the liver, and at higher doses, it can temporarily mimic many medical (e.g., diabetes) and psychiatric (e.g., depression) conditions. The lifetime risk for repetitive serious alcohol problems (e.g., alcohol use disorders as described below) in patients is at least 20% for men and 10% for women, regardless of a person's education or income, and U.S. yearly costs for these disorders exceed $249 billion. Although low doses of alcohol might have healthful benefits, drinking more than three standard drinks per day enhances the risk for cancer and vascular disease, and alcohol use disorders decrease the life span by ~10 years. Unfortunately, most clinicians have had only limited

training regarding identifying and treating alcohol-related disorders. This chapter presents a brief overview of clinically useful information about alcohol use and associated problems.

PHARMACOLOGY AND NUTRITIONAL IMPACT OF ETHANOL

Ethanol blood levels are expressed as milligrams or grams of ethanol per deciliter (e.g., 100 mg/dL = 0.10 g/dL), with values of ~0.02 g/dL resulting from the ingestion of one typical drink. In round figures, a standard drink is 10–12 g of ethanol, as seen in 340 mL (12 oz) of beer, 115 mL (4 oz) of nonfortified wine, and 43 mL (1.5 oz) (a shot) of 80-proof (40% ethanol by volume) beverage (e.g., whisky); 0.5 L (1 pint) of 80-proof beverage contains ~160 g of ethanol (~16 standard drinks), and 750 mL of wine contains ~60 g of ethanol. These beverages also have additional components (*congeners*) that affect the drink's taste and might contribute to adverse effects on the body. Congeners include methanol, butanol, acetaldehyde, histamine, tannins, iron, and lead. As a depressant drug, alcohol acutely decreases neuronal activity and has similar behavioral effects and cross-tolerance with other depressants, including benzodiazepines, barbiturates, and some anticonvulsants.

Alcohol is absorbed from mucous membranes of the mouth and esophagus (in small amounts), from the stomach and large bowel (in modest amounts), and from the proximal portion of the small intestine (the major site). The rate of absorption is increased by rapid gastric emptying (as seen with carbonation); by the absence of proteins, fats, or carbohydrates (which interfere with absorption); and by dilution to a modest percentage of ethanol (maximum at ~20% by volume).

Between 2% (at low blood alcohol concentrations) and 10% (at high blood alcohol concentrations) of ethanol is excreted directly through the lungs, urine, or sweat, but most is metabolized to acetaldehyde, primarily in the liver. The most important pathway occurs in the cell cytosol where alcohol dehydrogenase (ADH) produces acetaldehyde, which is then rapidly destroyed by aldehyde dehydrogenase (ALDH) in the cytosol and mitochondria **(Fig. 453-1)**. A second pathway occurs in the microsomes of the smooth endoplasmic reticulum (the microsomal ethanol-oxidizing system [MEOS]) that is responsible for ≥10% of ethanol oxidation at high blood alcohol concentrations.

Although a standard drink contains ~300 kJ, or 70–100 kcal, these are devoid of minerals, proteins, and vitamins. In addition, alcohol interferes with absorption of vitamins in the small intestine and decreases their storage in the liver with modest effects on folate (folacin or folic acid), pyridoxine (B_6), thiamine (B_1), nicotinic acid (niacin, B_3), and vitamin A.

Heavy drinking in a fasting, healthy individual can produce transient hypoglycemia within 6–36 h, secondary to the acute actions of ethanol that decrease gluconeogenesis. This can result in temporary abnormal glucose tolerance tests (with a resulting erroneous diagnosis of diabetes mellitus) until the heavy drinker has abstained for 2–4 weeks. Alcohol ketoacidosis, probably reflecting a decrease in fatty acid oxidation coupled with poor diet or persistent vomiting, can be misdiagnosed as diabetic ketosis. With alcohol-related ketoacidosis, patients show an increase in serum ketones along with a mild increase in glucose but a large anion gap, a mild to moderate increase in serum lactate, and a β-hydroxybutyrate/lactate ratio of between 2:1 and 9:1 (with normal being 1:1).

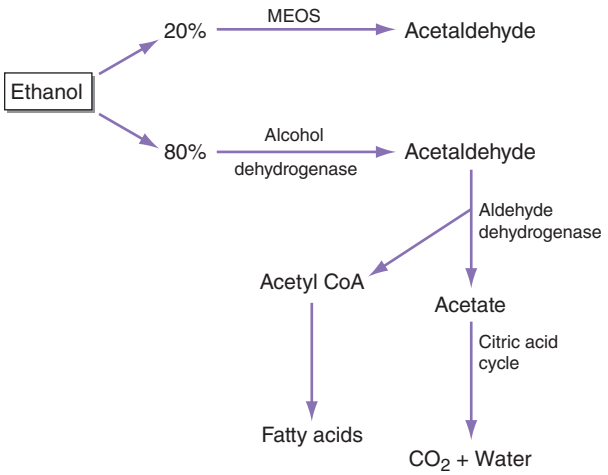

FIGURE 453-1 The metabolism of alcohol. CoA, coenzyme A; MEOS, microsomal ethanol oxidizing system.

In the brain, alcohol affects almost all neurotransmitter systems, with acute effects that are often the opposite of those seen following desistance after a period of heavy drinking. The most prominent acute actions relate to boosting γ-aminobutyric acid (GABA) activity, especially at $GABA_A$ receptors. Enhancement of this complex chloride channel system contributes to anticonvulsant, sleep-inducing, antianxiety, and muscle relaxation effects of all GABA-boosting drugs. Acutely administered alcohol produces a release of GABA, and continued use increases density of $GABA_A$ receptors, whereas alcohol withdrawal states are characterized by decreases in GABA-related activity. Equally important is the ability of acute alcohol to inhibit postsynaptic *N*-methyl-D-aspartate (NMDA) excitatory glutamate receptors, whereas chronic drinking and desistance are associated with an upregulation of these excitatory receptor subunits. The relationships between greater GABA and diminished NMDA receptor activity during acute intoxication and diminished GABA with enhanced NMDA actions during alcohol withdrawal explain much of intoxication and withdrawal phenomena.

As with all pleasurable activities, alcohol acutely increases dopamine levels in the ventral tegmentum and related brain regions, and this effect plays an important role in continued alcohol use, craving, and relapse. The changes in dopamine pathways are also linked to increases in "stress hormones," including cortisol and adrenocorticotropic hormone (ACTH), during intoxication and in the context of the stresses of withdrawal. Such alterations are likely to contribute to both feelings of reward during intoxication and depression during falling blood alcohol concentrations. Also closely linked to alterations in dopamine (especially in the nucleus accumbens) are alcohol-induced changes in opioid receptors, with acute alcohol causing release of β-endorphins.

Additional neurochemical changes include increases in synaptic levels of serotonin during acute intoxication and subsequent upregulation of serotonin receptors. Acute increases in nicotinic acetylcholine systems contribute to the impact of alcohol in the ventral tegmental region, which occurs in concert with enhanced dopamine activity. In the same regions, alcohol impacts on cannabinol receptors, with resulting release of dopamine, GABA, and glutamate as well as subsequent effects on brain reward circuits.

BEHAVIORAL EFFECTS, TOLERANCE, AND WITHDRAWAL

The acute effects of a drug depend on the dose, the rate of increase in plasma, the concomitant presence of other drugs, and past experience with the agent. "Legal intoxication" with alcohol in most states is based on a blood alcohol concentration of 0.08 g/dL, some states are considering lowering acceptable levels to <0.05 g/dL, and levels of 0.04 g/dL are cited for pilots in the United States and automobile drivers in some other countries. However, behavioral, psychomotor, and cognitive changes are seen at 0.02–0.04 g/dL (i.e., after one to two drinks) **(Table 453-1)**. Deep but disturbed sleep can be seen at 0.15 g/dL in individuals who have not developed tolerance, and death can occur with levels between 0.30 and 0.40 g/dL. Beverage alcohol is probably responsible for more overdose deaths than any other drug.

Repeated use of alcohol contributes to the need for a greater number of standard drinks to produce effects originally observed with fewer drinks (acquired tolerance), a phenomenon involving at least three compensatory mechanisms. (1) After 1–2 weeks of daily drinking, *metabolic* or *pharmacokinetic tolerance* can be seen, with up to 30% increases in the rate of hepatic ethanol metabolism. This alteration disappears almost as rapidly as it develops. (2) *Cellular or pharmacodynamic tolerance* develops through neurochemical changes that maintain relatively normal physiologic functioning despite the presence of alcohol. Subsequent decreases in blood levels contribute to symptoms

TABLE 453-1 Effects of Blood Alcohol Levels in the Absence of Tolerance

BLOOD LEVEL, g/dL	USUAL EFFECT
0.02	Decreased inhibitions, a slight feeling of intoxication
0.08	Decrease in complex cognitive functions and motor performance
0.20	Obvious slurred speech, motor incoordination, irritability, and poor judgment
0.30	Light coma and depressed vital signs
0.40	Death

of withdrawal. (3) Individuals learn to adapt their behavior so that they can function better than expected under the influence of the drug (*learned* or *behavioral tolerance*).

The cellular changes caused by chronic ethanol exposure may not resolve for several weeks or longer following cessation of drinking. Rapid decreases in blood alcohol levels before that time can produce a withdrawal syndrome, which is most intense during the first 5 days, but with some symptoms (e.g., disturbed sleep and anxiety) lasting up to 4–6 months as part of a "protracted withdrawal" syndrome.

THE EFFECTS OF ETHANOL ON ORGAN SYSTEMS

Relatively low doses of alcohol (one or two drinks per day) may have potential beneficial effects of increasing high-density lipoprotein cholesterol and decreasing aggregation of platelets, with a resulting possible decrease in risk for occlusive coronary disease and embolic strokes. Red wine has additional potential health-promoting qualities at relatively low doses due to flavinols and related substances. Such modest drinking might also decrease the risk for vascular dementia and, possibly, Alzheimer's disease. However, any potential healthful effects disappear with the regular consumption of three or more drinks per day, and knowledge about the deleterious effects of alcohol can both help the physician to identify patients with alcohol use disorders and supply them with information that might help motivate changes in behavior.

NERVOUS SYSTEM

Approximately 35% of drinkers overall, including as many as 50% of drinking college students and a much higher proportion of individuals with alcohol use disorders, ever experience a *blackout*. This is an episode of temporary anterograde amnesia, in which the person was awake but forgot all (en bloc blackouts at blood alcohol levels >0.20 mg/dL) or part (fragmentary blackouts at >0.12 mg/dL) of what occurred during a drinking period.

Another common problem, one seen after as few as one or two drinks shortly before bedtime, is disturbed sleep. Although alcohol might initially help a person fall asleep, it disrupts sleep throughout the rest of the night. The stages of sleep are altered, and times spent in rapid eye movement (REM) and deep sleep early in the night are reduced. Alcohol relaxes muscles in the pharynx, which can cause snoring and exacerbate sleep apnea; symptoms of the latter occur in 75% of men with alcohol use disorders aged ≥60 years. Patients may also experience prominent and sometimes disturbing dreams later in the night. All these sleep impairments can contribute to relapses to drinking in persons with alcohol use disorders.

Other common consequences of alcohol use even at relatively low alcohol levels are impaired judgment and coordination, which increase the risk of injuries. In the United States, ~40% of drinkers have at some time driven while intoxicated. Heavy drinking can also be associated with headache, thirst, nausea, vomiting, and fatigue the following day, a hangover syndrome that is responsible for much missed work and school time and temporary cognitive deficits.

Chronic high alcohol doses cause *peripheral neuropathy* in ~10% of individuals with alcohol use disorders: similar to diabetes, patients experience bilateral limb numbness, tingling, and paresthesias, all of which are more pronounced distally. Approximately 1% of those with alcohol use disorders develop *cerebellar degeneration* or *atrophy*, producing a syndrome of progressive unsteady stance and gait often accompanied by mild nystagmus; neuroimaging studies reveal atrophy of the cerebellar vermis. Perhaps 1 in 500 individuals with alcohol use disorders develop full *Wernicke's* (ophthalmoparesis, ataxia, and encephalopathy) and *Korsakoff's* (severe retrograde and anterograde amnesia) *syndromes*, although a higher proportion has one or more neuropathologic findings related to these conditions. These result from low levels of thiamine, especially in predisposed individuals with transketolase deficiencies. Repeated heavy drinking can contribute to *cognitive problems* and temporary memory impairment lasting for weeks to months after abstinence. Brain atrophy, evident as ventricular enlargement and widened cortical sulci on magnetic resonance imaging (MRI) and computed tomography (CT) scans, occurs in ~50% of individuals with long-term alcohol use disorders; these changes are usually reversible if abstinence is maintained. Adolescents may be especially vulnerable to alcohol-related brain changes, as indicated by preclinical studies and prospective investigations in humans suggesting that alcohol exposure in the developing brain may adversely impact future cognitive processes related to cognition, reward recognition, and cue processing. There is no single "alcoholic dementia" syndrome; rather, this label describes patients who have irreversible cognitive changes (possibly from diverse causes) in the context of chronic alcohol use disorders.

Psychiatric Comorbidity As many as two-thirds of individuals with alcohol use disorders meet criteria for another independent or temporary substance-induced psychiatric syndrome as defined in the fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5) of the American Psychiatric Association **(Chap. 452)**. A substantial proportion of those with independent psychiatric conditions (i.e., not just temporary symptoms only seen during intoxication or withdrawal) relate to a preexisting antisocial personality disorder (ASPD) manifesting as severe impulsivity and disinhibition that contribute to both alcohol and drug use disorders. The lifetime ASPD risk is 3% in males, and ≥80% of such individuals demonstrate alcohol- and/or drug-related conditions. Another common psychiatric comorbidity occurs with problems regarding other substances of abuse. The remainder of individuals with alcohol use disorders who have an independent psychiatric syndrome relate to preexisting conditions such as schizophrenia, manic-depressive disease, posttraumatic stress disorder, or anxiety syndromes such as panic disorder. The comorbidities of alcohol use disorders with independent psychiatric disorders might represent an overlap in genetic vulnerabilities, impaired judgment regarding the use of alcohol from the independent psychiatric condition, or an attempt to use alcohol to alleviate symptoms of the disorder or side effects of medications.

Many alcohol-related psychiatric syndromes can be seen *temporarily* during heavy drinking and subsequent withdrawal. These alcohol-induced conditions include an intense *sadness* lasting for days to weeks in the midst of heavy drinking seen in 40% of individuals with alcohol use disorders, which tends to disappear over several weeks of abstinence (alcohol-induced mood disorder); 10–30% have temporary severe *anxiety*, often beginning during alcohol withdrawal, which can persist for a month or more after cessation of drinking (alcohol-induced anxiety disorder); and 3–5% have auditory *hallucinations* and/or paranoid delusions while they are otherwise alert and oriented (*alcohol-induced psychotic disorder*).

Treatment of all forms of alcohol-induced psychopathology includes helping patients achieve abstinence and offering supportive care, as well as reassurance and "talk therapy" such as cognitive-behavioral approaches. However, with the exception of short-term antipsychotic medications for substance-induced psychoses, substance-induced psychiatric conditions only rarely require medications. Recovery is likely within several days to 4 weeks of abstinence. Conversely, because alcohol-induced conditions are temporary and do not indicate a need for long-term pharmacotherapy, a history of heavy alcohol intake is an important part of the workup for any patient who presents with any of these psychiatric symptoms.

THE GASTROINTESTINAL SYSTEM

Esophagus and Stomach Alcohol can cause inflammation of the esophagus and stomach causing epigastric distress and gastrointestinal bleeding, making alcohol one of the most common causes of hemorrhagic gastritis. Violent vomiting can produce severe bleeding through a Mallory-Weiss lesion, a longitudinal tear in the mucosa at the gastroesophageal junction.

Pancreas and Liver The incidence of acute pancreatitis (~25 per 1000 per year) is almost threefold higher in individuals with alcohol use disorders than in the general population, accounting for an estimated 10% or more of the total cases. Alcohol impairs gluconeogenesis in the liver, resulting in a fall in the amount of glucose produced from glycogen, increased lactate production, and decreased oxidation of fatty acids. These contribute to an increase in fat accumulation in liver cells. In healthy individuals, these changes are reversible, but with repeated exposure to ethanol, especially daily heavy drinking, more severe changes in the liver occur, including alcohol-induced hepatitis, perivenular sclerosis, and cirrhosis, with the latter observed in an estimated 15% of individuals with alcohol use disorders **(Chap. 342)**. Perhaps through an enhanced vulnerability to infections, individuals with alcohol use disorders have an elevated rate of hepatitis C, and drinking in the context of that disease is associated with more severe liver deterioration.

CANCER

As few as 1.5 drinks per day increases a woman's risk of breast cancer 1.4-fold. For both sexes, four drinks per day increases the risk for oral and esophageal cancers approximately threefold and rectal cancers by a factor of 1.5; seven to eight or more drinks per day produces an approximately fivefold increased risk for many other cancers. These consequences may result directly from cancer-promoting effects of alcohol and acetaldehyde or indirectly by interfering with immune homeostasis.

HEMATOPOIETIC SYSTEM

Ethanol causes an increase in red blood cell size (mean corpuscular volume [MCV]), which reflects its effects on stem cells. If heavy drinking is accompanied by folic acid deficiency, there can also be hypersegmented neutrophils, reticulocytopenia, and a hyperplastic bone marrow; if malnutrition is present, sideroblastic changes can be observed. Chronic heavy drinking can decrease production of white blood cells, decrease granulocyte mobility and adherence, and impair delayed-hypersensitivity responses to novel antigens (with a possible false-negative tuberculin skin test). Associated immune deficiencies can contribute to vulnerability toward infections, including hepatitis and HIV, and interfere with their treatment. Finally, many individuals with alcohol use disorders have mild thrombocytopenia, which usually resolves within a week of abstinence unless there is hepatic cirrhosis or congestive splenomegaly.

CARDIOVASCULAR SYSTEM

Acutely, ethanol decreases myocardial contractility and causes peripheral vasodilation, with a resulting mild decrease in blood pressure and a compensatory increase in cardiac output. Exercise-induced increases in cardiac oxygen consumption are higher after alcohol intake. These acute effects have little clinical significance for the average healthy drinker but can be problematic when persisting cardiac disease is present.

The consumption of three or more drinks per day results in a dose-dependent increase in blood pressure, which returns to normal within weeks of abstinence. Thus, heavy drinking is an important factor in mild to moderate hypertension. Chronic heavy drinkers also have a sixfold increased risk for coronary artery disease, related, in part, to increased low-density lipoprotein cholesterol, and carry an increased risk for cardiomyopathy through direct effects of alcohol on heart muscle. Symptoms of the latter include unexplained arrhythmias in the presence of left ventricular impairment, heart failure, hypocontractility of heart muscle, and dilation of all four heart chambers with associated potential mural thrombi and mitral valve regurgitation. Atrial or ventricular arrhythmias, especially paroxysmal tachycardia, can also occur temporarily after heavy drinking in individuals showing no other evidence of heart disease—a syndrome known as the "holiday heart."

GENITOURINARY SYSTEM CHANGES, SEXUAL FUNCTIONING, AND FETAL DEVELOPMENT

Heavy drinking in adolescence can affect normal sexual development and reproductive onset. At any age, modest ethanol doses (e.g., blood alcohol concentrations of 0.06 g/dL) can increase sexual drive but also decrease erectile capacity in men. Even in the absence of liver impairment, a significant minority of chronic heavy drinking men show irreversible testicular atrophy with shrinkage of the seminiferous tubules, decreases in ejaculate volume, and a lower sperm count **(Chap. 391)**.

The repeated ingestion of high doses of ethanol by women can result in amenorrhea, a decrease in ovarian size, absence of corpora lutea with associated infertility, and an increased risk of spontaneous abortion. Drinking during pregnancy results in the rapid placental transfer of both ethanol and acetaldehyde, which may contribute to a range of consequences known as fetal alcohol spectrum disorder (FASD). One severe result is the *fetal alcohol syndrome* (FAS), seen in ~5% of children born to heavy-drinking mothers, which can include any of the following: facial changes with epicanthal eye folds; poorly formed ear concha; small teeth with faulty enamel; cardiac atrial or ventricular septal defects; an aberrant palmar crease and limitation in joint movement; and microcephaly with intellectual impairment. Less pervasive FASD conditions include combinations of low birth weight, a lower intelligence quotient (IQ), hyperactive behavior, and some modest cognitive deficits. The amount of ethanol required and the time of vulnerability during pregnancy have not been defined, making it advisable for pregnant women to abstain from alcohol completely.

OTHER EFFECTS

Between one-half and two-thirds of individuals with alcohol use disorders have skeletal muscle weakness caused by acute *alcoholic myopathy*, a condition that improves but that might not fully remit with abstinence. Effects of repeated heavy drinking on the *skeletal system* include changes in calcium metabolism, lower bone density, and decreased growth in the epiphyses, leading to an increased risk for fractures and osteonecrosis of the femoral head. *Hormonal changes* include an increase in cortisol levels, which can remain elevated during heavy drinking; inhibition of vasopressin secretion at rising blood alcohol concentrations and enhanced secretion at falling blood alcohol concentrations (with the final result that most individuals with alcohol use disorders are likely to be slightly overhydrated); a modest and reversible decrease in serum thyroxine (T_4); and a more marked decrease in serum triiodothyronine (T_3). Hormone irregularities may disappear after a month or more of abstinence.

ALCOHOL USE DISORDERS

Because many drinkers occasionally imbibe to excess, temporary alcohol-related problems are common, especially in the late teens to the late twenties. However, repeated problems in multiple life areas can indicate an alcohol use disorder as defined in DSM-5.

DEFINITIONS AND EPIDEMIOLOGY

An *alcohol use disorder* (also called *alcoholism* or *alcohol dependence* in prior diagnostic manuals) is defined as repeated alcohol-related difficulties in at least 2 of 11 life areas that cluster together in the same 12-month period **(Table 453-2)**. Ten of the 11 items in DSM-5 (published in 2013) were taken directly from the 7 dependence and 4 abuse criteria in DSM-IV, after deleting legal problems and adding craving. Severity of an alcohol use disorder is based on the number of items endorsed: mild is two or three items; moderate is four or five; and severe is six or more of the criterion items. The 2013 diagnostic approach is similar enough to DSM-IV that the following descriptions of associated phenomena are still accurate.

The lifetime risk for an alcohol use disorder in most Western countries is ~10–20% for men and 5–10% for women; higher rates are seen in individuals who seek help from health care deliverers. Between 2001

TABLE 453-2 *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition, Classification of Alcohol Use Disorder (AUD)

Criteria
Two or more of the following items occurring in the same 12-month period must be endorsed for the diagnosis of an alcohol use disorder[a]:
Drinking resulting in recurrent failure to fulfill role obligations
Recurrent drinking in hazardous situations
Continued drinking despite alcohol-related social or interpersonal problems
Tolerance
Withdrawal, or substance use for relief/avoidance of withdrawal
Drinking in larger amounts or for longer than intended
Persistent desire/unsuccessful attempts to stop or reduce drinking
Great deal of time spent obtaining, using, or recovering from alcohol
Important activities given up/reduced because of drinking
Continued drinking despite knowledge of physical or psychological problems caused by alcohol
Alcohol craving

[a] *Mild AUD:* 2–3 criteria required; *moderate AUD*: 4–5 items endorsed; *severe AUD:* 6 or more items endorsed.

and 2013, the proportion of the U.S. population with a current (i.e., past 12 months) alcohol use disorder increased by 49% with increases of almost 100% in women, African Americans, and individuals aged ≥45. Rates are similar in the United States, Canada, Germany, Australia, and the United Kingdom; tend to be lower in most Mediterranean countries, such as Italy, Greece, and Israel; and may be higher in Ireland, France, Eastern Europe (e.g., Russia), and Scandinavia. An even higher lifetime prevalence has been reported for most native cultures, including Native Americans, Eskimos, Maori groups, and aboriginal tribes of Australia. These differences in prevalence reflect both cultural and genetic influences, as described below. In Western countries, the typical person with an alcohol use disorder is more often a blue- or white-collar worker or homemaker. The lifetime risk for this disorder among physicians is similar to that of the general population.

GENETICS

Approximately 60% of the risk for alcohol use disorders is attributed to genes, as indicated by the fourfold higher risk in children with an alcohol use disorder parent (even if adopted early in life and raised by nonalcoholics) and a higher risk in identical twins compared to fraternal twins of affected individuals. Like most medical and psychiatric conditions that are referred to as complex genetically influenced disorders, the risk for alcohol use disorders is related to hundreds of gene variations, each of which explains <1% of the vulnerability. These genetic variations operate primarily through intermediate characteristics that subsequently combine with environmental influences to alter the risk for heavy drinking and alcohol problems. These include genes relating to a high risk for all substance use disorders that operate through impulsivity, schizophrenia, and bipolar disorder. Another characteristic, an intense skin flushing response when drinking, decreases the risk for only alcohol use disorders through gene variations for several alcohol-metabolizing enzymes, especially ALDH (a mutation only seen in Japanese, Chinese, and Korean individuals), and to a lesser extent, variations in ADH.

An additional genetically influenced characteristic that increases the risk for heavy drinking, a low level of response or low sensitivity to alcohol, can be seen very early in the drinking career and before acquired tolerance or alcohol used disorders develop. The low response per drink operates, in part, through variations in genes relating to calcium and potassium channels, GABA, nicotinic, dopamine, and serotonin systems. Prospective studies have demonstrated that this need for higher doses of alcohol to achieve effects predicts future heavy drinking, alcohol problems, and alcohol use disorders, but not problems with drugs other than alcohol. The impact of a low response to alcohol on adverse drinking outcomes is partially mediated by a range of environmental and attitudinal influences, including the selection of heavier-drinking friends, more positive expectations of the effects of high doses of alcohol, and using alcohol to cope with stress. Several studies of college freshmen demonstrated that helping students who have a low sensitivity to alcohol modify these influences was associated with lower drinking quantities and fewer alcohol-related problems over the subsequent year.

NATURAL HISTORY

Although the average age of the first drink (~15 years) is similar in individuals who do and do not go on to develop alcohol use disorders, an earlier onset of regular drinking and drunkenness, especially in the context of conduct problems, is associated with a higher risk for later alcohol-related diagnoses. By the mid-twenties, most nonalcoholic men and women begin to moderate their drinking (perhaps learning from negative consequences), whereas those with alcohol use disorders are likely to escalate their drinking despite difficulties. The first major life problem from alcohol often appears in the late teens to early twenties, and a pattern of multiple alcohol difficulties by the mid-twenties. Once established, the course is likely to include exacerbations and remissions, with little difficulty in temporarily stopping or controlling alcohol use when problems develop, but without help, desistance usually gives way to escalations in alcohol intake and subsequent problems. Following treatment, between half and two-thirds of those with alcohol use disorders maintain abstinence for at least a year and often permanently. Even without formal treatment or self-help groups, there is at least a 20% chance of spontaneous remission with long-term abstinence. However, should the individual continue to drink heavily, the life span is shortened by ~10 years on average, with the leading causes of early death being enhanced rates of heart disease, cancer, accidents, and suicide.

TREATMENT

The approach to treating alcohol-related conditions is relatively straightforward: (1) recognize that at least 20% of patients have an alcohol use disorder; (2) learn how to identify and treat acute alcohol-related conditions (e.g., severe intoxication); (3) know how to help patients begin to address their alcohol problems; and (4) know how to treat alcohol withdrawal symptoms and to appropriately refer patients for additional help.

IDENTIFICATION OF PATIENTS WITH ALCOHOL USE DISORDERS

Even in affluent locales, the ~20% of patients who have an alcohol use disorder can be identified by asking questions about *alcohol problems* and noting laboratory test results that can reflect regular consumption of six to eight or more drinks per day. The two blood tests with ≥60% sensitivity and specificity for heavy alcohol consumption are γ-glutamyl transferase (GGT) (>35 U) and carbohydrate-deficient transferrin (CDT) (>20 U/L or >2.6%); the combination of the two tests is likely to be more accurate than either alone. The values for these serologic markers are likely to return toward normal within several weeks of abstinence. Other useful blood tests include high-normal MCVs (≥91 μm^3) and serum uric acid (>416 mol/L, or 7 mg/dL).

The diagnosis of an alcohol use disorder ultimately rests on the documentation of a pattern of repeated difficulties associated with alcohol (Table 453-2). Thus, in screening, it is important to probe for marital or job problems, legal difficulties, histories of accidents, medical problems, evidence of tolerance, and so on, and then attempt to relate these issues to use of alcohol. Some standardized questionnaires can be helpful, including the 10-item Alcohol Use Disorders Identification Test (AUDIT) **(Table 453-3)**, but these are only screening tools, and a face-to-face interview is still required for a meaningful diagnosis.

TREATMENT

Alcohol-Related Conditions

ACUTE INTOXICATION

The first priority in treating severe intoxication is to assess vital signs and manage respiratory depression, cardiac arrhythmias, and blood pressure instability, if present. The possibility of intoxication

TABLE 453-3 The Alcohol Use Disorders Identification Test (AUDIT)[a]

ITEM	5-POINT SCALE (LEAST TO MOST)
1. How often do you have a drink containing alcohol?	Never (0) to 4+ per week (4)
2. How many drinks containing alcohol do you have on a typical day?	1 or 2 (0) to 10+ (4)
3. How often do you have six or more drinks on one occasion?	Never (0) to daily or almost daily (4)
4. How often during the last year have you found that you were not able to stop drinking once you had started?	Never (0) to daily or almost daily (4)
5. How often during the last year have you failed to do what was normally expected from you because of drinking?	Never (0) to daily or almost daily (4)
6. How often during the last year have you needed a first drink in the morning to get yourself going after a heavy drinking session?	Never (0) to daily or almost daily (4)
7. How often during the last year have you had a feeling of guilt or remorse after drinking?	Never (0) to daily or almost daily (4)
8. How often during the last year have you been unable to remember what happened the night before because you had been drinking?	Never (0) to daily or almost daily (4)
9. Have you or someone else been injured as a result of your drinking?	No (0) to yes, during the last year (4)
10. Has a relative, friend, doctor, or other health worker been concerned about your drinking or suggested that you should cut down?	No (0) to yes, during the last year (4)

[a]The AUDIT is scored by simply summing the values associated with the endorsed response. A score ≥8 may indicate harmful alcohol use.

with other drugs should be considered by obtaining, if needed, toxicology screens for other central nervous system (CNS) depressants such as benzodiazepines and for opioids. Aggressive behavior should be handled by offering reassurance but also by calling for help from an intervention team. If the aggressive behavior continues, relatively low doses of a short-acting benzodiazepine such as lorazepam (e.g., 1–2 mg PO or IV) may be used and can be repeated as needed, but care must be taken not to destabilize vital signs or worsen confusion. An alternative approach is to use an antipsychotic medication (e.g., olanzapine 2.5–10 mg IM repeated at 2 and 6 h, if needed).

INTERVENTION

There are two main elements to highlighting the need for compliance with treatment in a person with an alcohol use disorder: motivational interviewing and brief interventions. During motivational interviewing, the clinician helps the patient to think through the assets (e.g., comfort in social situations) and liabilities (e.g., health- and interpersonal-related problems) of the current pattern of drinking. The clinician should listen empathetically to the responses, help the patient weigh options, and encourage the taking of responsibility for needed changes. Patients should be reminded that only they can decide to avoid the consequences that will occur if heavy drinking continues. The process of brief intervention, a similar approach, has been summarized by the acronym FRAMES: *F*eedback to the patient; *R*esponsibility to be taken by the patient; *A*dvice, rather than orders, on what needs to be done; *M*enus of options that might be considered; *E*mpathy for understanding the patient's thoughts and feelings; and *S*elf-efficacy, i.e., offering support for the capacity of the patient to make changes.

Once the patient begins to consider change, the discussions can focus more on the consequences of high alcohol consumption, suggested approaches to stopping drinking, and help in recognizing and avoiding situations likely to lead to heavy drinking such as going to night clubs or associating with heavy drinking friends. Both motivational interviewing and brief interventions can be carried out in 15-min sessions, but because patients often do not change behavior immediately, multiple meetings are often required to explore the problem and possible options, discuss optimal treatments, and explain the benefits of abstinence.

ALCOHOL WITHDRAWAL

If the patient agrees to stop drinking, sudden decreases in alcohol intake can produce withdrawal symptoms, most of which are the opposite of those produced by intoxication. Features include tremor of the hands (shakes); agitation and anxiety; autonomic nervous system overactivity including an increase in pulse, respiratory rate, sweating, and body temperature; and insomnia. These symptoms usually begin within 5–10 h of decreasing ethanol intake, peak on day 2 or 3, and improve by day 4 or 5, although mild levels of these problems may persist for 4–6 months as a protracted abstinence syndrome.

About 2% of individuals with alcohol use disorders experience a withdrawal seizure, with the risk increasing in the context of older age, concomitant medical problems, misuse of additional drugs, and higher alcohol quantities. The same risk factors also contribute to the ~1% rate of withdrawal delirium, also known as *delirium tremens* (DTs), where the withdrawal includes delirium (mental confusion, agitation, and fluctuating levels of consciousness) associated with a tremor and autonomic overactivity (e.g., marked increases in pulse, blood pressure, and respirations). The risks for seizures and DTs can be diminished by identifying and treating underlying medical conditions early in the course of withdrawal and by instituting adequate doses of depressant medications such as benzodiazepines.

Thus, the first step in dealing with possible withdrawal phenomena is a thorough physical examination in all heavy drinkers who are considering abstinence. This includes evaluation of possible liver impairment, gastrointestinal bleeding, cardiac arrhythmias, infection, and glucose or electrolyte imbalances. It is also important to offer adequate nutrition and oral multiple B vitamins, including 50–100 mg of oral thiamine daily for a week or more. Because most patients with alcohol use disorders who enter withdrawal are either normally hydrated or mildly overhydrated, IV fluids should be avoided unless there is a relevant medical problem or significant recent bleeding, vomiting, or diarrhea.

The next step is to recognize that because withdrawal symptoms reflect the rapid removal of a CNS depressant, alcohol, the symptoms can be controlled by administering any depressant in doses that decrease symptoms (e.g., a rapid pulse and tremor) and then tapering the dose over 3–5 days. Although most depressants are effective, benzodiazepines **(Chap. 452)** have the most supportive data for use in this situation, combining a high level of safety and low cost. Short-half-life benzodiazepines can be considered for patients with serious liver impairment or evidence of significant brain damage, but they must be given every 4 h to avoid abrupt blood-level fluctuations that may increase the risk for seizures. Therefore, most clinicians use drugs with longer half-lives (e.g., chlordiazepoxide), adjusting the dose if signs of withdrawal escalate and withholding the drug if the patient is sleeping or has orthostatic hypotension. The average patient requires 25–50 mg of chlordiazepoxide or 10 mg of diazepam given PO every 4–6 h on the first day, with doses then decreased to zero over the next 5 days. Although alcohol withdrawal can be treated in a hospital, patients in good physical condition who demonstrate mild signs of withdrawal despite low blood alcohol concentrations and who have no prior history of DTs or withdrawal seizures can be considered for outpatient detoxification. For the next 4 or 5 days, these patients should receive only 1 or 2 days of medications at a time and return daily for evaluation of vital signs. They can be hospitalized if signs and symptoms of withdrawal markedly escalate.

Treatment of patients with DTs can be challenging, and the condition is likely to run a course of 3–5 days regardless of the therapy used. However, conditions that meet the criteria for DTs outlined above represent medical emergencies that carry an estimated mortality as high as 5%, and treatment is best carried out in an intensive care unit by well-trained clinicians who closely monitor vital signs.

Medications can include high-dose benzodiazepines (e.g., as much as 800 mg/d of chlordiazepoxide has been reported) or, for those who do not respond to that regimen, closely monitored doses of propofol or dexmedetomidine. The focus of care is to identify and correct medical problems and to control behavior and prevent injuries. Antipsychotic medications are not recommended for treatment of alcohol withdrawal symptoms; although antipsychotics are less likely than benzodiazepines to exacerbate confusion, they may increase the risk of seizures.

Generalized withdrawal seizures rarely require more than the administration of an adequate dose of benzodiazepines. There is little evidence that anticonvulsants such as phenytoin or gabapentin are more effective than benzodiazepines for alcohol-withdrawal seizures, and the risk of seizures has usually passed by the time effective drug levels are reached. The rare patient with status epilepticus must be treated aggressively **(Chap. 425)**.

HELPING INDIVIDUALS WITH ALCOHOL USE DISORDERS TO STOP DRINKING: THE REHABILITATION PHASE

An Overview After completing alcoholic rehabilitation, ≥60% of individuals with alcohol use disorders, especially highly functioning patients, maintain abstinence for at least a year; many also achieve long-term sobriety. The core components of the rehabilitation phase of treatment include cognitive-behavioral approaches to help patients recognize the need to change, while working with them to alter their behaviors to enhance compliance. A key step is to optimize motivation toward abstinence through education of patients and their significant others about alcohol use disorders and their likely course over time. It is important to recognize that contrary to what some physicians might think, the typical person with an alcohol use disorder is likely to have a job and a family and not fit the inaccurate "down and out" stereotype. However, after years of heavy drinking, some patients require vocational or avocational counseling to help to structure their days, and all patients should try self-help groups such as Alcoholics Anonymous (AA) to assist them in developing a sober peer group and to learn how to deal with life's stresses while remaining sober. *Relapse prevention education* helps patients identify situations in which a return to drinking is likely (e.g., stopping in a bar to meet friends but planning to only have a nonalcoholic beverage), formulate ways to avoid the risky situation, and if not possible, mitigate the risks to which they are exposed. It is also important to develop coping strategies that increase the chances of a quick return to abstinence after an episode of drinking.

Although many patients can be treated as outpatients, more intense interventions are more effective, and some individuals with alcohol use disorders do not respond to just AA or outpatient groups. Whatever the setting, ongoing contact with outpatient treatment staff should be maintained for at least 6 months and preferably for a year after abstinence. Counseling focuses on areas of improved functioning in the absence of alcohol (i.e., why it is a good idea to continue abstinence), helping patients to manage free time without alcohol, encouraging them to develop a nondrinking peer group, and discussions of ways to handle stress without drinking.

The physician serves an important role in identifying the alcohol problem, diagnosing and treating associated medical and independent or substance-induced psychiatric syndromes, overseeing detoxification, referring the patient to outpatient or inpatient rehabilitation programs, providing counseling, and, if appropriate, selecting which (if any) medication might be needed. For insomnia, patients should be reassured that troubled sleep is temporary after alcohol withdrawal and will begin to improve over subsequent weeks. They should be taught the elements of "sleep hygiene" including maintaining consistent schedules for bedtime and awakening, avoiding exercise or consumption of large meals before bedtime, and keeping the bedroom cool, dark, and quiet at night **(Chap. 31)**. Depressant sleep medications are not the optimal approach for this type of insomnia that often continues for several weeks or months. Patients are likely to develop rebound insomnia when the depressant dose is decreased or stopped. The rebound increases the chance they will increase the dose and potentially develop problems controlling the prescribed depressant drug. Sedating antidepressants (e.g., trazodone) should not be used because they interfere with cognitive functioning the next morning and disturb the normal sleep architecture, but occasional use of over-the-counter sleeping medications (sedating antihistamines) can be considered. An additional problem, anxiety symptoms, can be addressed by increasing patients' insights into the temporary nature of the symptoms and helping them develop strategies to achieve relaxation by using forms of cognitive therapy.

Medications for the Alcohol Rehabilitation Treatment Phase Several medications have modest benefits when used in the first 6–12 months of recovery. The opioid antagonist naltrexone may shorten subsequent relapses, whether used in the oral form (50–150 mg/d) or as a once-per-month 380-mg injection. By blocking opioid receptors, naltrexone decreases activity in the dopamine-rich ventral tegmental reward system and decreases the feeling of pleasure if alcohol is imbibed. A second medication, acamprosate (Campral) (~2 g/d divided into three oral doses), has similar modest effects. Acamprosate inhibits NMDA receptors, decreasing mild symptoms of protracted withdrawal. Several trials of combined naltrexone and acamprosate have reported that the combination is well tolerated and the efficacy might be superior to either drug alone, although not all studies agree.

It is more difficult to establish the asset-to-liability ratio of a third drug, disulfiram, an ALDH inhibitor, used clinically at doses of 250 mg/d, a dose usually selected to avoid the side effects of the more effective 500 mg/d regimen. This drug produces vomiting and autonomic nervous system instability in the presence of alcohol as a result of rapidly rising blood levels of acetaldehyde. This reaction can be dangerous, especially for patients with heart disease, stroke, diabetes mellitus, or hypertension. The drug itself carries potential risks of temporary depressive or psychotic symptoms, peripheral neuropathy, and liver damage. Disulfiram is best given under supervision by someone (such as a spouse), especially during high-risk drinking situations (such as the Christmas holidays).

A 16-week, placebo-controlled trial in patients with relatively severe acute withdrawal reported better outcomes with use of a depressant medication (gabapentin 1200 mg/d), but those results have not yet been replicated. Additional drugs under investigation include another opioid antagonist, nalmefene; the nicotinic receptor agonist varenicline; the serotonin antagonist ondansetron; the α-adrenergic agonist prazosin; the $GABA_B$ receptor agonist baclofen; the anticonvulsant topiramate; and cannabinol receptor antagonists. At present, there are insufficient data to determine the asset-to-liability ratio for these medications in treating alcohol use disorders, and therefore, few data yet offer solid support for their routine use in clinical settings.

GLOBAL CONSIDERATIONS

As described above, rates of alcohol use disorders differ across sex, age, ethnicity, and country. There are also differences across countries regarding the definition of a standard drink (e.g., 10–12 g of ethanol in the United States and 8 g in the United Kingdom) and the definition of being legally drunk. The preferred alcoholic beverage also varies across groups, even within countries. That said, regardless of sex, ethnicity, or country, the actual drug in the drink is still ethanol, and the risks for problems, course of alcohol use disorders, and approaches to treatment are similar across the world.

454 Nicotine Addiction

David M. Burns

The use of tobacco leaf to create and satisfy nicotine addiction was introduced to Columbus by Native Americans and spread rapidly to Europe. Use of tobacco as cigarettes, however, only became popular in the twentieth century and so is a modern phenomenon, as is the epidemic of disease caused by this form of tobacco use.

Nicotine is the principal constituent of tobacco responsible for its addictive character, but other smoke constituents and behavioral associations contribute to the strength of the addiction. Addicted smokers regulate their nicotine intake by adjusting the frequency and intensity of their tobacco use both to obtain the desired psychoactive effects and avoid withdrawal.

Unburned cured tobacco used orally contains nicotine, carcinogens, and other toxicants capable of causing gum disease, oral and pancreatic cancers, and an increase in the risk of heart disease. When tobacco is burned, the resultant smoke contains, in addition to nicotine, >7000 other compounds that result from volatilization, pyrolysis, and pyrosynthesis of tobacco leaf and various chemical additives used in making different tobacco products. Tobacco smoke is composed of a fine aerosol and a vapor phase; the aerosol is of a size range that results in deposition in the airways and alveolar surfaces of the lungs. The aggregate of particulate matter, after subtracting nicotine and moisture, is referred to as tar.

The alkaline pH of smoke from blends of tobacco used for pipes and cigars allows sufficient absorption of nicotine across the oral mucosa to satisfy the smoker's need for this drug. Therefore, those who smoke pipes and cigars exclusively tend not to inhale the smoke into the lung, confining the toxic and carcinogenic exposure (and the increased rates of disease) largely to the upper airway. The acidic pH of smoke generated by the tobacco used in cigarettes dramatically reduces absorption of nicotine in the mouth, necessitating inhalation of the smoke into the larger surface of the lungs in order to absorb quantities of nicotine sufficient to satisfy the smoker's addiction. The shift to using tobacco as cigarettes, with resultant increased deposition and absorption of smoke in the lung, has created the epidemic of heart disease, lung disease, and lung cancer that dominates the current disease manifestations of tobacco use.

Several genes have been associated with nicotine addiction. Some reduce the clearance of nicotine, and others have been associated with an increased likelihood of becoming dependent on tobacco and other drugs as well as a higher incidence of depression. It is likely that genetic susceptibility can influence the probability that adolescent experimentation with tobacco will lead to addiction as an adult. Rates of smoking cessation have increased, and rates of nicotine addiction have decreased dramatically, since the mid-1950s, suggesting that factors other than genetics are more important influences for tobacco use.

Adult cigarette smoking prevalence has declined to below 14% in the United States, with only 75% of the cigarette smokers smoking every day. The rapidly rising smoking rate observed in the developing world is of concern, and the World Health Organization Framework Convention on Tobacco Control is encouraging effective tobacco control approaches in these countries with the hope of preventing a future epidemic of tobacco-related illness.

DISEASE MANIFESTATIONS OF CIGARETTE SMOKING

More than 480,000 individuals die prematurely each year in the United States from cigarette use; this represents almost one of every five deaths in the United States. Approximately 40% of cigarette smokers will die prematurely due to cigarette smoking unless they are able to quit.

The major diseases caused by cigarette smoking are listed in **Table 454-1**. The ratio of smoking-related disease rates in smokers compared to never smokers (relative risk) increases with advancing age for most cancers and for chronic obstructive pulmonary disease (COPD). However, relative risk declines with advancing age for cardiovascular diseases due to the increasing contribution of other risk factors as age advances. Nevertheless, even for cardiovascular disease, the absolute difference in mortality rate between smokers and never smokers, called excess death rate, continues to increase with advancing age, as one would expect from a process of cumulative injury.

TABLE 454-1 Relative Risks for Current Smokers of Cigarettes

AGE	35–44	45–64	65–74	≥75
Males				
Lung cancer	14.33	19.03	28.29	22.51
Coronary heart disease	3.88	2.99	2.76	1.98
Cerebrovascular disease	2.17	1.48	1.23	1.12
Other vascular diseases			7.25	4.93
Chronic obstructive pulmonary disease (COPD)			29.69	23.01
All causes	2.55	2.97	3.02	2.40
Females				
Lung cancer	13.30	18.95	23.65	23.08
Other tobacco-related cancers	1.28	2.08	2.06	1.93
Coronary heart disease	4.98	3.25	3.29	2.25
Cerebrovascular disease	2.27	1.70	1.24	1.10
Other vascular diseases			6.81	5.77
COPD			38.89	20.96
All causes	1.79	2.63	2.87	2.47

Relative Risks for Selected Other Cancers		
Other cancers	Male	Female
Larynx	14.6	13
Lip, oral cavity, pharynx	10.9	5.1
Esophagus	6.8	7.8
Bladder	3.3	2.2
Kidney	2.7	1.3
Pancreas	2.3	2.3
Stomach	2	1.4
Liver	1.7	1.7
Colorectal	1.2	1.2
Cervix		1.6
Acute myeloid leukemia	1.4	1.4

CARDIOVASCULAR DISEASES

Cigarette smokers are more likely than nonsmokers to develop both large-vessel atherosclerosis and small-vessel disease. Approximately 90% of peripheral vascular disease in the nondiabetic population can be attributed to cigarette smoking, as can ~50% of aortic aneurysms. In contrast, 24% of coronary artery disease and ~11% of ischemic and hemorrhagic strokes are caused by cigarette smoking. There is a multiplicative interaction between cigarette smoking and other cardiac risk factors such that the increment in risk produced by smoking among individuals with hypertension or elevated serum lipids is substantially greater than the increment in risk produced by smoking for individuals without these risk factors.

In addition to its role in promoting atherosclerosis, cigarette smoking also increases the likelihood of myocardial infarction and sudden cardiac death by promoting platelet aggregation and vascular occlusion. Reversal of these effects on coagulation may explain the rapid benefit of smoking cessation for a new coronary event demonstrable among those who have survived a first myocardial infarction. This effect may also explain the substantially higher rates of graft occlusion among continuing smokers following vascular bypass surgery for cardiac or peripheral vascular disease.

Cessation of cigarette smoking reduces the risk of a second coronary event within 6–12 months. Rates of first myocardial infarction and death from coronary heart disease decline within 2–4 years following cessation among those with no prior cardiovascular history. After 15 years of abstinence, the risk of a new myocardial infarction or death from coronary heart disease in former smokers is similar to that for those who have never smoked.

CANCER

Tobacco smoking causes cancer of the lung; lip; oral cavity; naso-, oro-, and hypopharynx; nasal cavity and paranasal sinuses; larynx; esophagus; stomach; pancreas; liver (hepatocellular); colon and rectum; kidney (body and pelvis); ureter; urinary bladder; uterine cervix; and acute myeloid leukemia. There is evidence suggesting that cigarette smoking may play a role in increasing the risk of breast cancer, particularly for premenopausal women. There does not appear to be a causal link between cigarette smoking and cancer of the endometrium, and there is a lower risk of uterine cancer among postmenopausal women who smoke. The risks of cancer increase with the increasing number of cigarettes smoked per day and with increasing duration of smoking. Additionally, there are synergistic interactions between cigarette smoking and alcohol use for cancer of the oral cavity and esophagus. Several occupational exposures synergistically increase lung cancer risk among cigarette smokers, most notably occupational asbestos and radon exposure.

Cessation of cigarette smoking reduces the risk of developing cancer relative to continuing smoking after about 4 years of abstinence, but even 20 years after cessation, there is a persistent two- to threefold increased risk of developing lung cancer.

RESPIRATORY DISEASE

Cigarette smoking is responsible for 80% of COPD. Within 1–2 years of beginning to smoke regularly, many young smokers will develop inflammatory changes in their small airways, although lung function measures of these changes do not predict development of chronic airflow obstruction. Pathophysiologic changes in the lungs manifest and progress over longer durations of smoking proportional to smoking intensity and duration. Chronic mucous hyperplasia of the larger airways results in a chronic productive cough in as many as 80% of smokers >60 years of age. Chronic inflammation and narrowing of the small airways and/or enzymatic digestion of alveolar walls resulting in pulmonary emphysema can reduce expiratory airflow sufficiently to produce clinical symptoms of respiratory limitation in ~15–25% of smokers.

Changes in the small airways of young smokers will reverse after 1–2 years of cessation. There is also a small increase in measures of expiratory airflow following cessation among many individuals who have developed chronic airflow obstruction, but the major change following cessation is a slowing of the rate of decline in lung function with advancing age rather than a return of lung function toward normal.

PREGNANCY

Cigarette smoking is associated with several maternal complications of pregnancy: premature rupture of membranes, abruptio placentae, and placenta previa; there is also a small increase in the risk of spontaneous abortion among smokers. Infants of smoking mothers are more likely to experience preterm delivery, have a higher perinatal mortality rate, be small for their gestational age, and have higher rates of infant respiratory distress syndrome. They are more likely to die of sudden infant death syndrome and appear to have a developmental lag for at least the first several years of life.

OTHER CONDITIONS

Smoking delays healing of peptic ulcers; increases the risk of developing periodontal disease, diabetes, active tuberculosis, rheumatoid arthritis, osteoporosis, senile cataracts, and neovascular and atrophic forms of macular degeneration; and results in premature menopause, wrinkling of the skin, gallstones, and cholecystitis in women, and male impotence. Patients who continue to smoke during treatment for cancer with chemotherapy or radiation have poorer outcomes and reduced survival.

ENVIRONMENTAL TOBACCO SMOKE

Long-term exposure to environmental tobacco smoke increases the risk of lung cancer and coronary artery disease among nonsmokers. It also increases the incidence of respiratory infections, chronic otitis media, and asthma in children and causes exacerbation of asthma in children. Some evidence suggests that environmental tobacco smoke exposure may increase the risk of premenopausal breast cancer.

PHARMACOLOGIC INTERACTIONS

Cigarette smoking may interact with a variety of other drugs **(Table 454-2)**. Cigarette smoking induces the cytochrome P450 system, which may alter the metabolic clearance of drugs such as warfarin. This may result in inadequate serum levels in smokers as outpatients when the dosage is established in the hospital under nonsmoking conditions. Correspondingly, serum levels may rise when smokers are hospitalized and not allowed to smoke. Smokers may also have higher first-pass clearance for drugs such as lidocaine, and the stimulant effects of nicotine may reduce the effect of benzodiazepines or beta blockers.

OTHER FORMS OF TOBACCO USE

Other major forms of tobacco use are moist snuff deposited between the cheek and gum, chewing tobacco, pipes and cigars, and recently bidi (tobacco wrapped in tendu or temburni leaf; commonly used in India), clove cigarettes, and water pipes. Oral tobacco use leads to gum disease and can result in oral and pancreatic cancer as well as heart disease. There are dramatic differences in the risks evident for products used in Africa or Asia as compared to those in the United States and Europe.

The risk of upper airway cancers is similar among cigarette, pipe, and cigar smokers, whereas those who have smoked only pipes and cigars have a much lower risk of lung cancer, heart disease, and COPD. Cigarette smokers who switch to pipes or cigars do tend to inhale the smoke, increasing their risk. Use of combusted tobacco in forms resembling and smoking like a cigarette, but classified as a cigar, represents a growing fraction of combusted tobacco use and likely has disease risks similar to those of cigarette smoking.

A resurgence of cigar, bidi, and water pipe use among adolescents of both genders has raised concerns that these older forms of tobacco use are once again causing a public health problem.

ELECTRONIC CIGARETTES

Electronic cigarettes (e-cigarettes) are devices with a heating element that produces an inhalable aerosol from a liquid usually containing nicotine. Multiple different designs exist, but there are three general categories. Disposable devices that look like cigarettes or ball point

TABLE 454-2 Interactions of Smoking and Prescription Drugs

DRUG	INTERACTION
Cardiovascular and Pulmonary Drugs	
β blockers	Reduced lowering of heart rate and blood pressure
Flecainide	Increased first-pass clearance
Heparin	Faster clearance
Lidocaine	Increased first-pass clearance
Mexiletine	Increased first-pass clearance
Propranolol	Increased first-pass clearance
Theophylline	Faster metabolic clearance
Verapamil	Increased clearance
Warfarin	Increased metabolism lowers serum levels
Neuropsychiatric Drugs	
Amitriptyline	Increased clearance
Benzodiazepines	Less sedation
Clomipramine, Imipramine	Decreased serum concentrations
Chlorpromazine	Decreased serum concentrations
Clozapine	Decreased serum concentrations
Duloxetine	Decreased serum concentrations
Fluphenazine	Decreased serum concentrations
Fluvoxamine	Decreased serum concentrations
Haloperidol	Decreased serum concentrations
Naratriptan	Increased clearance
Olanzapine	Faster clearance
Trazodone	Decreased serum concentrations
Anticancer Drugs	
Erlotinib	Increased clearance, higher response rate, and improved survival in nonsmokers
Gefitinib	Higher response rate and improved survival in nonsmokers
Irinotecan	Increased clearance
Other Drugs	
Dextropropoxyphene	Less analgesia
Estrogens (oral)	Increased hepatic clearance
Fentanyl	Increased clearance
Insulin	Delayed absorption due to skin vasoconstriction
Rivastigmine	Increased clearance

pens are the oldest products, but they generally do not deliver levels of nicotine comparable to a cigarette. Later vaping devices utilize a larger power source and a bulky refillable tank to store the nicotine-containing liquid. These devices deliver aerosolized nicotine at levels comparable to cigarette smoking. Liquids to refill the tanks come in different concentrations of nicotine, but liquids with high concentrations of nicotine create throat irritation, deterring their use. More recent designs include smaller devices that resemble computer USB flash drives and deliver nicotine as the salt of a mild acid. The nicotine salt aerosol leaving the device is mildly acidic, markedly lowering the percentage of the nicotine that is in the free base form. This reduces the irritation in the upper airway. However, as the aerosol moves down the airway, its pH rapidly converts to the lung tissue pH of ~7.4, releasing substantial amounts of free base nicotine, which is readily absorbed across the alveolar capillary wall. As the absorbed nicotine is carried away by the pulmonary blood flow, the remaining nicotine salt converts to the free base form, further enhancing the amount of nicotine that can be delivered to the brain. Limited data suggest that the nicotine intake is higher for users of devices delivering nicotine salts. It is likely that the transition to use of nicotine salts substantially contributed to the rise in use of e-cigarettes and addiction to nicotine among adolescents.

The role of e-cigarettes in smoking cessation remains conflicted. There is convincing randomized controlled evidence that the use of refillable-tank e-cigarettes is twice as effective as nicotine-replacement medications in achieving sustained abstinence from conventional cigarettes. However, 80% of those who achieved abstinence were still using e-cigarettes at 12 months, suggesting continued nicotine addiction. Evidence on exposure to toxicants in smoke demonstrates markedly lower exposures among those using e-cigarettes exclusively, but evidence on e-cigarette use in the United States shows that approximately one-half of adult e-cigarette users continue to also smoke conventional cigarettes, negating the benefits of reduced toxicant exposure. Rates of relapse back to smoking among those with persistent nicotine addiction and the effectiveness of devices containing nicotine salts remain to be demonstrated.

E-cigarette use among U.S. adolescents has risen dramatically over recent years, becoming the most common form of nicotine delivery among adolescents. Adolescents who ever use an inhaled nicotine product are more likely to be a conventional cigarette smoker 1 year later (three times more likely with ever e-cigarette use and four times as likely with ever conventional cigarette use). These data show that adolescents who experiment with nicotine in any form are likely to become continuing users; nevertheless, the steeply rising level of adolescent e-cigarette prevalence has been accompanied by an independently driven dramatic fall in adolescent conventional cigarette prevalence. Concerns about e-cigarette use becoming a meaningful gateway to conventional cigarette use among adolescents and young adults are thus far not borne out by prevalence data for both product types.

Refillable or reloadable e-cigarette devices can be used to aerosolize a variety of liquids other than those provided by the manufacturer. Disposable "pods" and liquids for these devices can be purchased from the manufacturer but are also available from other sources that may use poor-quality manufacturing practices and control of contaminants. They may also contain marijuana oils, other drugs, and flavors not evaluated for potential lung injury with inhalation. Many of these liquids are provided on the black market with little oversight of the production process. Beginning in the spring of 2019, a rapidly accelerating epidemic of severe hypoxic lung injury was associated with e-cigarette use. The lung pathology includes diffuse alveolar damage, acute fibrinous pneumonitis, and organizing pneumonia. The closest associations were for cannabinoid products and vitamin E in the aerosolized liquid, but ~15% of those affected reported using only nicotine-containing liquids. Following widespread publicity of this toxicity and its association with irregular product sources, there has been a reduction in the incidence of this form of lung injury. Given the capacity of e-cigarettes to produce small particles that readily penetrate to the alveolar level, multiple toxicants may contribute to the epidemic. Nevertheless, vitamin E has the strongest evidence to support its role as a major contributor. Vitamin E is sometimes used as a thickening agent in tetrahydrocannabinol (THC)-containing products. Given the difficulty in controlling the illicit market for e-liquids, it is likely that episodic exposure to pulmonary toxicants will continue to occur. Regulatory control may need to focus on the delivery devices.

LOWER TAR AND NICOTINE CIGARETTES

Filtered cigarettes with lower machine-measured yields of tar and nicotine commonly use ventilation holes in the filters and other engineering designs to artificially lower the machine measurements. Smokers compensate for the lowered nicotine delivery resulting from these design changes by changing the manner in which they puff on the cigarette or the number of cigarettes smoked per day. Actual tar and nicotine deliveries are not reduced with use of these products, negating any reduction in disease risks with their use.

The amount of carcinogenic tobacco-specific nitrosamines in the tobacco used in cigarettes has increased over time, and cigarette design changes that reduce machine-measured tar and nicotine also led to deeper inhalation of the smoke. Presentation of more carcinogenic smoke to the alveolar portions of the lung increases the risk of adenocarcinoma of the lung. The increased adenocarcinoma risk produces a substantively greater overall risk for lung cancer among current smokers compared with smokers of cigarettes manufactured prior to the 1960s. This increased risk may also be present for COPD. It is the changes in cigarette design and composition of cigarettes over the past

six decades that caused the dramatic rise in rates of adenocarcinoma of the lung observed over the past half century. There has been no increase in risk of lung cancer or adenocarcinoma of the lung over the same period among never smokers.

CESSATION

The process of stopping smoking is commonly a cyclical one, with the smoker sometimes making multiple attempts to quit and failing before finally being successful. Approximately 70–80% of smokers would like to quit smoking. More than one-half of current smokers attempted to quit in the last year, but only 6% quit for 6 months, and only 3% remain abstinent for 2 years. Clinician-based smoking interventions should repeatedly encourage smokers to try to quit and to use different forms of cessation assistance with each new cessation attempt, rather than focusing exclusively on immediate cessation at the time of the first visit.

Advice from a physician to quit smoking, particularly at the time of an acute illness, is a powerful trigger for cessation attempts, with up to half of patients who are advised to quit making a cessation effort. Other triggers that may be enhanced by timely physician advice to quit include increases in the tax on cigarettes, media campaigns, and changes in rules to restrict smoking in the workplace.

PHYSICIAN INTERVENTION (TABLE 454-3)

All patients should be asked whether they smoke, how much they smoke, how long they have smoked, their past experience with quitting, and whether they are currently interested in quitting. The number of cigarettes smoked per day and smoking within 30 min of waking are useful measures of the intensity of nicotine addiction. Even those who are not interested in quitting should be encouraged and motivated to quit; provided a clear, strong, and personalized message by the clinician that smoking is an important health concern; and offered assistance if they become interested in quitting in the future. Many of those not currently expressing an interest in quitting may nevertheless make an attempt to quit in the subsequent year. For those interested in quitting, a quit date should be negotiated, usually not the day of the visit but within the next few weeks, and a follow-up contact by office staff around the time of the quit date should be provided. There is a relationship between the amount of assistance a patient is willing to accept and the success of the cessation attempt.

There are a variety of nicotine-replacement products, including over-the-counter nicotine patches, gum, and lozenges, as well as nicotine nasal and oral inhalers available by prescription. These products can be used for up to 3–6 months, and some products are formulated to allow a gradual step-down in dosage with increasing duration of smoking abstinence. Antidepressants such as bupropion (300 mg in divided doses for up to 6 months) have also been shown to be effective, as has varenicline, a partial agonist for the nicotinic acetylcholine receptor (initial dose 0.5 mg daily increasing to 1 mg twice daily at day 8; treatment duration up to 6 months). Combined use of nicotine-replacement therapy (NRT) and antidepressants as well as the use of gum or lozenges for acute cravings in patients using patches can increase cessation outcomes. Pretreatment with antidepressants or varenicline is recommended for 1–2 weeks prior to the quit date. Pretreatment with nicotine-replacement products is also useful prior to a cessation date. Longer duration of nicotine replacement as a maintenance therapy for those who are unsuccessful in quitting with a shorter duration of use is a useful strategy. NRT is provided in different dosages, with higher doses being recommended for more intense smokers. Clonidine or the tricyclic antidepressant nortriptyline should be reserved for patients who have failed on first-line pharmacologic treatment or who are unable to use other therapies. Antidepressants are more effective among smokers with a history of depression symptoms.

Current recommendations are to offer pharmacologic treatment, usually with nicotine patches or varenicline, to all who will accept it and to provide counseling and other support as a part of the cessation attempt. Cessation advice alone by a physician or his or her staff is likely to increase success compared with no intervention; a more comprehensive approach with advice, pharmacologic assistance, and counseling can increase cessation success nearly threefold.

For adult addicted smokers, switching to exclusive use of e-cigarettes, but not dual use with combusted cigarettes, can promote combusted cigarette cessation, particularly for those unlikely to try to quit with other proven cessation modalities.

Incorporation of cessation assistance into a practice requires a change of the care delivery infrastructure. Simple changes include (1) adding questions about smoking and interest in cessation on patient-intake questionnaires, (2) asking patients whether they smoke as part of the initial vital sign measurements made by office staff, (3) listing smoking as a problem in the medical record, and (4) automating follow-up contact with the patient on the quit date. These changes are essential to institutionalizing smoking intervention within the practice setting; without this institutionalization, the best intentions of physicians to intervene with their patients who smoke are often lost in the time crush of a busy practice.

TABLE 454-3 Clinical Practice Guidelines

Physician Actions
Ask: Systematically identify all tobacco users at every visit
Advise: Strongly urge all smokers to quit
Identify smokers willing to quit
Assist the patient in quitting
Arrange follow-up contact
Effective Pharmacologic Interventions[a]
First-line therapies
Nicotine gum (1.5)
Nicotine patch (1.9)
Nicotine nasal inhaler (2.3)
Nicotine oral inhaler (2.1)
Nicotine lozenge (2 mg: 2.0, 4 mg: 2.8)
Bupropion (2.0)
Varenicline (3.1)
Second-line therapies
Clonidine (2.1)
Nortriptyline (1.8)
Other Effective Interventions[a]
Physician or other medical personnel counseling (10 min) (1.84)
Intensive group smoking cessation programs (at least 4–7 sessions of 20- to 30-min duration lasting at least 2 and preferably 8 weeks) (1.3)
Intensive individual counseling (1.7)
Clinic-based smoking status identification system (3.1)
Telephone counseling (1.6)
Exclusive E-cigarette use (3.0)

[a]Numerical value following the intervention is the multiple for cessation success compared to no intervention.

PREVENTION

Approximately 85% of individuals who become cigarette smokers initiate the behavior during adolescence. Factors that promote adolescent initiation are parental or older-sibling cigarette smoking, tobacco advertising and promotional activities, the availability of cigarettes, and the social acceptability of smoking. The need for an enhanced self-image and to imitate adult behavior is greatest for those adolescents who have the least external validation of their self-worth, which may explain in part the enormous differences in adolescent smoking prevalence by socioeconomic and school performance strata.

Prevention of smoking initiation must begin early, preferably in the elementary school years. Physicians who treat adolescents should be sensitive to the prevalence of this problem even in the preteen population. Physicians should ask all adolescents whether they have experimented with nicotine or currently use nicotine products, reinforce the fact that most adolescents and adults do not smoke or use nicotine, and explain that all forms of nicotine intake are both addictive and harmful.

455 Marijuana and Marijuana Use Disorders

Nora D. Volkow, Aidan Hampson, Ruben Baler

Marijuana is the most widely used illicit drug, with ~192 million users worldwide and with >43 million Americans having used it in 2018. Cannabis strains fall into those grown for their euphorigenic and medical properties (i.e., for their Δ-9-tetrahydrocannabinol [THC] content), and "hemp," which is grown for seed, fiber, and cannabidiol (CBD). As of August 2020, Canada and 43 U.S. states have decriminalized and/or "medicalized" marijuana or marijuana-derived products, which has increased the availability of cannabis strains and derived products. Between 2008 and 2017, the average THC content in marijuana increased from 8.9% to 17.1%. Today, THC concentrations in marijuana flowers found in dispensaries can exceed 25%, while oil extracts used for "vaping" can contain >95% THC. Similar high THC concentrations are found in solid cannabis concentrates (e.g., wax or shatter) used for "dabbing," which involves vaporization with a propane torch. Vaping and dabbing both provide very high THC levels with a rapid absorption and speed of effect onset, a phenomenon that increases addiction risk. Cannabis-infused "edibles" (e.g., gummy bears, cookies, chocolates, and drinks) are also widely available and valued for their discreet administration and perception of reduced harm.

PHARMACOLOGIC EFFECTS

Cannabis is used recreationally because it enhances the subjective sense of well-being, provides rewarding sensations, and can decrease stress responses. However, consumption of high THC doses can induce anxiety, paranoia, and panic. THC is primarily an agonist (activator) of G protein–coupled cannabinoid receptors (CB1R and CB2R), with the euphoric effects mediated through CB1Rs located on excitatory glutamatergic and inhibitory γ-aminobutyric acid (GABA)-ergic interneurons and glial cells in brain regions that process stress, mood, and reward. These receptors are the effectors of the endocannabinoid system (ECS), which is physiologically activated by 2-arachidonoylglycerol (2-AG, a full agonist) and anandamide (a partial agonist). According to current understanding, 2-AG modulates synaptic signaling by inhibiting overstimulated synapses. Endocannabinoids are synthesized and eliminated on demand and thus provide a temporally and regionally specific control signal. In contrast, the effect of THC is not defined by synaptic necessity but by the dose taken and pharmacokinetics, and so it disrupts ECS neuroregulation. THC is a partial CB1/2R agonist (it produces less signal per receptor bound) and thus does not inhibit glutamate release as effectively as 2-AG but can outcompete endocannabinoids by mass action. However, GABA-releasing interneurons have more CB1R than they have connecting intracellular signaling components, and so THC and 2-AG inhibit GABA release to a similar degree. This may explain the subjective similarity of THC and GABA inhibitors such as benzodiazepines.

The rewarding effects of THC are thought to be mediated by modulation of glutamatergic and GABAergic activity in the ventral tegmental area in the midbrain, the nucleus that contains the dopaminergic neurons projecting into the nucleus accumbens, which integrates glutamate and dopamine signals to produce reward responses. The anxiety-reducing effects of THC are mediated by its effects in the amygdala, a region critical for threat perception and emotional reactivity.

CANNABIS PHARMACOKINETICS

Traditional smoking (e.g., joints and water pipes) is the main route of administration, but the rise of e-cigarette–derived vaping concentrates (vape pens) has led to a move to small dosing and more regular administration, also known as micro-dosing. Vape pens use concentrate liquids and offer both an easier dose control mechanism and more discreet consumption. The subjective effects of marijuana are affected by dose, route of administration, (smoked, vaped, ingested), and the subject's prior experience. Smoked THC exhibits a bioavailability of 10–35%, with interindividual differences stemming from individual variations in the capacity to hold smoke in the lungs long enough for maximal absorption. The pharmacokinetics (PKs) of heated (not burnt) marijuana is similar to that of the smoked flower, but no data are available to address the PKs of oils and solid concentrates. When smoked, THC is rapidly absorbed (T_{max} within 5–10 min) and displays three phases of elimination. After T_{max}, plasma levels drop rapidly (alpha half-life [$t_{1/2}$] ~6 min) due to redistribution from plasma to lipophilic tissues such as adipose and brain. As a result, the brain continues to accumulate THC while plasma levels decline, so subjective effects max out at ~20–30 min. This "hysteresis" phase continues for several hours, wherein subjective effects decline more slowly than plasma levels. Most of the pharmacologic effects (i.e., subjective, cardiovascular, and conjunctival reddening) occur during the initial 20–30 min and last for 4–8 h. Finally, there is a terminal elimination phase, during which relatively low concentrations of THC and metabolites (primarily THC 11-COOH) leach out from adipose tissues with a $t_{1/2}$ ranging from 20–35+ h. Generally, metabolite levels drop below 100 ng/mL within 3–5 days, although considerable variation exists, and in frequent marijuana users, urinary metabolites can remain detectable for weeks. High metabolite levels during long leach-out periods in frequent users typically do not indicate impairment, even when similar concentrations in occasional users might indicate recent marijuana use and substantial impairment. This difficulty in correlating THC levels in biological matrices with behavioral effect has hampered efforts to regulate marijuana-impaired driving.

PK studies using cannabis edibles have demonstrated only 6–12% bioavailability. Lipophilic cannabinoids are poorly absorbed in the water/mucus-rich intestinal environment and are rapidly metabolized by intestinal and hepatic systems, even before they reach the systemic circulation. Interestingly, cannabinoids consumed with fatty food display 200–400% improved bioavailability. Fatty foods stimulate bile release, which emulsifies fats (and dissolved cannabinoids) to increase the surface area for absorption. However, fats are not absorbed into hepatic portal blood but secreted as chylomicrons into lymphatic lacteals, which allows dissolved cannabinoids to bypass hepatic elimination. Since lymphatic flow is slower than portal blood transport, the higher cannabinoid bioavailability and slower effect onset in the presence of fat are overdose risks for the unwary who may consume additional doses when failing to perceive effects as quickly as expected.

HARMFUL EFFECTS

The frequency and severity of marijuana's adverse effects are influenced by the user's age, dose, frequency of use, route of administration, underlying health status, and genetics. Especially concerning are the potential negative effects of marijuana on the brain during early life stages. Perturbation of ECS signaling during early fetal development affects neuronal development, migration, and connectivity. The relevant studies, which are few and confounded by the frequent use of other drugs, suggested an association between maternal marijuana use and fetal growth restriction and preterm delivery but yielded substantial evidence of lower birth weight. As a consequence, the American College of Obstetricians and Gynecologists recommends discouraging the use of marijuana by women who are pregnant or planning a pregnancy. Children and adolescents are also more vulnerable to the harmful effects of marijuana use, which increases markedly during adolescence and has been associated with lower grades, lower IQ, and higher risk of dropping out of school, although causality associations are hindered by poor control of confounding variables. Brain imaging studies have revealed that use of marijuana at this stage is associated with structural and functional brain changes often (but findings are not always replicated) in the form of reduced brain connectivity and cortical thickness. It is not clear whether these are *caused* by early exposure to marijuana, a question that the Adolescent Brain and Child Development study, a longitudinal neuroimaging, behavioral, and genetic study of close to 12,000 children in the United States, may be able to answer. Finally, there is increasing evidence of cardiovascular adverse effects, including higher risk of myocardial infarction among cannabis smokers.

Cannabis Use Disorder Repeated marijuana use, especially during adolescence, can result in cannabis use disorder (CUD), which the fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5) defines as "a problematic pattern of cannabis use leading to clinically significant impairment or distress." Use becomes problematic when at least two of the criteria (which include craving, failure to fulfill role obligations due to recurrent use, tolerance, and withdrawal) have manifested themselves in a 12-month period. In regular marijuana users, abstinence results in a withdrawal syndrome that manifests within 1–3 days of drug discontinuation as anxiety, restlessness, insomnia, depression, and reduced appetite. Many of the withdrawal symptoms resolve within approximately 2 weeks of discontinuation, but symptoms such as insomnia can persist longer and contribute to drug taking as a means to combat the symptoms of withdrawal. The risk of CUD increases with earlier age of initiation, frequency of use, and exposure to marijuana with high THC content.

PREVENTION Preventing marijuana use during adolescence reduces the risk for CUD and also the risk for other substance use disorders. There are several evidence-based prevention strategies focused in children and adolescents that have shown benefits in decreasing marijuana use during adolescence or in delaying its age of initiation. Evidence-based prevention interventions target the individual (e.g., Keepin' It Real, Life Skills, InShape), the family (e.g., Brief Strategic Family Therapy, Coping Power Program [CPP], Familia Adelante), and the community (e.g., The Abecedarian Project, Midwestern Prevention Project, Caring School Community). School-based prevention programs are the most widely implemented, and the cumulative evidence (from randomized controlled trials and prospective cohort and longitudinal studies) indicates that comprehensive interventions that include antidrug information with refusal skills, self-management skills, and social skills training appear to be the most effective approaches for long-term reduction of marijuana (and alcohol) use in adolescents.

TREATMENT The treatment of CUD is managed by tapering marijuana use and, in severe cases, by providing support to combat withdrawal symptoms. The treatment of severe CUD is much more challenging and requires continuous care. Although there are no U.S. Food and Drug Administration (FDA)–approved medications for the treatment of CUD, there are several behavioral interventions, including contingency management and cognitive-behavioral and motivational enhancement therapies for which there is evidence of benefit. Several studies have found a broad reduction in cannabinoid receptors in the brain of cannabis users when compared to healthy controls, but receptors recover rapidly, returning to values similar to those of nonusers after 28 days of abstinence.

Mental Illness An area of major concern is the association between marijuana use and increased risk for mental illnesses, particularly psychosis, the risk of which increases with the frequent consumption of high-THC-content marijuana (>10% content). High-potency marijuana can trigger acute psychotic episodes, which is one of the main causes for emergency department (ED) visits associated with cannabis use that can occur even upon first exposure. While most of these psychotic episodes are transient, with regular marijuana use, they can become chronic, and in those who are vulnerable, they might trigger or exacerbate the presentation of schizophrenia. Multiple studies, although not all, have linked adolescent marijuana use with higher risk and earlier onset of chronic psychosis, particularly for those using marijuana at higher frequency or with higher THC content. Furthermore, recent evidence suggests that the difference in the prevalence of psychosis across different countries may be attributable in part to the differences in the prevalence of regular use of high-THC-content marijuana. Concerns have also been raised regarding an association between marijuana use during adolescence and a higher risk for depression and suicidality, although these associations have been much less studied.

Accidents Marijuana use increases the risk of injuries when driving under its influence. THC impairs judgment, motor coordination, and reaction time, all of which are necessary for safe driving. Laboratory studies have found a direct relationship between blood THC levels and impaired driving ability. Not surprisingly, marijuana use while driving increases the risk of fatal and nonfatal accidents, and its use while flying aircraft may have also contributed to increased fatalities among pilots. However, roadside surveillance of marijuana intoxication has been difficult to implement because circulating cannabinoid levels do not correlate with the degree of impairment.

Acute and Chronic Toxicity The increased availability of high-THC-content products over the past decade has been paralleled by increased marijuana-related ED visits and hospital admissions. Such illnesses can be caused by acute toxicity (inappropriate dosing) and chronic use syndromes. Cannabis edibles represent a significant portion of acute cannabis toxicity events. Patients include children accidentally consuming sweet treats and infrequent users such as "cannabis tourists" with limited experience with consumed products. As described in the PK section, edibles have a slow onset of effect, and THC bioavailability can differ greatly when taken on an empty stomach or with fatty foods. For a variety of reasons, actual dose is also more difficult to envisage, so naïve or infrequent users are at increased risk of overdosing. Cannabis toxicity is frequently manifested by severe anxiety, tachycardia, and even acute psychoses.

Chronic high-dose cannabis use can also induce a *cannabis hyperemesis syndrome (CHS)*, a growing cause for ED and hospital admissions. CHS presents in the ED as severe cycles of nausea, vomiting, and abdominal pain, but has a prodromal phase of abdominal pain and nausea that can last several years. CHS does not respond to CB1R agonist medications such as dronabinol and nabilone that are FDA approved to treat nausea and vomiting. CHS treatment includes intravenous hydration and proton pump inhibitors for gastritis. Very hot showers and capsaicin creams are popularly used, but efficacy data are limited. Droperidol reduces hospital stay times and antiemetic use, but only cannabis abstinence leads to long-term recovery.

The widespread medicalization of marijuana and its dispensation outside of the pharmacy system is exposing patients to possible drug-drug interactions (DDIs), potentially without their physician's or pharmacist's knowledge. However, the long history of population exposure has not provided much evidence for cannabis (i.e., THC)–related DDIs, except for a couple of case studies where THC (metabolized by

cytochrome P450 [CYP3A, 2C9]) affected a patient's warfarin levels. In contrast, the legalization of hemp-derived CBD has made it available at doses never experienced with marijuana. CBD in the Epidiolex formulation has been FDA approved as a high-dosage (see below) add-on drug against childhood epilepsies. Recent reports of possible interactions between CBD and benzodiazepines, methadone, and the antirejection drug tacrolimus suggest more research is needed to ensure safety of CBD medications.

THERAPEUTIC POTENTIAL

Currently, no FDA-approved medications contain cannabis-derived THC, although synthetic THC (or dronabinol) is approved for treatment of chemotherapy-induced nausea and appetite stimulation. Several countries have approved the cannabis-derived THC:CBD formulation Sativex for treating chronic pain and multiple sclerosis (MS)–induced spasticity. However, evidence of Sativex efficacy in MS is largely based on patient reports, with little electromyographic evidence or physician-scored improvement. Chronic pain is one of the most frequent indications for which medical marijuana is used, although the effect is generally modest and possibly related to its mood-enhancement effects.

High-dose Epidiolex is an FDA-approved oil formulation of CBD for use as an add-on treatment for Dravet's and Lennox-Gastaut syndromes and tuberous sclerosis epilepsies. There is clinical evidence for CBD, at lower doses, as an anxiolytic for the treatment of posttraumatic stress, anxiety, and relapse of substance use disorders. Animal studies suggest that this effect of CBD may be mediated by the 5-hydroxytryptamine 1A receptor.

456 Opioid-Related Disorders

Thomas R. Kosten, Colin N. Haile

Opioid analgesics have been used since at least 300 B.C. Nepenthe (Greek for "free from sorrow") helped the hero of the *Odyssey*, but widespread opium smoking in China and the Near East has caused harm for centuries. Since the first chemical isolation of opium and codeine 200 years ago, a wide range of synthetic opioids have been developed, and opioid receptors were cloned in the 1990s. Two of the most important adverse effects of all these agents are the development of opioid use disorder and overdose. Prescription opioids are primarily used for pain management, but due to ease of availability, individuals procure and misuse these drugs with dire consequences. In 2015, for example, 3.8 million individuals in the United States were current misusers of pain relievers. More concerning, during 2015, >20,000 overdose deaths involved opioids with an additional 12,990 overdose deaths related to heroin alone. These numbers continue to increase and have accelerated due to mixing high-potency fentanyl derivatives with heroin. The accelerating death rates are partially because reversal of fentanyl overdoses can require severalfold larger doses of naloxone than the doses in the intranasal devices used for nonmedical street resuscitations. An additional spike in fentanyl-associated deaths has also been associated with the COVID-19 pandemic. According to the most recent World Drug Report, opioid misuse causes the greatest global burden of morbidity and mortality; disease transmission; increased health care, crime, and law enforcement costs; and less tangible costs of family distress and lost productivity.

The terms *dependence* and *addiction* are no longer used to describe substance use disorders. Opioid-related disorders encompass opioid use disorder, opioid intoxication, and opioid withdrawal. The diagnosis of opioid use disorder, as defined in the *Diagnostic and Statistical Manual of Mental Disorders,* Fifth Edition (DSM-5), requires the repeated use of the opiate while producing problems in two or more areas in a 12-month period. The areas include tolerance, withdrawal, use of greater amounts of opioids than intended, craving, and use despite adverse consequences. This new definition of opioid use disorder, reducing the criteria for diagnosis from three problem areas to two, is not expected to change the rates of these disorders because most individuals using these substances meet more than three criteria.

A striking recent aspect of illicit opioid use has been its marked increase as the gateway to illicit drugs in the United States. Since 2007, prescription opiates have surpassed marijuana as the most common illicit drug that adolescents initially use, although overall rates of opioid use are far lower than marijuana. The most commonly used opioids are diverted prescriptions for oxycodone and hydrocodone, followed by heroin and morphine, and—among health professionals—meperidine and fentanyl. Heroin is metabolized into 6-monoacetylmorphine and morphine thus acting as a prodrug that more readily penetrates the brain and is converted rapidly to morphine in the body. Two opioid maintenance treatment agents—methadone and buprenorphine—are also misused, but at substantially lower rates, and the partial opioid agonists such as butorphanol, tramadol, and pentazocine are misused even less frequently. Because the chemistry and general pharmacology of these agents are covered in major pharmacology texts, this chapter focuses on the neurobiology and pharmacology relevant to opioid use disorder and its treatments. Although the neurobiology of misuse involves all four of the known opioid receptors—mu, kappa, delta, and nociceptin/orphanin—this discussion focuses on the mu receptor targeted by most of the clinically used opioids.

NEUROBIOLOGY

The neurobiology of opioids and their effects not only include opioid receptors, but also downstream intracellular messenger systems and ion channels that the receptors regulate. The different functional activities of opioid receptors are summarized in **Table 456-1**. Abuse liability of opioids is primarily associated with the mu receptor. All opioid receptors are G protein–linked and coupled to the cyclic adenosine monophosphate (cAMP) second messenger system and to G protein–coupled, inwardly rectifying potassium channels (GIRKs). Opioids

TABLE 456-1 Actions of Opioid Receptors

RECEPTOR TYPE	ACTIONS
Mu (μ) (e.g., morphine, buprenorphine)	Analgesia, reinforcement euphoria, cough and appetite suppression, decreased respirations, decreased GI motility, sedation, hormone changes, dopamine and acetylcholine release
Kappa (κ) (e.g., butorphanol)	Dysphoria, decreased GI motility, decreased appetite, decreased respiration, psychotic symptoms, sedation, diuresis, analgesia
Delta (δ) (e.g., etorphine)	Analgesia, euphoria, physical dependence, hormone changes, appetite suppression, dopamine release
Nociceptin/orphanin (e.g., buprenorphine)	Analgesia, appetite, anxiety, tolerance to opioids, hypotension, decreased GI motility, 5-HT and NE release

Abbreviations: GI, gastrointestinal; 5-HT, serotonin; NE, norepinephrine.

activate GIRKs, increasing permeability to potassium ions to cause hyperpolarization, which inhibits the production of action potentials. Thus, opioids inhibit the activity of diverse and widely distributed neuronal types. The major effects of opioids, such as analgesia, sedation, and drug reinforcement, are produced through this inhibition of neurons that belong to specific brain pathways.

Many opioid actions are related to the specific neuroanatomic locations of mu receptors. Reinforcing and euphoric effects of opioids relate primarily to activation of the mesolimbic dopaminergic pathway from the ventral tegmental area (VTA) to the nucleus accumbens (NAc), where opioids increase synaptic levels of dopamine. This increase is due to inhibition of GABAergic neurons that inhibit the activity of neurons within both the VTA and the NAc. The positive subjective effects of opioid drugs also include mu receptor desensitization and internalization, potentially related to stimulation of β-arrestin signaling pathways. However, the "high" only occurs when the *rate of change* in dopamine is fast. Large, rapidly administered doses of opioids block γ-aminobutyric acid (GABA) inhibition and produce a burst of VTA dopamine neuron activity that is associated with a "high" in commonly misused substances. Therefore, routes of administration that slowly increase opioid blood and brain levels, such as oral and transdermal routes, are effective for analgesia and sedation but do not produce an opioid "high" that follows smoking and intravenous routes. Other acute effects such as analgesia and respiratory depression involve opioid receptors located in other brain areas such as the locus coeruleus (LC).

Opioid tolerance and withdrawal are chronic effects related to the cAMP-protein kinase A (PKA)-cAMP response-element binding protein (CREB) intracellular cascade **(Fig. 456-1)**. These effects are also reflective of genetic risk factors for developing opioid use disorder, with estimates of up to 50% of the risk due to polygenic inheritance. Specific functional polymorphisms in the mu opiate receptor gene appear to be associated with this risk for opioid misuse, including one producing a threefold increase in this receptor's affinity for opiates and the endogenous ligand β-endorphin. Epigenetic methylation changes also occur on DNA in the region of the mu receptor gene in individuals with opioid use disorder, inhibiting gene transcription. This molecular cascade links acute intoxication and sedation to opioid tolerance and withdrawal mediated by the LC. Noradrenergic (NE) neurons in the LC mediate activation of the cortical hemispheres. When large opioid doses saturate and activate all of its mu receptors, action potentials cease. When this direct inhibitory effect is sustained over weeks and months of opioid use, a secondary set of adaptive changes occur that lead to tolerance and withdrawal symptoms (Fig. 456-1). Withdrawal symptoms reflect, in part, overactivity of NE neurons in the LC. This molecular model of NE neuronal activation during withdrawal has had important treatment implications, such as the use of the α_2-agonist clonidine to treat opioid withdrawal. Other contributors to withdrawal include deficits within the dopamine reward system.

PHARMACOLOGY

Tolerance and withdrawal commonly occur with chronic daily use, developing as quickly as 6–8 weeks depending on dose concentration and dosing frequency. Tolerance appears to be primarily a pharmacodynamic rather than pharmacokinetic effect, with relatively limited induction of cytochrome P450 or other liver enzymes. The metabolism of opioids occurs in the liver, primarily through the cytochrome P450 systems of 2D6 and 3A4. They then are conjugated to glucuronic acid and excreted in small amounts in feces. The plasma half-lives generally range from 2.5 to 3 h for morphine and >22 h for methadone. The shortest half-lives of several minutes are for fentanyl-related opioids, and the longest are for buprenorphine and its active metabolites, which can block opioid withdrawal for up to 3 days after a single dose. Tolerance to opioids leads to the need for increasing amounts of drugs to sustain the desired euphoric effects—as well as to avoid the discomfort of withdrawal. This combination has the expected consequence of strongly reinforcing misuse once it has started. Methadone taken chronically at maintenance doses is stored in the liver, which may reduce the occurrence of withdrawal between daily doses. The role of endogenous opioid peptides in tolerance and withdrawal is uncertain.

The clinical features of opioid misuse are tied to route of administration and rapidity of the drug reaching the brain. Intravenous and smoked administration rapidly produces high drug concentrations in the brain. This produces a "rush," followed by euphoria, a feeling of tranquility, and sleepiness ("the nod"). Heroin produces effects that last 3–5 h, and several doses a day are required to forestall manifestations of withdrawal in chronic users. Symptoms of opioid withdrawal begin 8–10 h after the last dose; lacrimation, rhinorrhea, yawning, and sweating appear first. Restless sleep followed by weakness, chills, gooseflesh ("cold turkey"), nausea and vomiting, muscle aches, involuntary movements ("kicking the habit"), hyperpnea, hyperthermia, and hypertension occur in later stages of the withdrawal syndrome. The acute course of withdrawal may last 7–10 days. A secondary phase of protracted abstinence lasts for 26–30 weeks and is characterized by hypotension, bradycardia, hypothermia, mydriasis, and decreased responsiveness of the respiratory center to carbon dioxide.

Besides the brain effects of opioids on sedation and euphoria and the combined brain and peripheral nervous system effects on analgesia, a wide range of other organs can be affected. The release of several

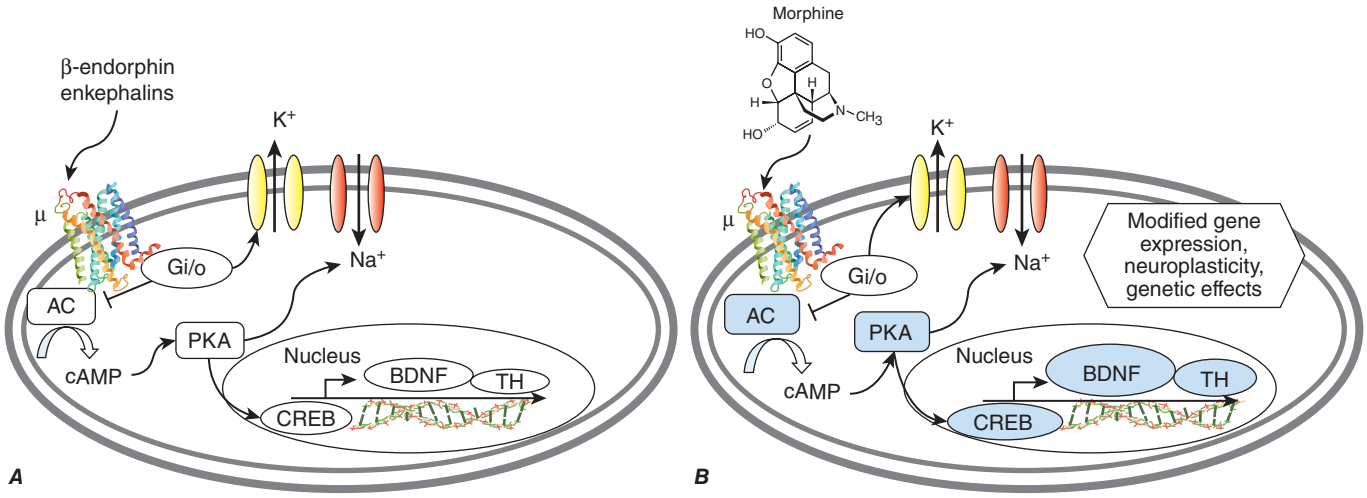

FIGURE 456-1 Normal mu-receptor activation by endogenous opioids inhibits the cyclic adenosine monophosphate (cAMP)-protein kinase A (PKA)-cAMP response-element binding protein (CREB) cascade in noradrenergic neurons within the locus coeruleus ***(A)*** through inhibitory Gi/o protein influence on adenylyl cyclase (AC). Similarly, acute exposure to opioids (e.g., morphine) inhibits this system, whereas chronic exposure to opiates ***(B)*** leads to upregulation of the cAMP pathway in an attempt to oppose opioid-induced inhibitory influence. Upregulation of this system is involved in opioid tolerance, and when the opioid is removed, unopposed noradrenergic neurotransmission is involved in opioid withdrawal. Upregulated PKA phosphorylates CREB, initiating the expression of various genes such as tyrosine hydroxylase (*TH*) and brain-derived neurotrophic factor (*BDNF*). *BDNF* is implicated in long-term neuroplastic changes in response to chronic opioids.

pituitary hormones is inhibited, including corticotropin-releasing factor (CRF) and luteinizing hormone, which reduces levels of cortisol and sex hormones and can lead to impaired stress responses and reduced libido. An increase in prolactin also contributes to the reduced sex drive in males. Two other hormones affected are thyrotropin, which is reduced, and growth hormone, which is increased. Respiratory depression results from opioid-induced insensitivity of brainstem neurons to increases in carbon dioxide, and in patients with pulmonary disease, this can result in clinically significant complications. In overdoses, aspiration pneumonia is common due to loss of the gag reflex. Opioids reduce gut motility, which is helpful for treating diarrhea, but can lead to nausea, constipation, and anorexia with weight loss. Deaths occurred in early methadone maintenance programs due to severe constipation and toxic megacolon. Opioids such as methadone may prolong QT intervals and lead to sudden death in some patients. Orthostatic hypotension may occur due to histamine release and peripheral blood vessel dilation, which is an opioid effect usefully applied to managing acute myocardial infarction. During opioid maintenance, interactions with other medications are of concern; these include inducers of the cytochrome P450 system (usually CYP3A4) such as rifampin and carbamazepine.

Heroin users in particular tend to use opioids intravenously and are likely to be polydrug users, also using alcohol, sedatives, cannabinoids, and stimulants. None of these other drugs are substitutes for opioids, but they have desired additive effects. Therefore, one needs to be sure that the person undergoing a withdrawal reaction is not also withdrawing from alcohol or sedatives, which might be more dangerous and more difficult to manage.

Intravenous opioid use carries with it the risk of serious complications. The common sharing of hypodermic syringes can lead to infections with hepatitis B and HIV/AIDS, among others. Bacterial infections can lead to septic complications such as meningitis, osteomyelitis, and abscesses in various organs. Off-target effects of opioids synthesized in illicit drug labs can lead to serious toxicity. For example, attempts to illicitly manufacture meperidine in the 1980s resulted in the production of a highly specific neurotoxin, MPTP, which produced parkinsonism in users **(Chap. 435)**.

Lethal overdose is a relatively common complication of opioid use disorder. Rapid recognition and treatment with naloxone, a highly specific reversal agent that is relatively free of complications, are essential. The diagnosis is based on recognition of characteristic signs and symptoms, including shallow and slow respirations, pupillary miosis (mydriasis does not occur until significant brain anoxia supervenes), bradycardia, hypothermia, and stupor or coma. Blood or urine toxicology studies can confirm a suspected diagnosis, but immediate management must be based on clinical criteria. If naloxone is not administered, progression to respiratory and cardiovascular collapse leading to death occurs. At autopsy, cerebral edema and sometimes frothy pulmonary edema are generally found. Opioids generally do not produce seizures except for unusual cases of polydrug use with the opioid meperidine, with high doses of tramadol, or in the newborn.

TREATMENT

Opioid Overdose

Beyond the acute treatment of opioid overdose with naloxone, clinicians have two general treatment options: opioid maintenance or detoxification. Opioid agonist and partial agonist medications are commonly used for both maintenance and detoxification purposes. α_2-Adrenergic agonists are primarily used for detoxification. Antagonists are used to accelerate detoxification and then continued after detoxification to prevent relapse. Only the residential medication-free programs have had success that comes close to matching that of the medication-based programs. Success of the various treatment approaches is assessed as retention in treatment and reduced opioid and other drug use; secondary outcomes, such as reduced HIV risk behaviors, crime, psychiatric symptoms, and medical comorbidity, also indicate successful treatment.

Stopping opioid use is much easier than preventing relapse. Long-term relapse prevention for individuals with opioid use disorder requires combined pharmacologic and psychosocial approaches. Chronic users tend to prefer pharmacologic approaches; those with shorter histories of drug use are more amenable to detoxification and psychosocial interventions.

TABLE 456-2 Management of Opioid Overdose

Establish airway. Intubation and mechanical ventilation may be necessary.
Naloxone 0.4–2.0 mg (IV, IM, or endotracheal tube). Onset of action with IV is ~1–2 min.
Repeat doses of naloxone if needed to restore adequate respiration or a continuous infusion of naloxone can be used.
One-half to two-thirds of the initial naloxone dose that reversed the respiratory depression is administered on an hourly basis (note: naloxone dosing is not necessary if the patient has been intubated).

OPIOID OVERDOSE

Managing overdose requires naloxone and support of vital functions, including intubation if needed **(Table 456-2)**. If the overdose is due to buprenorphine, then naloxone might be required at total doses of 10 mg or greater, but primary buprenorphine overdose is nearly impossible because this agent is a partial opioid agonist, meaning that as the dose of buprenorphine is increased it has greater opioid antagonist than agonist activity. Thus, a 0.2-mg buprenorphine dose leads to analgesia and sedation, while a hundred times greater 20-mg dose produces profound opioid antagonism, precipitating opioid withdrawal in a person who had opioid use disorder on morphine or methadone. It is important to recognize that the goal is to reverse the respiratory depression and not to administer so much naloxone that it precipitates opiate withdrawal. Because naloxone only lasts a few hours and most opioids last considerably longer, an IV naloxone drip with close monitoring is frequently employed to provide a continuous level of antagonism for 24–72 h depending on the opioid used in the overdose (e.g., morphine vs methadone). Whenever naloxone has only a limited effect, other sedative drugs that produce significant overdoses must be considered. The most common are benzodiazepines, which have produced overdoses and deaths in combination with buprenorphine. A specific antagonist for benzodiazepines—flumazenil at 0.2 mg/min—can be given to a maximum of 3 g/h, but it may precipitate seizures and increase intracranial pressure. Like naloxone, administration for a prolonged period is usually required because most benzodiazepines remain active for considerably longer than flumazenil. Support of vital functions may include oxygen and positive-pressure breathing, IV fluids, pressor agents for hypotension, and cardiac monitoring to detect QT prolongation, which might require specific treatment. Activated charcoal and gastric lavage may be helpful for oral ingestions, but intubation will be needed if the patient is stuporous.

OPIOID WITHDRAWAL

The principles of detoxification are the same for all drugs: to substitute a longer-acting, orally active, pharmacologically equivalent medication for the substance being used, stabilize the patient on that medication, and then gradually withdraw the substituted medication. Methadone and buprenorphine are the two medications used to treat opioid use disorder. Clonidine, a centrally acting sympatholytic agent, has also been used for detoxification in the United States. By reducing central sympathetic outflow, clonidine mitigates many of the signs of sympathetic overactivity but typically requires augmentation with other agents. Clonidine has no narcotic action and is not addictive. Lofexidine, a clonidine analogue with less hypotensive effect, is not yet approved in the United States.

Methadone for Detoxification Dose-tapering regimens for detoxification using methadone range from 2–3 weeks to as long as 180 days, but this approach is controversial given the relative effectiveness of methadone maintenance and the low success rates of detoxification. Unfortunately, the vast majority of patients tend to relapse to heroin or other opioids during or after the detoxification period, indicative of the chronic and relapsing nature of opioid use disorder.

Buprenorphine for Detoxification Buprenorphine does not appear to lead to better outcomes than methadone but is superior to clonidine in reducing symptoms of withdrawal, in retaining patients in a withdrawal protocol, and in completing treatment.

α_2-Adrenergic Agonists for Detoxification Several α_2-adrenergic agonists have relieved opioid withdrawal by suppressing brain NE hyperactivity. Clonidine relieves some signs and symptoms of opioid withdrawal such as lacrimation, rhinorrhea, muscle pain, joint pain, restlessness, and gastrointestinal symptoms. Related agents are lofexidine, guanfacine, and guanabenz acetate. Lofexidine can be dosed up to ~2 mg/d and appears to be associated with fewer adverse effects. Clonidine or lofexidine is typically administered orally, in three or four doses per day, with dizziness, sedation, lethargy, and dry mouth as the primary adverse side effects. Outpatient-managed withdrawal will require close follow-up, often with naltrexone maintenance to prevent relapse.

Rapid and Ultrarapid Opioid Detoxification The opioid antagonist naltrexone typically combined with an α_2-adrenergic agonist has been purported to shorten the duration of withdrawal without significantly increasing patient discomfort. Completion rates using naltrexone and clonidine range from 75 to 81% compared to 40 to 65% for methadone or clonidine alone. Ultrarapid opioid detoxification is an extension of this approach using anesthetics but is highly controversial due to the medical risks and mortality associated with it.

Opioid Agonist Medications For Maintenance Methadone maintenance substitutes a once-daily oral opioid dose for three to four times daily heroin. Methadone saturates the opioid receptors and, by inducing a high level of opioid tolerance, blocks the euphoria from additional opioids. Buprenorphine, a partial opioid agonist, also can be given once daily at sublingual doses of 4–32 mg daily, and in contrast to methadone, it can be given in an office-based primary care setting.

METHADONE MAINTENANCE Methadone's slow onset of action when taken orally, long elimination half-life (24–36 h), and production of cross-tolerance at doses from 80 to 150 mg are the basis for its efficacy in treatment retention and reductions in IV drug use, criminal activity, and HIV risk behaviors and mortality. Methadone can prolong the QT interval at rates as high as 16% above the rates in non-methadone-maintained, drug-injecting patients, but it has been used safely in the treatment of opioid use disorder for 40 years.

BUPRENORPHINE MAINTENANCE While France and Australia have had sublingual buprenorphine maintenance since 1996, it was first approved by the U.S. Food and Drug Administration (FDA) in 2002 as a Schedule III drug for managing opioid use disorder. Unlike the full agonist methadone, buprenorphine is a partial agonist of mu-opioid receptors with a slow onset and long duration of action. Its partial agonism reduces the risk of unintentional overdose but limits its efficacy to patients who need the equivalent of only 60–70 mg of methadone, and many patients in methadone maintenance require higher doses of up to 150 mg daily. Buprenorphine is combined with naloxone at a 4:1 ratio in order to reduce its abuse liability. Because of pediatric exposures and diversion of buprenorphine to illicit use, a new formulation, using mucosal films rather than sublingual pills that were crushed and snorted, is now marketed. A subcutaneous buprenorphine implant that lasts up to 6 months has FDA approval as a formulation to prevent pediatric exposures and illicit diversion and to enhance compliance.

In the United States, the ability of primary care physicians to prescribe buprenorphine for opioid use disorder represents an important opportunity to improve access and quality of treatment as well as reduce social harm. Europe, Asia, and Australia have found reduced opioid-related deaths and drug-injection-related medical morbidity with buprenorphine available in primary care. Retention in office-based buprenorphine treatment has been as high as 70% at 6-month follow-ups.

Opioid Antagonist Medications The rationale for using narcotic antagonist therapy is that blocking the action of self-administered opioids should eventually extinguish the habit, but this therapy is poorly accepted by patients. Naltrexone, a long-acting orally active pure opioid antagonist, can be given three times a week at doses of 100–150 mg. Because it is an antagonist, the patient must first be detoxified from opioids before starting naltrexone. It is safe even when taken chronically for years, is associated with few side effects (headache, nausea, abdominal pain), and can be given to patients infected with hepatitis B or C without producing hepatotoxicity. However, most providers refrain from prescribing naltrexone if liver function tests are three times above normal levels. Naltrexone maintenance combined with psychosocial therapy is effective in reducing heroin use, but medication adherence is low. Depot injection formulations lasting up to 4 weeks markedly improve adherence, retention, and drug use. Subcutaneous naltrexone implants in Russia, China, and Australia have doubled treatment retention and reduced relapse to half that of oral naltrexone. In the United States, a depot naltrexone formulation is available for monthly use and maintains blood levels equivalent to 25 mg of daily oral use.

Medication-Free Treatment Most opioid users enter medication-free treatments in inpatient, residential, or outpatient settings, but 1- to 5-year outcomes are very poor compared to pharmacotherapy except for residential settings lasting 6–18 months. The residential programs require full immersion in a regimented system with progressively increasing levels of independence and responsibility within a controlled community of fellow drug users. These medication-free programs, as well as the pharmacotherapy programs, also include counseling and behavioral treatments designed to teach interpersonal and cognitive skills for coping with stress and for avoiding situations leading to easy access to drugs or to craving. Relapse is prevented by having the individual very gradually reintroduced to greater responsibilities and to the working environment outside of the protected therapeutic community.

PREVENTION

Preventing the development of opioid use disorder represents a critically important challenge for physicians. Opioid prescriptions are the most common source of drugs accessed by adolescents who begin a pattern of illicit drug use. The major sources of these drugs are family members, not drug dealers or the Internet. Pain management involves providing sufficient opioids to relieve the pain over as short a time as the pain warrants **(Chap. 13)**. The patient then needs to dispose of any remaining opioids, not save them in the medicine cabinet, because this behavior leads to diversion by adolescents. Finally, physicians should never prescribe opioids for themselves.

457 Cocaine, Other Psychostimulants, and Hallucinogens

Karran A. Phillips, Wilson M. Compton

The use of cocaine, methamphetamine, other psychostimulants, and hallucinogens reflects a complex interaction between the pharmacology of the drug, the personality and expectations of the user, and the environmental context in which the drug is used. These substances cause significant harm, although they are less commonly used than other addictive substances such as alcohol **(Chap. 453)**, nicotine **(Chap. 454)**, cannabis **(Chap. 455)**, and opioids **(Chap. 456)**. It is also important to recognize that polydrug use, involving the concurrent use of several drugs with different pharmacologic effects, is common. Sometimes one drug is used to enhance the effects of another, as with the combined use of cocaine and nicotine, or cocaine and heroin in methadone-treated patients. Some forms of polydrug use, such as the combined use of intravenous (IV) heroin and cocaine, are especially dangerous and account for many hospital emergency department visits. Cocaine and psychostimulant use (especially chronic patterns of use) may cause adverse health consequences and exacerbate preexisting disorders such as hypertension and cardiac disease. In addition, the combined use of two or more drugs may accentuate medical complications associated with use of one drug. Chronic use is often associated with immune system dysfunction and increased vulnerability to infections, including risk for HIV infection. The concurrent use of cocaine and opiates ("speedball") is frequently associated with needle sharing by people using drugs intravenously. People who use IV drugs represent the largest single group of individuals with HIV infection in several major metropolitan areas in the United States as well as in many parts of Europe and Asia. Furthermore, several outbreaks of HIV in the United States since 2015 in rural and suburban areas have been attributed to clusters of injection drug use.

Psychostimulants and hallucinogens have been used for centuries to induce euphoria and alter consciousness. Hallucinogens have become popular recently, and new drugs are continually being developed. This chapter describes the subjective and adverse medical effects of cocaine, other psychostimulants including methamphetamine, 3,4-methylenedioxymethamphetamine (MDMA), and cathinones; hallucinogens such as phencyclidine (PCP), D-lysergic acid diethylamide (LSD), and *Salvia divinorum*; and emerging drugs.

PSYCHOSTIMULANTS

Psychostimulants include cocaine and methamphetamine, as well as drugs with stimulant-like properties such as MDMA and cathinones. In addition, prescribed psychostimulants such as methylphenidate, dextroamphetamine, and amphetamine are considered here.

COCAINE

Cocaine is a powerful psychostimulant drug made from the cocoa plant. It has local anesthetic, vasoconstrictor, and stimulant properties. Cocaine is a Schedule II drug, which means that it has high potential for abuse but can be administered by a physician for legitimate medical uses, such as local anesthesia for some eye, ear, and throat surgeries.

Pharmacology Cocaine comes in a variety of forms, the most-used being the hydrochloride salt, sulfate, and a base. The salt is an acidic, water-soluble powder with a high melting point, used by snorting or sniffing intranasally or by dissolving it in water and injecting it. When used intranasally the bioavailability of cocaine is about 60%. Cocaine sulfate ("paste") has a melting point of almost 200°C, so it has limited use, but is sometimes smoked with tobacco. The base form can be freebase or crystallized as crack. Cocaine freebase is made by adding a strong base to an aqueous solution of cocaine and extracting the alkaline freebase precipitate. It has a melting point of 98°C and can be vaporized and inhaled. Freebase cocaine can also be crystallized and sold as crack or rock, which is also smoked or inhaled. Street dealers often dilute (or "cut") cocaine with nonpsychoactive substances such as cornstarch, talcum powder, flour, or baking soda, or adulterate it with other substances with similar effects (like procaine or amphetamine) to increase their profits. A recent concern has been the adulteration of cocaine (and other psychostimulants) with fentanyl-related opioids, resulting in overdose deaths due to opioid effects or polydrug use.

Given the extensive pulmonary vasculature, smoked or vaporized cocaine reaches the brain very quickly, similar in speed of onset to injected cocaine. The result is a rapid, intense, transient high, which enhances its addictive potential. Cocaine binds to the dopamine (DA) transporter and blocks DA reuptake, which increases synaptic levels of the monoamine neurotransmitters DA, norepinephrine (NE), and serotonin (5HT), in both the central nervous system (CNS) and the peripheral nervous system (PNS). Use of cocaine, like other drugs of abuse, induces long-term changes in the brain. Animal studies have shown adaptations in neurons that release the excitatory neurotransmitter glutamate after cocaine exposure.

Epidemiology According to the National Survey on Drug Use and Health (NSDUH), in 2019 an estimated 5.5 million people aged 12 years or older (2.0% of the population) were past-year consumers of cocaine, including about 778,000 (0.3% of the population) consumers of crack. Among those, 671,000 used cocaine for the first time (1800 cocaine initiates/day) including 59,000 adolescents aged 12–17 years. About 1 million people aged 12 years or older (0.4% of the population) in 2019 had a cocaine use disorder, but fewer than 1 in 5 received treatment, in the past year. According to the CDC National Center for Health Statistics, drug overdose deaths involving cocaine rose from 3822 in 1999 to 15,833 in 2019, with continued increases projected in 2020. Cocaine was involved in more than 1 in 5 overdose deaths in 2019. The number of deaths in combination with any opioid has been increasing steadily since 2014 and is mainly driven by the involvement of synthetic opioids including fentanyl and fentanyl analogs.

METHAMPHETAMINE

Methamphetamine is a psychostimulant drug usually used as a white, bitter-tasting powder or a pill. Crystal methamphetamine is a form of the drug that looks like glass fragments or shiny, bluish-white rocks. It can be inhaled/smoked, swallowed (pill), snorted, or injected (after being dissolved in water or alcohol).

Pharmacology When smoked, methamphetamine exhibits 90.3% bioavailability, compared to 67.2% for oral ingestion. Methamphetamine exists in two stereoisomers, the L- and D-forms. D-Methamphetamine, or the dextrorotatory enantiomer, is a more powerful psychostimulant, with 3–5 times the CNS activity as compared with L-methamphetamine. Methamphetamine is a cationic lipophilic molecule, which stimulates the release, and partially blocks the reuptake, of newly synthesized catecholamines in the CNS. Methamphetamine has a similar structure to the DA, NE, 5HT, and vesicular monoamine transporters and reverses their endogenous function, resulting in release of monoamines from storage vesicles into the synapse. Methamphetamine also attenuates the metabolism of monoamines by inhibiting monoamine oxidase.

Methamphetamine is more potent than amphetamine, resulting in much higher concentrations of synaptic DA and more toxic effects on nerve terminals. Outside the medical context, methamphetamine's pharmacokinetics and low cost often result in a chronic and continuous, high-dose self-administered use pattern.

Epidemiology According to the NSDUH, in 2019 approximately 2 million people aged 12 years or older (0.7% of the population) used methamphetamine in the past year, of those 184,000 used methamphetamine for the first time (510 people per day), and about 25% reported injecting methamphetamine. In 2019, an estimated 1 million people aged 12 years or older (0.4% of the population and 50% of those with past-year use) had a methamphetamine use disorder. High rates of co-occurring substance use or mental illness exist in adults who

use methamphetamine and only about one-third of adults with past-year methamphetamine use disorder received addiction treatment. Methamphetamine availability and methamphetamine-related harms (overdose deaths, treatment admissions, infectious disease transmission, etc.) continue to increase in the United States. According to CDC data, psychostimulants with abuse potential (primarily methamphetamine) caused 16,167 overdose deaths in 2019. These substances were the second leading cause of overdose death nationwide accounting for 23% of overdose deaths (compared to 49,860 deaths from an opioid in 2019). Of note there is significant geographic variation in the role of methamphetamine in overdose deaths; in four western regions methamphetamine was the #1 cause of overdose death accounting for 21–38% of all overdose deaths. Geographic variation is also apparent in overall psychostimulant-involved mortality rates; from 2015–2018 the highest increase was observed in West Virginia for psychostimulant use alone. Mortality associated with psychostimulants combined with opioids ranged from 15% in Hawaii to 91% in New Hampshire.

MDMA AND CATHINONES

MDMA also known as Molly, ecstasy, or X, is an illegal synthetic drug that has stimulant and psychedelic effects. Khât is a plant found in East Africa and the Middle East; it has been used for centuries for its mild stimulant-like effect. Synthetic cathinones or "bath salts" are manufactured psychostimulants that are chemically similar to the naturally occurring substance cathinone found in the khât plant and are discussed under "Emerging Drugs" below.

MDMA Molly, slang for "molecular," refers to the crystalline powder form of MDMA usually sold as powder or in capsules. The content of Molly varies and is often not MDMA at all but rather contains methylone or ethylone, which are synthetic substances commonly found in so-called bath salts and pose significant health risks. The clinician should always consider the possibility that the drug reported by the user may be incorrect or contaminated with other substances.

With MDMA use, individuals experience increased physical and mental energy, distortions in time and perception, emotional warmth, empathy toward others, a general sense of well-being, decreased anxiety, and an enhanced enjoyment of tactile experiences. MDMA is usually taken orally in a tablet, capsule, or liquid form with first effect at 45 min on average, peak effect at 1–2 h, and duration ~3–6 h. MDMA binds to serotonin transporters and increases the release of serotonin, NE, and DA. Research in animals has shown that MDMA in moderate to high doses can cause loss of serotonin-containing nerve endings and permanent damage. MDMA is a Schedule I drug, along with other substances with no proven therapeutic value. MDMA is currently in clinical trials as a possible treatment for posttraumatic stress disorder and anxiety and for patients with terminal illness including cancer. The evidence on MDMA's therapeutic effects is quite limited to date, and research is ongoing.

Adulteration of MDMA tablets with methamphetamine, ketamine, caffeine, the over-the-counter cough suppressant dextromethorphan (DXM), the diet drug ephedrine, and cocaine is common. MDMA is rarely used alone and is often mixed with other substances, such as alcohol and marijuana, making the scope of its use difficult to ascertain. According to the NSDUH, >18 million people in the United States have tried MDMA at least once in their life. MDMA is predominantly used by men 18–25 years of age, with use typically beginning at age 21 years. There is evidence that gay or bisexual men and women are more likely than their heterosexual counterparts to have used MDMA in the last 30 days.

Cathinone Is an alkaloid psychostimulant structurally similar to amphetamine found in the khât (*Catha edulis*) plant, which grows at high altitudes in East Africa and the Middle East and whose leaves are chewed for their mild stimulant-like effect. The extraction of cathinone and other alkaloids from the leaves by chewing is very effective leaving little as unabsorbed residue. The leaves and twigs can also be smoked, infused in tea, or sprinkled on food. Cathinone increases dopamine release and reduces dopamine reuptake.

Originally limited to its area of cultivation, with advances in rapid transportation and postal delivery khât is now available in several continents including Europe and North America. Worldwide it is estimated that 10 million people chew khât, including up to 80% of all adults in some areas where the evergreen shrub is indigenous. In regions where the plant is indigenous, there have also been reports of khât use as a study aid among university students. Cathinone is a Schedule I drug in the United States, making its use illegal; however, the khât plant itself is not controlled.

PRESCRIBED PSYCHOSTIMULANTS

Methylphenidate, dextroamphetamine, and dextroamphetamine/amphetamine combination products are psychostimulants approved in the United States for treatment of attention-deficit hyperactivity disorder (ADHD), weight control, and narcolepsy. Prescription psychostimulants increase alertness, attention, and energy. Phenylpropanolamine, a psychostimulant used primarily for weight control, was found to be related to hemorrhagic stroke in women and removed from the market in 2005. Nonprescribed amphetamines or methylphenidate is used quite frequently by college students, and as an energy and productivity booster by others. According to the 2019 NSDUH, past-year prescription stimulant misuse was reported by 4.9 million (1.8%) people aged 12 years or older. Past-year initiates of prescription stimulant misuse totaled 901,000, which averages to about 2500 people misusing prescription stimulants for the first time each day, including 1000 young adults each day. Among people aged 12 years or older, 0.2% (558,000 people) had a prescription stimulant use disorder in the past year.

PSYCHOSTIMULANT CLINICAL MANIFESTATIONS

Psychostimulants produce the same acute CNS effects: euphoria/elevated mood, increased energy/decreased fatigue, reduced need for sleep, decreased appetite, heightened sense of alertness, decreased distractibility, dosed-dependent effects on focus, attention, and curiosity, increased self-confidence, increased libido, and prolonged orgasm, independent of the specific psychostimulant or route of administration. Peripheral effects may include tremor, diaphoresis, hypertonia, tachypnea, hyperreflexia, and hyperthermia. Many of the effects are biphasic; for example, low doses improve psychomotor performance, while higher doses may cause tremors or convulsions. α-adrenergically mediated cardiovascular effects are also biphasic, with low doses resulting in increased vagal tone and decreased heart rate, and high doses causing increased heart rate and blood pressure. Psychostimulant use can result in restlessness, irritability, and insomnia and, at higher doses, suspiciousness, repetitive stereotyped behaviors, and bruxism. Endocrine effects resulting from chronic use may include impotence, gynecomastia, menstrual function disruptions, and persistent hyperprolactinemia **(Table 457-1)**.

Overdose presents as sympathetic nervous system overactivity with psychomotor agitation, hypertension, tachycardia, headache, and mydriasis, and can lead to convulsions, cerebral hemorrhage or infarction, cardiac arrhythmias or ischemia, respiratory failure, or rhabdomyolysis. It is a medical emergency; treatment is largely symptomatic and should occur in an intensive care or telemetry unit. Inhalation of crack cocaine that is vaporized at high temperatures can cause airway burns, bronchospasm, and other symptoms of pulmonary disease. MDMA has also been shown to raise body temperature and can occasionally result in liver, kidney, or heart failure, or even death.

Psychostimulants are often used with other drugs, including opioids and alcohol, whose CNS-depressant effects tend to attenuate psychostimulant-induced CNS stimulation. These combinations often have additive deleterious effects, increasing the risk of morbidity and mortality. An example of this risk is the use of cocaine with alcohol, which results in the metabolite, cocaethylene. Cocaethylene's effects on the cardiovascular system are additive to that of cocaine's effects, resulting in intensified pathophysiologic consequences.

Adulteration of psychostimulants, particularly cocaine, with other drugs is common and can have additional potential health consequences. In addition to contamination with fentanyl-related compounds, potentially resulting in fatal overdose, multiple other

TABLE 457-1 Complications of Psychostimulant Use

Cardiovascular	Acute • Arterial vasoconstriction • Thrombosis • Tachycardia • Hypertension • Increased myocardial oxygen demand • Increased vascular shearing forces • Coronary vasoconstriction • Cardiac ischemia • Left ventricular dysfunction/heart failure (high blood concentrations) • Supraventricular and ventricular dysrhythmias • Aortic dissection/rupture Chronic • Accelerated atherogenesis • Left ventricular hypertrophy • Dilated cardiomyopathy
Central and Peripheral Nervous Systems	• Hyperthermia • Psychomotor agitation • Tremor • Hyperreflexia • Hypertonia • Headache • Seizures • Coma • Intracranial hemorrhage • Focal neurologic symptoms
Pulmonary	• Angioedema (inhaled) • Pharyngeal burns (inhaled) • Pneumothorax • Pneumomediastinum • Pneumopericardium • Reversible airway disease exacerbations • Bronchospasm • Shortness of breath ("crack lung") • Tachypnea • Pulmonary infarction
Gastrointestinal	• Perforated ulcers • Ischemic colitis • Bowel infarction • Impaction (body packing) • Hepatic enzyme elevation
Renal	• Metabolic acidosis • Renal infarction • Rhabdomyolysis
Endocrine	• Impotence • Gynecomastia • Menstrual function disruptions • Hyperprolactinemia
Other	• Diaphoresis • Irritability • Insomnia • Bruxism • Stereotypy • Splenic infarction • Acute angle-closure glaucoma • Vasospasm of the retinal vessels (unilateral or bilateral vision loss) • Mydriasis • Madarosis • Abruptio placentae

substances have been noted as contaminants of psychostimulants. Levamisole, an anthelminthic and immunomodulator used primarily in veterinary medicine, has been found in cocaine and can cause agranulocytosis, leukoencephalopathy, and cutaneous vasculitis, which has resulted in cutaneous necrosis. Clenbuterol, a sympathomimetic amine used clinically as a bronchodilator, has also been found in cocaine and can result in tachycardia, hyperglycemia, palpitations, and hypokalemia. Studies in Europe have found that, in addition to levamisole, some of the most common adulterants in cocaine include phenacetin, lidocaine, caffeine, diltiazem, hydroxyzine, procaine, tetracaine, paracetamol, creatine, and benzocaine.

Withdrawal from psychostimulants often includes hypersomnia, increased appetite, and depressed mood. Acute withdrawal typically lasts 7–10 days, but residual symptoms, possibly associated with neurotoxicity, may persist for several months. Debate remains whether psychostimulant withdrawal symptoms decline monotonically or occur in discrete phases, becoming worse before they improve. Psychostimulant withdrawal is not thought to be a major driver of ongoing use. Most current theories of psychostimulant addiction emphasize the primary role of conditioned craving, which can persist long after physiological withdrawal has abated. Conditioned craving includes the urge to use drugs in response to cues in the environment associated with drug use, such as drug-using associates, drug paraphernalia, drug-using locations, etc.

Injection of psychostimulants places people at increased risk of contracting infectious diseases from exposure to HIV and hepatitis B or C in blood or other bodily fluids, as well as with skin abscesses and endocarditis. Psychostimulant use can also increase risk for infection by causing altered judgment and decision-making, leading to risky behaviors, such as unprotected sex. There is some evidence that psychostimulant use may worsen the progression of HIV/AIDS via increased injury to nerve cells exacerbating cognitive problems.

The actions and effects of khât are like those of other psychostimulants. Short-term effects include euphoria, increased alertness and arousal, loss of appetite, insomnia, headaches, and tremors. Long-term use may result in gastrointestinal disorders such as constipation, ulcers, and stomach inflammation as well as increased risk for acute myocardial infarction and stroke, due to inotropic and chronotropic effects on the heart, vasospasm of coronary arteries, and catecholamine-induced platelet aggregation. There is evidence that, rarely, heavy khât use may cause mild to moderate psychological dependence. Compulsive use has been described, with resulting grandiose delusions, paranoia, and hallucinations. Mild withdrawal from khât has been described and can include depression, nightmares, low blood pressure, and lack of energy.

DIAGNOSIS

The *Diagnostic and Statistical Manual of Psychiatric Disorders*, 5th edition (*DSM*-5) defines a stimulant use disorder (SUD) as a pattern of use of amphetamine-type substances, cocaine, or other stimulants leading to clinically significant impairment or distress, as manifested by at least 2 of the following 11 problems within a 12-month period: taking larger amounts, or over a longer period of time, than intended; persistent desire or unsuccessful efforts to reduce or control use; a great deal of time spent in activities necessary to obtain, use, or recover; craving; use resulting in failure to fulfill major role obligations; continued use, despite recurrent social or interpersonal problems; giving up social, occupational, or recreational activities; recurrent use in physically hazardous situations; continued use despite persistent or recurrent physical or psychological problems; tolerance; and withdrawal symptoms, or avoidance of withdrawal symptoms, by continued use.

The International Classification of Diseases (ICD) 10th Revision (ICD-10) recognizes "stimulant dependence syndrome" and "stimulant withdrawal state" and the ICD 11th Revision (ICD-11) further specifies the definition to "stimulant dependence including amphetamines, methamphetamines, or methcathinone."

TREATMENT

Acute Intoxication

As with all emergency situations the first task is to check a patient's airway, breathing, and circulation. With cocaine use, succinylcholine is relatively contraindicated in rapid-sequence intubation; consider rocuronium (1 mg/kg IV) or another nondepolarizing agent as an alternative. If psychomotor agitation occurs, rule out hypoglycemia and hypoxemia first, and then administer benzodiazepines (e.g., diazepam 10 mg IV and then 5–10 mg IV every 3–5 min until agitation controlled). Benzodiazepines are usually sufficient to address cardiovascular side effects. Severe or symptomatic hypertension can be treated with phentolamine, nitroglycerin, or nitroprusside. Hyperthermic patients should be cooled within ≤30 min with the goal to achieve a core body temperature of <39°C (102°F). Evaluation of chest pain in someone using cocaine should include an electrocardiogram, chest radiograph, and biomarkers to exclude myocardial infarction. The treatment approach is similar to nonstimulant-induced chest pain; however, it is recommended that whenever possible beta blockers not be used in people who use cocaine. The concern arises from the potential unopposed alpha-adrenergic stimulation that results from beta blockade possibly causing coronary arterial vasoconstriction, ischemia, and infarction and limited data supporting the benefit of beta blockers in cocaine-related cardiovascular complications. If beta blockers are to be given, it is suggested that mixed alpha/beta blockers, e.g., labetalol and carvedilol, be used rather than nonselective beta blockers, and only in situations where the benefits outweigh the risks. Because many instances of psychostimulant-related mortality have been associated with concurrent use of other illicit drugs (particularly opioids), the physician must be prepared to institute effective emergency treatment for multiple drug toxicities.

Psychostimulant Use Disorders

Treatment of stimulant use disorders requires the combined efforts of primary care physicians, psychiatrists, and psychosocial care providers. Early abstinence from psychostimulant use is often complicated by symptoms of depression and guilt, insomnia, and anorexia, which may be as severe as those observed in major affective disorders and can last for months and even years after use has stopped.

Behavioral therapies, including cognitive-behavioral therapy (CBT), the community reinforcement approach (CRA), contingency management (CM; providing rewards to patients who remain substance free), motivational enhancement therapy (MET), combinations of these, and others remain the mainstay of treatment for stimulant use disorders and show modest benefit. These behavioral therapies are designed to help modify the patient's thinking, expectancies, and behaviors, and to increase life-coping skills, with behavioral interventions to support long-term, drug-free recovery. Based on systematic reviews, contingency management has been noted to be particularly effective. However, the effect of these behavioral therapies is often not sustained, and they may be less effective in individuals with severe use disorder.

There are no U.S. Food and Drug Administration (FDA)-approved medications for psychostimulant addiction. Current research includes several neurotransmitter-based strategies, including DA agonist-, serotonin-, γ-aminobutyric acid (GABA)-, and glutamate-based approaches. Trials of agonist therapy with longer-acting psychostimulant medications such as dexamphetamine and methylphenidate have not been conclusive. Studies with the antidepressants mirtazapine, bupropion, sertraline, imipramine, and atomoxetine have been equivocal as have studies with the atypical antipsychotic, aripiprazole, and the anticonvulsant, topiramate. Other therapies being studied for the treatment of psychostimulant use disorder include: acamprosate (possibly via a role in Ca^{2+} supply), galantamine (reversible acetylcholine esterase inhibitor, which may strengthen impulse control, as well as cognitive and social abilities depleted by long-term psychostimulant use), naltrexone (opiate receptor antagonist), doxazosin (alpha-adrenergic antagonist), and varenicline (partial agonist at the α4β2 nicotinic acetylcholine receptors and DA neurotransmission enhancer). Overall, it is promising that some of the medications studied showed statistically significant outcome improvement over placebo, but many of these studies were underpowered due to issues of small sample size, sample bias, low participant retention, and low treatment adherence rates. Ongoing studies are investigating lisdexamfetamine (a dexamphetamine pro-drug), a combination of extended-release naltrexone with bupropion, pomaglumetad (a glutamate agonist), and monoclonal antibodies. Special attention needs to be paid to the inclusion of underrepresented populations including women in future stimulant use disorder medication trials. Vaccines for cocaine and methamphetamine use disorders are also being developed. Finally, recent preliminary studies have brought attention to the potential use of brain stimulation techniques such as transcranial magnetic stimulation (TMS), theta-burst stimulation (TBS), and transcranial direct current stimulation (tDCS) to treat psychostimulant use disorders, although further studies will be required to determine their value, if any, in this situation.

HALLUCINOGENS

Hallucinogens are a diverse group of drugs causing alteration of thoughts, feelings, sensations, and perceptions. Some hallucinogens are found naturally in plants and mushrooms, while others are synthetic. They include: ayahuasca (a tea made from Amazonian plants containing dimethyltryptamine (DMT), the primary mind-altering ingredient); DMT (aka Dimitri, can also be synthesized in a lab); LSD (clear or white odorless material made from lysergic acid found in rye and other grain fungus); peyote (mescaline, derived from a small, spineless cactus or made synthetically); and 4-phosphoryloxy-N,N-dimethyltryptamine (psilocybin, comes from certain South and North American mushrooms).

A subgroup of hallucinogens produces the added sensation of feeling out of control or disconnected from one's body or surroundings. These dissociative drugs include: DXM (an over-the-counter cough suppressant, when used in high doses); ketamine (a human and veterinary anesthetic as well as an antidepressant medication recently approved by the FDA); phencyclidine (PCP; a cyclohexylamine derivative and dissociative anesthetic); and *Salvia divinorum* (salvia, a Mexican, Central, and South American plant). Dissociative drugs distort the way the user perceives time, motion, color, sound, and self, and their use can lead to bizarre and dangerous behavior and cause respiratory depression, heart rate abnormalities, and a withdrawal syndrome including drug craving, confusion, headache, and sweating.

Use of hallucinogens in religious and spiritual rituals goes back centuries, and they are ingested in a wide variety of ways, including orally, by smoking, intranasally, and transmucosally. Especially when taken orally, the onset of action of hallucinogens is within 20–90 min and the duration of action can be as long as 6–12 h, except for salvia, whose effects generally last about 30 min. Hallucinogens specifically disrupt the neurotransmitters serotonin and glutamate. Effects on the serotonin system can disturb mood, sensory perception, sleep, appetite, body temperature, sexual behavior, and muscle control. Glutamate system effects include perturbations in pain perception, responses to the environment, emotion, and learning and memory.

According to the NSDUH, in 2019 1.9 million adults reported past-month hallucinogen use and 6 million (2.2% of the population) reported past-year hallucinogen use, an increase from 4.7 million (1.8%) in 2015. Of these, 1.2 million used hallucinogens for the first time. These estimates are similar to 2015 and 2018 estimates for those aged 12–17 years but reflect an increase in past-year use among those aged 26 years and older. Of note, these statistics include ecstasy (MDMA or "Molly") in the overall hallucinogen use as well as LSD, PCP, peyote, mescaline, psilocybin mushrooms, ketamine, DMT/AMT/"Foxy", and *Salvia divinorum*. New initiates to drug use per day

among people age 12 years and older include 2421 for LSD, 83 for PCP, and 2039 for ecstasy. According to 2019 Monitoring the Future Data, the annual prevalence of use among 12th graders was 1.1% for PCP, 2.2% for ecstasy, and 0.7% for salvia, which was similar to 2018.

Clinical manifestations of hallucinogen use include false sensory experiences (i.e., hallucinations), intensified feelings, heightened sensory experiences, and time perturbations. Additional physiologic responses include nausea; increased heart rate, blood pressure, respiratory rate, or body temperature; loss of appetite; xerostomia; sleep problems; synesthesia; impaired coordination; and hyperhidrosis. Extremely negative experiences with hallucinogen use (the "bad trip") can include panic, paranoia, and psychosis, which may persist for up to 24 h. Such experiences are best treated with supportive reassurance, but benzodiazepines (e.g., diazepam 10 mg or lorazepam, if liver damage is present) may be administered if agitation is severe. There is some evidence that chronic effects of hallucinogen use can occur, including persistent psychosis, memory loss, anxiety, depression, and flashbacks. Long-term effects of PCP and other dissociative drug use can include persistent speech difficulties, memory loss, depression, suicidal thoughts, anxiety, and social withdrawal that may persist for a year or more after chronic use stops.

Psilocybin is under active investigation for its possible benefit in treatment of depression and some anxiety disorders.

Hallucinogen addiction is atypical, as use patterns are generally not chronic, and there are currently no FDA-approved medications for the treatment of hallucinogen addiction. Research on behavioral treatments for hallucinogen addiction is underway.

EMERGING DRUGS

With the aid of the Internet, and some basic over-the-counter (and other) ingredients, the rise of the "kitchen chemist" is upon us. The production of new psychoactive substances (NPSs), such as synthetic cathinones (bath salts) and synthetic cannabinoids (spice), is on the rise and has resulted in the use of unregulated psychoactive substances that are intended to copy the effects of more expensive illegal drugs, such as methamphetamine and cocaine.

Synthetic cathinones (bath salts) are human-made drugs chemically similar to khât and are often stronger and more dangerous than the natural product. They usually take the form of a white or brown crystal-like powder, packaged in small plastic or foil bundles labeled "not for human consumption," or as "plant food," "jewelry cleaner," or "phone screen cleaner," and sold online and in drug paraphernalia stores. The popular nickname Molly (slang for "molecular") often refers to the purported "pure" crystalline powder form of MDMA, usually sold in capsules. However, people who purchase powder or capsules sold as Molly often actually receive other drugs, such as synthetic cathinones. The uncertainty of what is actually in these synthetic products, whose components might change from batch to batch, makes them even more dangerous as anyone using them is unaware of what the products contain and how their bodies will react.

The three most common synthetic cathinones are mephedrone, methylone, and MDPV (*3,4-methylenedioxypyrovalerone*). With oral ingestion, these drugs have an onset of action from 15–45 min, and a duration that varies from 2–7 h. A recent study found that MDPV affects the brain in a manner similar to cocaine but is at least 10 times more potent. MDPV is the most common synthetic cathinone found in the blood and urine of patients admitted to EDs after taking "bath salts." High doses, or chronic use, of synthetic cathinones can lead to dangerous medical consequences, including psychosis, violent behaviors, tachycardia, hyperthermia, and even death.

The ability to synthesize addictive and dangerous drugs relatively simply and rapidly, changing just a few molecules, yet retaining the effects, has allowed many of these emerging drugs to outpace efforts to regulate them, resulting in a developing global public health concern.

SUBSTANCE USE AND MENTAL HEALTH

According to the NSDUH, in 2019, among adults with no mental illness 16.6% consumed illicit drugs, compared to 49.4% with severe mental illness and 38.8% with any mental illness. In 2019, among adults 18 years of age or older, 61.2 million people had either mental illness or a substance use disorder in the past year, 42 million had mental illness in the absence of a substance use disorder, 9.7 million had a substance use disorder and no mental illness, and 9.5 million (3.8% of the population) had both. Furthermore, based on 2018 NSDUH data it is estimated that more than 1 in 10 adults (27.5 million) in the United States reported ever having a substance use problem. Among those with a problem, nearly 75% (20.5 million) reported being in recovery, which was associated with lower prevalence of past-year substance use and having received substance use treatment. Self-reported prevalence of ever having a substance use problem was 31.9% among adults with a lifetime mental health problem but not in recovery, followed by 29.7% among adults in recovery, compared with 7.0% among adults without a lifetime mental health problem. Taken together, these data all point to the significant overlap of substance-related and other mental health problems.

GLOBAL CONSIDERATIONS

After nicotine, alcohol, and cannabis, stimulants are the next most commonly used drugs globally, accounting for 68 million past-year consumers. Past-year stimulant use worldwide for individuals aged 15–65 years approaches 29 million. Globally 7.4 million individuals have a stimulant use disorder and it is thought that 11% of all people who use stimulants develop such a disorder. The United Nations Office on Drugs and Crime (UNODC) estimates that 1 in 7 people with substance use disorders receives treatment, and this number is thought much lower in individuals with stimulant use disorder due to the lack of pharmacologic treatments. Cocaine use globally had remained stable until 2010 when it began to rise, driven by an increase in its use in South America. Amphetamine use in Western Europe is still well below 5% lifetime prevalence for most countries, and methamphetamine problems have been largely restricted to the Czech Republic; however, evidence indicates growing spread through Europe. Over three-quarters of the world's production of amphetamine-type stimulants occurs in Southeast Asia and in recent years there has been a dramatic increase in use in this region, particularly Thailand. In Japan and the Philippines, methamphetamine use predominates. Lifetime experience with ecstasy among the general population is still well below 5% in most European countries, which is slightly lower than levels seen in Australia (6%). Ecstasy is more prevalent in the West; however, over the past decade use has increasingly become evident in other regions, including Africa, South and Central America, the Caribbean, and parts of Asia. Globally, psychostimulant use has been associated with elevated mortality, increased incidence of HIV and hepatitis C infection, poor mental health (suicidality, psychosis, depression, and violence), and increased risk of cardiovascular events. Globally, stigma and marginalization make treatment of drug use disorders difficult and hinder sustainable inclusive development incorporating gender and racial equity and the empowerment of women and underrepresented minorities.

FUTURE DIRECTIONS

Despite their prevalence and public health impact, psychostimulant and hallucinogen use disorders have no FDA-approved treatment medications. While behavioral therapies, such as contingency management and CBT, have been shown effective in psychostimulant use disorders, further research needs to be done regarding their utility for hallucinogen use disorders. Furthermore, based upon experience with opioid and alcohol use disorders, it is likely that the most efficacious treatments will employ a combination of behavioral and pharmacologic therapy.

Additionally, new approaches that utilize emerging technologies have considerable potential for future treatment of psychostimulant use disorders. These include neurostimulation/neuromodulation (TMS, TBS, tDCS), wearable biosensors, and mobile technology, including ecologic and geographic momentary assessment (EMA/GMA) as well as real-time interventions delivered via smartphone or other mobile devices.

458 Heavy Metal Poisoning

Howard Hu

Toxic metals (hereafter referred to simply as "metals") pose a significant threat to health through low-level as well as high level environmental and occupational exposures. One indication of their importance relative to other potential hazards is their ranking by the U.S. Agency for Toxic Substances and Disease Registry, which maintains an updated list of all hazards present in toxic waste sites according to their prevalence and the severity of their toxicity. The first, second, third, and seventh hazards on the list are heavy metals: arsenic, lead, mercury, and cadmium, respectively (*http://www.atsdr.cdc.gov/spl/*). Specific information pertaining to each of these four metals, including sources and metabolism, toxic effects produced, diagnosis, and the appropriate treatment for poisoning, is summarized in **Table 458-1**.

Metals are inhaled primarily as dusts and fumes (the latter defined as tiny particles generated by combustion). Metal poisoning can also result from exposure to vapors (e.g., mercury vapor in creating dental amalgams). When metals are ingested in contaminated food or drink or by hand-to-mouth activity (implicated especially in children), their gastrointestinal absorption varies greatly with the specific chemical form of the metal and the nutritional status of the host. Once a metal is absorbed, blood is the main medium for its transport, with the precise kinetics dependent on diffusibility, protein binding, rates of biotransformation, availability of intracellular ligands, and other factors. Some organs (e.g., bone, liver, and kidney) sequester metals in relatively high concentrations for years. Most metals are excreted through renal clearance and gastrointestinal excretion; some proportion is also excreted through salivation, perspiration, exhalation, lactation, skin exfoliation, and loss of hair and nails. The intrinsic stability of metals facilitates tracing and measurement in biologic material, although the clinical significance of the levels measured is not always clear.

Some metals, such as copper and selenium, are essential to normal metabolic function as trace elements **(Chap. 333)** but are toxic at high levels of exposure. Others, such as lead and mercury, are xenobiotic and theoretically are capable of exerting toxic effects at any level of exposure. Indeed, much research is currently focused on the contribution of low-level xenobiotic metal exposure to chronic diseases and to subtle changes in health that may have significant public health consequences. Genetic factors, such as polymorphisms that encode for variant enzymes with altered properties in terms of metal binding, transport, and effects, also may modify the impact of metals on health and thereby account, at least in part, for individual susceptibility to metal effects.

The most important component of treatment for metal toxicity is the termination of exposure. *Chelating agents* are used to bind metals into stable cyclic compounds with relatively low toxicity and to enhance their excretion. The principal chelating agents are dimercaprol (British anti-Lewisite [BAL]), ethylenediamine tetraacetic acid (EDTA), succimer (dimercaptosuccinic acid [DMSA]), and penicillamine; their specific use depends on the metal involved and the clinical circumstances. Activated charcoal does not bind metals and thus is of limited usefulness in cases of acute metal ingestion.

In addition to the information provided in Table 458-1, several other aspects of exposure, toxicity, or management are worthy of discussion with respect to the four most hazardous toxicants (arsenic, cadmium, lead, and mercury).

Arsenic, even at moderate levels of exposure, has been clearly linked with increased risks for cancer of the skin, bladder, renal pelvis, ureter, kidney, liver, and lung. These risks appear to be modified by smoking, folate and selenium status, genetic traits (such as ability to methylate arsenic), and other factors. Recent studies in community-based populations have generated strong evidence that arsenic exposure is also a risk factor for increased risk of hypertension, coronary heart disease and stroke, lung function impairment, acute respiratory tract infections, respiratory symptoms, and nonmalignant lung disease mortality. The association with cardiovascular disease may hold at levels of exposure in drinking water that are below the World Health Organization (WHO) provisional guideline value of 10 μg/L. Evidence has also continued to build indicating that low-level arsenic is a likely cause of neurodevelopmental delays in children and likely contributes to the development of diabetes.

Serious *cadmium* poisoning from the contamination of food and water by mining effluents in Japan contributed to the 1946 outbreak of "itai-itai" ("ouch-ouch") disease, so named because of cadmium-induced bone toxicity that led to painful bone fractures. Modest exposures from environmental contamination have been associated in some studies with a lower bone density, a higher incidence of fractures, and a faster decline in height in both men and women, effects that may be related to cadmium's calciuric and other toxic effects on the kidney. Cadmium burdens have also been associated with an increased risk of long-term kidney graft failure, and there is evidence for synergy between the adverse impacts of cadmium and lead on kidney function. Environmental exposures have also been linked to lower lung function (even after adjusting for smoking cigarettes, which contain cadmium) as well as increased risk of cardiovascular disease and mortality, stroke, and heart failure. Cadmium triggers pulmonary inflammation, and a recent population-based study of U.S. adults found that higher cadmium burdens are associated with higher mortality from influenza or pneumonia. The International Agency for Research on Cancer has classified cadmium as a known carcinogen, with evidence indicating it contributes to elevated risks of prostate, lung, breast, and endometrial cancer. Overall, this growing body of research indicates that cadmium exposure is contributing significantly to morbidity and mortality rates in the general population.

Advances in our understanding of *lead* toxicity have recently benefited by the development of K x-ray fluorescence (KXRF) instruments for making safe in vivo measurements of lead levels in bone, which, in turn, reflect cumulative exposure over many years, as opposed to blood lead levels, which mostly reflect recent exposure. Higher levels of cumulative lead exposure are now known to be a risk factor for chronic disease, even though blood lead levels have continued to decline in the general population over the past few decades following the removal of lead from gasoline, plumbing, solder in food cans, and other consumer products, with mean levels in the U.S. population now hovering in the 1–2 μg/dL range. For example, higher bone lead levels measured by KXRF have been linked to increased risk of hypertension and accelerated declines in cognition in both men and women living in urban communities. These relationships, in conjunction with other epidemiologic and toxicologic studies, persuaded a federal expert panel to conclude they were causal. Prospective studies have also demonstrated that higher bone lead levels, as well as blood lead levels as low as 1–7 μg/dL, are a major risk factor for increased cardiovascular morbidity and mortality rates in both community-based and occupational-exposed populations. Lead exposure at community levels has also been associated with increased risks of hearing loss, Parkinson's disease, and amyotrophic lateral sclerosis. With respect to pregnancy-associated risks, high maternal bone lead levels were found to predict lower birth weight, head circumference, birth length, and neurodevelopmental performance in offspring by age 2 years. Offspring have also been shown to have higher blood pressures at age 7–14 years, an age range at which higher blood pressures are known to predict an elevated risk of developing hypertension. In a randomized trial, calcium supplementation (1200 mg daily) was found to significantly reduce the mobilization of lead from maternal bone into blood during pregnancy.

The toxicity of low-level organic *mercury* exposure (as manifested by neurobehavioral performance) is of increasing concern

TABLE 458-1 Heavy Metals

MAIN SOURCES	METABOLISM	TOXICITY	DIAGNOSIS	TREATMENT
Arsenic				
Smelting and microelectronics industries; wood preservatives, pesticides, herbicides, fungicides; contaminant of deep-water wells; folk remedies; and coal; incineration of these products.	Organic arsenic (arsenobetaine, arsenocholine) is ingested in seafood and fish, but is nontoxic; inorganic arsenic is readily absorbed (lung and GI); sequesters in liver, spleen, kidneys, lungs, and GI tract; residues persist in skin, hair, and nails; biomethylation results in detoxification, but this process saturates.	Acute arsenic poisoning results in necrosis of intestinal mucosa with hemorrhagic gastroenteritis, fluid loss, hypotension, delayed cardiomyopathy, acute tubular necrosis, and hemolysis. Chronic arsenic exposure causes diabetes, vasospasm, peripheral vascular insufficiency and gangrene, peripheral neuropathy, and cancer of skin, lung, liver (angiosarcoma), bladder, and kidney. Lethal dose: 120–200 mg (adults); 2 mg/kg (children).	Nausea, vomiting, diarrhea, abdominal pain, delirium, coma, seizures; garlicky odor on breath; hyperkeratosis, hyperpigmentation, exfoliative dermatitis, and Mees' lines (transverse white striae of the fingernails); sensory and motor polyneuritis, distal weakness. Radiopaque sign on abdominal x-ray; ECG–QRS broadening, QT prolongation, ST depression, T-wave flattening; 24-h urinary arsenic >67 μmol/d or 50 μg/d; (no seafood × 24 h); if recent exposure, serum arsenic >0.9 μmol/L (7 μg/dL). High arsenic in hair or nails.	If acute ingestion, ipecac to induce vomiting, gastric lavage, activated charcoal with a cathartic. Supportive care in ICU. Dimercaprol 3–5 mg/kg IM q4h × 2 days; q6h × 1 day, then q12h × 10 days; alternative: oral succimer.
Cadmium				
Metal plating, pigment, smelting, battery, and plastics industries; tobacco; incineration of these products; ingestion of food that concentrates cadmium (grains, cereals, organ meats).	Absorbed through ingestion or inhalation; bound by metallothionein, filtered at the glomerulus, but reabsorbed by proximal tubules (thus, poorly excreted). Biologic half-life: 10–30 y. Binds cellular sulfhydryl groups, competes with zinc, calcium for binding sites. Concentrates in liver and kidneys.	Acute cadmium inhalation causes pneumonitis after 4–24 h; acute ingestion causes gastroenteritis. Chronic exposure causes anosmia, yellowing of teeth, emphysema, minor LFT elevations, microcytic hypochromic anemia unresponsive to iron therapy, proteinuria, increased urinary β_2-microglobulin, calciuria, leading to chronic renal failure, osteomalacia, and fractures. Possible risks of cardiovascular disease and cancer.	With inhalation: pleuritic chest pain, dyspnea, cyanosis, fever, tachycardia, nausea, noncardiogenic pulmonary edema. With ingestion: nausea, vomiting, cramps, diarrhea. Bone pain, fractures with osteomalacia. If recent exposure, serum cadmium >500 nmol/L (5 μg/dL). Urinary cadmium >100 nmol/L (10 μg/g creatinine) and/or urinary β_2-microglobulin >750 μg/g creatinine (but urinary β_2-microglobulin also increased in other renal diseases such as pyelonephritis).	There is no effective treatment for cadmium poisoning (chelation not useful; dimercaprol can exacerbate nephrotoxicity). Avoidance of further exposure, supportive therapy, vitamin D for osteomalacia.
Lead				
Manufacturing of auto batteries, lead crystal, ceramics, fishing weights, etc.; demolition or sanding of lead-painted houses, bridges; stained glass making, plumbing, soldering; environmental exposure to paint chips, house dust (in homes built <1975), firing ranges (from bullet dust), food or water from improperly glazed ceramics, lead pipes; contaminated herbal remedies, candies; exposure to the combustion of leaded fuels.	Absorbed through ingestion or inhalation; organic lead (e.g., tetraethyl lead) absorbed dermally. In blood, 95–99% sequestered in RBCs—thus, must measure lead in whole blood (not serum). Distributed widely in soft tissue, with half-life ~30 days; 15% of dose sequestered in bone with half-life of >20 years. Excreted mostly in urine, but also appears in other fluids including breast milk. Interferes with mitochondrial oxidative phosphorylation, ATPases, calcium-dependent messengers; enhances oxidation and cell apoptosis.	Acute exposure with blood lead levels (BPb) of >60–80 μg/dL can cause impaired neurotransmission and neuronal cell death (with central and peripheral nervous system effects); impaired hematopoiesis and renal tubular dysfunction. At higher levels of exposure (e.g., BPb >80–120 μg/dL), acute encephalopathy with convulsions, coma, and death may occur. Subclinical exposures in children (BPb 25–60 μg/dL) are associated with anemia; mental retardation; and deficits in language, motor function, balance, hearing, behavior, and school performance. Impairment of IQ appears to occur at even lower levels of exposure with no measurable threshold above the limit of detection in most assays of 1 μg/dL. In adults, chronic subclinical exposures (BPb >40 μg/dL) are associated with an increased risk of anemia, demyelinating peripheral neuropathy (mainly motor), impairments of reaction time and hearing, accelerated declines in cognition, hypertension, ECG conduction delays, hypertension, higher risk of cardiovascular disease and death, interstitial nephritis and chronic renal failure, diminished sperm counts, and spontaneous abortions.	Abdominal pain, irritability, lethargy, anorexia, anemia, Fanconi's syndrome, pyuria, azotemia in children with blood lead level (BPb) >80 μg/dL; may also see epiphyseal plate "lead lines" on long bone x-rays. Convulsions, coma at BPb >120 μg/dL. Noticeable neurodevelopmental delays at BPb of 40–80 μg/dL; may also see symptoms associated with higher BPb levels. Screening of all U.S. children when they begin to crawl (~6 months) is recommended by the CDC; source identification and intervention is begun if the BPb >10 μg/dL. In adults, acute exposure causes similar symptoms as in children as well as headaches, arthralgias, myalgias, depression, impaired short-term memory, loss of libido. Physical examination may reveal a "lead line" at the gingiva-tooth border, pallor, wrist drop, and cognitive dysfunction (e.g., declines on the mini-mental state exam); lab tests may reveal a normocytic, normochromic anemia, basophilic stippling, an elevated blood protoporphyrin level (free erythrocyte or zinc), and motor delays on nerve conduction. U.S. OSHA requires regular testing of lead-exposed workers with removal if BPb >40 μg/dL. Newer guidelines have been proposed recommending that BPb be maintained at <10 μg/dL, removal of workers if BPb >20 μg/dL, and monitoring of cumulative exposure parameters.	Identification and correction of exposure sources is critical. In some U.S. states, screening and reporting to local health boards of children with BPb >10 μg/dL and workers with BPb >40 μg/dL are required. In the highly exposed individual with symptoms, chelation is recommended with oral DMSA (succimer); if acutely toxic, hospitalization and IV or IM chelation with ethylenediaminetetraacetic acid calcium disodium (CaEDTA) may be required, with the addition of dimercaprol to prevent worsening of encephalopathy. It is uncertain whether children with asymptomatic lead exposure (e.g., BPb 20–40 μg/dL) benefit from chelation; a recent randomized trial showed no benefit. Correction of dietary deficiencies in iron, calcium, magnesium, and zinc will lower lead absorption and may also improve toxicity. Vitamin C is a weak but natural chelating agent. Calcium supplements (1200 mg at bedtime) have been shown to lower blood lead levels in pregnant women.

(*Continued*)

TABLE 458-1 Heavy Metals (Continued)

MAIN SOURCES	METABOLISM	TOXICITY	DIAGNOSIS	TREATMENT
Mercury				
Metallic, mercurous, and mercuric mercury (Hg, Hg^{+}, Hg^{2+}) exposures occur in some chemical, metal-processing, electrical equipment, automotive industries; they are also in thermometers, dental amalgams, batteries. Mercury is dispersed by waste incineration. Environmental bacteria convert inorganic to organic mercury, which then bioconcentrates up the aquatic food chain to contaminate tuna, swordfish, and other pelagic fish.	Elemental mercury (Hg) is not well absorbed; however, it will volatilize into highly absorbable vapor. Inorganic mercury is absorbed through the gut and skin. Organic mercury is well absorbed through inhalation and ingestion. Elemental and organic mercury cross the blood-brain barrier and placenta. Mercury is excreted in urine and feces and has a half-life in blood of ~60 days; however, deposits will remain in the kidney and brain for years. Exposure to mercury stimulates the kidney to produce metallothionein, which provides some detoxification benefit. Mercury binds sulfhydryl groups and interferes with a wide variety of critical enzymatic processes.	Acute inhalation of Hg vapor causes pneumonitis and noncardiogenic pulmonary edema leading to death, CNS symptoms, and polyneuropathy. Chronic high exposure causes CNS toxicity (mercurial *erethism*; see Diagnosis); lower exposures impair renal function, motor speed, memory, coordination. Acute ingestion of inorganic mercury causes gastroenteritis, the nephritic syndrome, or acute renal failure, hypertension, tachycardia, and cardiovascular collapse, with death at a dose of 10–42 mg/kg. Ingestion of organic mercury causes gastroenteritis, arrhythmias, and lesions in the basal ganglia, gray matter, and cerebellum at doses >1.7 mg/kg. High exposure during pregnancy causes derangement of fetal neuronal migration resulting in severe mental retardation. Mild exposures during pregnancy (from fish consumption) are associated with declines in neurobehavioral performance in offspring. Dimethylmercury, a compound only found in research labs, is "supertoxic"—a few drops of exposure via skin absorption or inhaled vapor can cause severe cerebellar degeneration and death.	Chronic exposure to metallic mercury vapor produces a characteristic intention tremor and mercurial *erethism*: excitability, memory loss, insomnia, timidity, and delirium ("mad as a hatter"). On neurobehavioral tests: decreased motor speed, visual scanning, verbal and visual memory, visuomotor coordination. Children exposed to mercury in any form may develop *acrodynia* ("pink disease"): flushing, itching, swelling, tachycardia, hypertension, excessive salivation or perspiration, irritability, weakness, morbilliform rashes, desquamation of palms and soles. Toxicity from elemental or inorganic mercury exposure begins when blood levels >180 nmol/L (3.6 µg/dL) and urine levels >0.7 µmol/L (15 µg/dL). Exposures that ended years ago may result in a >20-µg increase in 24-h urine after a 2-g dose of succimer. Organic mercury exposure is best measured by levels in blood (if recent) or hair (if chronic); CNS toxicity in children may derive from fetal exposures associated with maternal hair Hg >30 nmol/g (6 µg/g).	Treat acute ingestion of mercuric salts with induced emesis or gastric lavage and polythiol resins (to bind mercury in the GI tract). Chelate with dimercaprol (up to 24 mg/kg per day IM in divided doses), DMSA (succimer), or penicillamine, with 5-day courses separated by several days of rest. If renal failure occurs, treat with peritoneal dialysis, hemodialysis, or extracorporeal regional complexing hemodialysis and succimer. Chronic inorganic mercury poisoning is best treated with *N*-acetyl penicillamine.

Abbreviations: ATPase, adenosine triphosphatase; BPb, blood lead; CDC, Centers for Disease Control and Prevention; CNS, central nervous system; DMSA, dimercaptosuccinic acid; ECG, electrocardiogram; GI, gastrointestinal; ICU, intensive care unit; IQ, intelligence quotient; LFT, liver function tests; OSHA, Occupational Safety and Health Administration; RBC, red blood cell.

based on studies of the offspring of mothers who ingested mercury-contaminated fish. With respect to whether the consumption of fish by women during pregnancy is good or bad for offspring neurodevelopment, balancing the trade-offs of the beneficial effects of the omega-3-fatty acids (FAs) in fish versus the adverse effects of mercury contamination in fish has led to some confusion and inconsistency in public health recommendations. Overall, it would appear that it would be best for pregnant women to either limit fish consumption to those species known to be low in mercury contamination but high in omega-3-FAs (such as sardines or mackerel) or to avoid fish and obtain omega-3-FAs through supplements or other dietary sources. Accumulated evidence has not supported the contention that ethyl mercury, used as a preservative in multiuse vaccines administered in early childhood, has played a significant role in causing neurodevelopmental problems such as autism. With regard to adults, there is conflicting evidence as to whether mercury exposure is associated with increased risk of hypertension and cardiovascular disease. There is also some evidence that mercury exposure in the general population is associated with the development of diabetes, perturbations in markers of autoimmunity, and depression. At this point, conclusions cannot be drawn and the clinical significance of these findings remains unclear.

Heavy metals pose risks to health that are especially burdensome in selected parts of the world. For example, *arsenic* exposure from natural contamination of shallow tube wells inserted for drinking water is a major environmental problem for millions of residents in parts of Bangladesh and Western India. Contamination was formerly considered only a problem with deep wells; however, the geology of this region allows most residents only a few alternatives for potable drinking water. Arsenic contamination of drinking water is also a major problem in China, Argentina, Chile, Mexico, and some regions of the United States (Maine, New Hampshire, Massachusetts). The global campaign to phase out *leaded* gasoline has had continued success, with only a few countries still remaining (Algeria, Iraq, Yemen, Myanmar, North Korea, and Afghanistan). However, significant population exposures to lead remain, particularly in the United States with respect to older housing that contains lead paint or that receives drinking water through lead pipes, and there are indications that exposures are beginning to increase again in many low- and middle-income countries due to industrial pollution, electronic waste, and a variety of contaminated consumer products. Populations living in the Arctic have been shown to have particularly high exposures to *mercury* due to long-range transport patterns that concentrate mercury in the polar regions, as well as the traditional dependence of Arctic peoples on the consumption of fish and other wildlife that bioconcentrate methylmercury.

A few additional metals deserve brief mention but are not covered in Table 458-1 because of the relative rarity of their being clinically encountered or the uncertainty regarding their potential toxicities. *Aluminum* contributes to the encephalopathy in patients with severe renal disease, who are undergoing dialysis **(Chap. 410)**. High levels of aluminum are found in the neurofibrillary tangles in the cerebral

cortex and hippocampus of patients with Alzheimer's disease, as well as in the drinking water and soil of areas with an unusually high incidence of Alzheimer's. The experimental and epidemiologic evidence for the aluminum–Alzheimer's disease link remains relatively weak, however, and it cannot be concluded that aluminum is a causal agent or a contributing factor in neurodegenerative disease. Hexavalent chromium is corrosive and sensitizing. Workers in the chromate and chrome pigment production industries have consistently had a greater risk of lung cancer. The introduction of *cobalt* chloride as a fortifier in beer led to outbreaks of fatal cardiomyopathy among heavy consumers. Occupational exposure (e.g., of miners, dry-battery manufacturers, and arc welders) to *manganese* (Mn) can cause a parkinsonian syndrome within 1–2 years, including gait disorders; postural instability; a masked, expressionless face; tremor; and psychiatric symptoms. With the introduction of methylcyclopentadienyl manganese tricarbonyl (MMT) as a gasoline additive, there is concern for the toxic potential of environmental manganese exposure. Some epidemiologic studies have found an association between the prevalence of parkinsonian disorders and estimated manganese exposures emitted by local ferroalloy industries; others have found evidence suggesting that manganese may interfere with early childhood neurodevelopment in ways similar to that of lead. Manganese toxicity is clearly associated with dopaminergic dysfunction, and its toxicity is likely influenced by age, gender, ethnicity, genetics, and preexisting medical conditions. *Nickel* exposure induces an allergic response, and inhalation of nickel compounds with low aqueous solubility (e.g., nickel subsulfide and nickel oxide) in occupational settings is associated with an increased risk of lung cancer. Overexposure to selenium may cause local irritation of the respiratory system and eyes, gastrointestinal irritation, liver inflammation, loss of hair, depigmentation, and peripheral nerve damage. Workers exposed to certain organic forms of *tin* (particularly trimethyl and triethyl derivatives) have developed psychomotor disturbances, including tremor, convulsions, hallucinations, and psychotic behavior.

Thallium, which is a component of some insecticides, metal alloys, and fireworks, is absorbed through the skin as well as by ingestion and inhalation. Severe poisoning follows a single ingested dose of >1 g or >8 mg/kg. Nausea and vomiting, abdominal pain, and hematemesis precede confusion, psychosis, organic brain syndrome, and coma. Thallium is radiopaque. Induced emesis or gastric lavage is indicated within 4–6 h of acute ingestion; Prussian blue prevents absorption and is given orally at 250 mg/kg in divided doses. Unlike other types of metal poisoning, thallium poisoning may be less severe when activated charcoal is used to interrupt its enterohepatic circulation. Other measures include forced diuresis, treatment with potassium chloride (which promotes renal excretion of thallium), and peritoneal dialysis.

Chelation therapy remains the treatment of choice for most toxic metals in the setting of severe acute clinical poisoning. However, the use of chelation for treating chronic diseases remains controversial, in part because of the lack of evidence from rigorous randomized clinical trials. One area for which there is moderate evidence is the use of chelation in patients with higher than average levels of accumulated lead burdens as a means of improving kidney function. The results from a series of randomized trials conducted in Taiwan suggest that among individuals with mildly elevated lead burdens (defined as between 150 and 600 μg of lead per 72-h urine upon an EDTA mobilization test [1 g EDTA]), weekly calcium disodium EDTA chelation treatments for between 2 and 27 months can improve renal function outcomes, both in individuals with and without type 2 diabetes.

The Trial to Assess Chelation Therapy (TACT), a multicenter, double-blind, placebo-controlled, prospective randomized trial funded by the National Institutes of Health of 1708 patients aged ≥50 years who had experienced a myocardial infarction (MI), found that a protocol of repeated intravenous chelation with disodium EDTA, compared with placebo, modestly but significantly reduced the risk of adverse cardiovascular outcomes, many of which were revascularization procedures. The effect was particularly pronounced among those with concurrent diabetes. However, the trial did not include rigorous measures of exposure to lead or other metals or any selection criteria based on metals exposure; thus, even though chelation reduces metal burdens, which have been associated with adverse cardiovascular effects (especially lead), it remains unclear whether the beneficial effects result from a reduction in metal burden. In view of the risks of side effects associated with chelation, by themselves, the results are not sufficient to support the routine use of chelation therapy for treatment of patients either who have had an MI or who have had low-level lead exposure. A follow-up trial with rigorous measures of metals exposure is ongoing.

459 Poisoning and Drug Overdose

Mark B. Mycyk

Poisoning refers to the development of dose-related adverse effects following exposure to chemicals, drugs, or other xenobiotics. To paraphrase Paracelsus, the dose makes the poison. Although most poisons have predictable dose-related effects, individual responses to a given dose may vary because of genetic polymorphism, enzymatic induction or inhibition in the presence of other xenobiotics, or acquired tolerance. Poisoning may be local (e.g., skin, eyes, or lungs) or systemic depending on the route of exposure, the chemical and physical properties of the poison, and its mechanism of action. The severity and reversibility of poisoning also depend on the functional reserve of the individual or target organ, which is influenced by age and preexisting disease.

EPIDEMIOLOGY

More than 5 million poison exposures occur in the United States each year. Most are acute, are accidental (unintentional), involve a single agent, occur in the home (>90%), result in minor or no toxicity, and involve children <6 years of age. Pharmaceuticals are involved in 47% of poisoning exposures and in 84% of serious or fatal poisonings. Household cleaning substances and cosmetics/personal care products

are the most common nonpharmaceutical exposures reported to the National Poison Data System (NPDS). In the last decade, the rate of injury-related deaths from poisoning has overtaken the rate of deaths related to motor-vehicle crashes in the United States. According to the Centers for Disease Control and Prevention (CDC), twice as many Americans died from drug overdoses in 2014 compared to 2000. Although prescription opioids have appropriately received attention as a major reason for the increased number of poisoning deaths, the availability of other pharmaceuticals and rapid proliferation of novel drugs of abuse also contribute to the increasing death rate. In many parts of the United States, where these issues are particularly prevalent, there are efforts to develop better prescription drug databases and enhanced training for health care professionals in pain management and the use of opioids. Unintentional exposures can result from the improper use of chemicals at work or play; label misreading; product mislabeling; mistaken identification of unlabeled chemicals; uninformed self-medication; and dosing errors by nurses, pharmacists, physicians, parents, and the elderly. Excluding the recreational use of ethanol, attempted suicide (deliberate self-harm) is the most common reported reason for intentional poisoning. Recreational use of prescribed and over-the-counter drugs for psychotropic or euphoric effects (*abuse*) or excessive self-dosing (*misuse*) is increasingly common and may also result in unintentional self-poisoning.

About 20–25% of exposures require bedside health-professional evaluation, and 5% of all exposures require hospitalization. Poisonings account for 5–10% of all ambulance transports, emergency department visits, and intensive care unit admissions. Hospital admissions related to poisoning are also associated with longer lengths of stay and increase the utilization of resources such as radiography and other laboratory services. Up to 35% of psychiatric admissions are prompted by attempted suicide via overdosage with cases involving adolescents steadily increasing during the last decade. Overall, the mortality rate is low: <1% of all poisoning exposures. It is significantly higher (1–2%) among hospitalized patients with intentional (suicidal) overdose or complications from drugs of abuse, who account for the majority of serious poisonings. Acetaminophen is the pharmaceutical agent most often implicated in fatal poisoning. Overall, carbon monoxide is the leading cause of death from poisoning, but this prominence is not reflected in hospital or poison center statistics because patients with such poisoning are typically dead when discovered and are referred directly to medical examiners.

DIAGNOSIS

Although poisoning can mimic other illnesses, the correct diagnosis can usually be established by the history, physical examination, routine and toxicologic laboratory evaluations, and characteristic clinical course.

HISTORY

The *history* should include the time, route, duration, and circumstances (location, surrounding events, and intent) of exposure; the name and amount of each drug, chemical, or ingredient involved; the time of onset, nature, and severity of symptoms; the time and type of first-aid measures provided; the medical and psychiatric history; and occupation.

In many cases, the patient is confused, comatose, unaware of an exposure, or unable or unwilling to admit to one. Suspicious circumstances include unexplained sudden illness in a previously healthy person or a group of healthy people; a history of psychiatric problems (particularly depression or bipolar disorder); recent changes in health, economic status, or social relationships; and onset of illness during work with chemicals or after ingestion of food, drink (especially ethanol), or medications. When patients become ill soon after arriving from a foreign country or being arrested for criminal activity, "body packing" or "body stuffing" (ingesting or concealing illicit drugs in a body cavity) should be suspected. Relevant information may be available from family, friends, paramedics, police, pharmacists, physicians, and employers, who should be questioned regarding the patient's habits, hobbies, behavioral changes, available medications, and antecedent events. Patients need to be asked explicitly about their prescribed medications and recreational drug use. Drugs previously considered "illicit" such as cannabinoids are now legal in many states and prescribed for therapeutic purposes. A search of clothes, belongings, and place of discovery may reveal a suicide note or a container of drugs or chemicals. Without a clear history in a patient clinically suspected to be poisoned, all medications available anywhere in the patient's home or belongings should be considered as possible agents, including medications for pets. Review of the patient's record in the state prescription monitoring program (PMP) may disclose relevant history of Schedule II, III, IV, and V controlled substance use. The imprint code on pills and the label on chemical products may be used to identify the ingredients and potential toxicity of a suspected poison by consulting a reference text, a computerized database, the manufacturer, or a regional poison information center (800-222-1222). Occupational exposures require review of any available safety data sheet (SDS) from the worksite. Because of increasing globalization from travel and internet consumerism, unfamiliar poisonings may result in local emergency department evaluation. Pharmaceuticals, industrial chemicals, or drugs of abuse from foreign countries may be identified with the assistance of a regional poison center or via the World Wide Web.

PHYSICAL EXAMINATION AND CLINICAL COURSE

The *physical examination* should focus initially on vital signs, the cardiopulmonary system, and neurologic status. The neurologic examination should include documentation of neuromuscular abnormalities such as dyskinesia, dystonia, fasciculations, myoclonus, rigidity, and tremors. The patient should also be examined for evidence of trauma and underlying illnesses. Focal neurologic findings are uncommon in poisoning, and their presence should prompt evaluation for a structural central nervous system (CNS) lesion. Examination of the eyes (for nystagmus and pupil size and reactivity), abdomen (for bowel activity and bladder size), and skin (for burns, bullae, color, warmth, moisture, pressure sores, and puncture marks) may reveal findings of diagnostic value. When the history is unclear, all orifices should be examined for the presence of chemical burns and drug packets. The odor of breath or vomitus and the color of nails, skin, or urine may provide important diagnostic clues.

The diagnosis of poisoning in cases of unknown etiology primarily relies on pattern recognition. The first step is to assess the pulse, blood pressure, respiratory rate, temperature, and neurologic status and to characterize the overall physiologic state as stimulated, depressed, discordant, or normal **(Table 459-1)**. Obtaining a complete set of vital signs and reassessing them frequently are critical. Measuring core temperature is especially important, even in difficult or combative patients, since temperature elevation is the most reliable prognosticator of poor outcome in poisoning from stimulants (e.g., cocaine) or drug withdrawal (e.g., alcohol or γ-hydroxybutyric acid [GHB]). The next step is to consider the underlying causes of the physiologic state and to attempt to identify a pathophysiologic pattern or toxic syndrome (*toxidrome*) based on the observed findings. Assessing the severity of physiologic derangements **(Table 459-2)** is useful in this regard and also for monitoring the clinical course and response to treatment. In cases of polydrug overdose involving different drug classes, identifying a clear toxidrome can be challenging if the different drugs counteract the physiologic effects of one another. The final step is to attempt to identify the particular agent involved by looking for unique or relatively poison-specific physical or ancillary test abnormalities. Distinguishing among toxidromes on the basis of the physiologic state is summarized next.

The Stimulated Physiologic State Increased pulse, blood pressure, respiratory rate, temperature, and neuromuscular activity characterize the *stimulated* physiologic state, which can reflect sympathetic, anticholinergic, or hallucinogen poisoning or drug withdrawal (Table 459-1). Other features are noted in Table 459-2. Mydriasis, a characteristic feature of all stimulants, is most marked in anticholinergic poisoning since pupillary reactivity relies on muscarinic control. In sympathetic poisoning (e.g., due to cocaine), pupils are also enlarged, but some reactivity to

TABLE 459-1 Differential Diagnosis of Poisoning Based on Physiologic State

STIMULATED	DEPRESSED	DISCORDANT	NORMAL
Sympathetics	Sympatholytics	Asphyxiants	Nontoxic exposure
Sympathomimetics	α_1-Adrenergic antagonists	Cytochrome oxidase inhibitors	Psychogenic illness
Ergot alkaloids	α_2-Adrenergic agonists	Inert gases	"Toxic time-bombs"
Methylxanthines	ACE inhibitors	Irritant gases	Slow absorption
Monoamine oxidase inhibitors	Angiotensin receptor blockers	Methemoglobin inducers	Anticholinergics
Thyroid hormones	Antipsychotics	Oxidative phosphorylation inhibitors	Carbamazepine
Anticholinergics	β-Adrenergic blockers	AGMA inducers	Concretion formers
Antihistamines	Calcium channel blockers	Alcohol (ketoacidosis)	Extended-release phenytoin sodium capsules (Dilantin Kapseals)
Antiparkinsonian agents	Cardiac glycosides	Ethylene glycol	Drug packets
Antipsychotics	Cyclic antidepressants	Iron	Enteric-coated pills
Antispasmodics	Cholinergics	Methanol	Diphenoxylate-atropine (Lomotil)
Belladonna alkaloids	Acetylcholinesterase inhibitors	Other alcohols	Opioids
Cyclic antidepressants	Muscarinic agonists	Salicylate	Salicylates
Mushrooms and plants	Nicotinic agonists	Toluene	Sustained-release pills
Hallucinogens	Opioids	CNS syndromes	Valproate
Cannabinoids (marijuana)	Analgesics	Extrapyramidal reactions	Slow distribution
LSD and analogues	GI antispasmodics	Hydrocarbon inhalation	Cardiac glycosides
Mescaline and analogues	Heroin	Isoniazid	Lithium
Mushrooms	Sedative-hypnotics	Lithium	Metals
Phencyclidine and analogues	Alcohols	Neuroleptic malignant syndrome	Salicylate
Withdrawal syndromes	Anticonvulsants	Serotonin syndrome	Valproate
Barbiturates	Barbiturates	Strychnine	Toxic metabolite
Benzodiazepines	Benzodiazepines	Membrane-active agents	Acetaminophen
Ethanol	GABA precursors	Amantadine	Carbon tetrachloride
GHB products	Muscle relaxants	Antiarrhythmics	Cyanogenic glycosides
Opioids	Other agents	Antihistamines	Ethylene glycol
Sedative-hypnotics	GHB products	Antipsychotics	Methanol
Sympatholytics		Carbamazepine	Methemoglobin inducers
		Cyclic antidepressants	Mushroom toxins
		Local anesthetics	Organophosphate insecticides
		Opioids (some)	Paraquat
		Quinoline antimalarials	Metabolism disruptors
			Antineoplastic agents
			Antiviral agents
			Colchicine
			Hypoglycemic agents
			Immunosuppressive agents
			MAO inhibitors
			Metals
			Other oral anticoagulants
			Salicylate
			Warfarin

Abbreviations: ACE, angiotensin-converting enzyme; AGMA, anion-gap metabolic acidosis; CNS, central nervous system; GABA, γ-aminobutyric acid; GHB, γ-hydroxybutyrate; GI, gastrointestinal; LSD, lysergic acid diethylamide; MAO, monoamine oxidase.

light remains. The anticholinergic toxidrome is also distinguished by hot, dry, flushed skin; decreased bowel sounds; and urinary retention. Other stimulant syndromes increase sympathetic activity and cause diaphoresis, pallor, and increased bowel activity with varying degrees of nausea, vomiting, abnormal distress, and occasionally diarrhea. The absolute and relative degree of vital-sign changes and neuromuscular hyperactivity can help distinguish among stimulant toxidromes. Since sympathetics stimulate the peripheral nervous system more directly than do hallucinogens or drug withdrawal, markedly increased vital signs and organ ischemia suggest sympathetic poisoning. Findings helpful in suggesting the particular drug or class causing physiologic stimulation include reflex bradycardia from selective α-adrenergic stimulants (e.g., decongestants), hypotension from selective β-adrenergic stimulants (e.g., asthma therapeutics), limb ischemia from ergot alkaloids, rotatory nystagmus from phencyclidine and ketamine (the only physiologic stimulants that cause this finding), and delayed cardiac conduction from high doses of cocaine and some anticholinergic agents (e.g., antihistamines, cyclic antidepressants, and antipsychotics). Seizures suggest a sympathetic etiology, an anticholinergic agent with membrane-active properties (e.g., cyclic antidepressants, phenothiazines), or a withdrawal syndrome. Close attention to core temperature is critical in patients with grade 4 physiologic stimulation (Table 459-2).

The Depressed Physiologic State Decreased pulse, blood pressure, respiratory rate, temperature, and neuromuscular activity are indicative of the *depressed* physiologic state caused by "functional" sympatholytics (agents that decrease cardiac function and vascular tone as well as sympathetic activity), cholinergic (muscarinic and nicotinic) agents, opioids, and sedative-hypnotic γ-aminobutyric acid (GABA)-ergic agents (Tables 459-1 and 459-2). Miosis is also common and is most pronounced in opioid and cholinergic poisoning. Miosis

TABLE 459-2 Severity of Physiologic Stimulation and Depression in Poisoning and Drug Withdrawal

Physiologic Stimulation	
Grade 1	Anxious, irritable, tremulous; vital signs normal; diaphoresis, flushing or pallor, mydriasis, and hyperreflexia sometimes present
Grade 2	Agitated; may have confusion or hallucinations but can converse and follow commands; vital signs mildly to moderately increased
Grade 3	Delirious; unintelligible speech, uncontrollable motor hyperactivity; moderately to markedly increased vital signs; tachyarrhythmias possible
Grade 4	Coma, seizures, cardiovascular collapse
Physiologic Depression	
Grade 1	Awake, lethargic, or sleeping but arousable by voice or tactile stimulation; able to converse and follow commands; may be confused
Grade 2	Responds to pain but not voice; can vocalize but not converse; spontaneous motor activity present; brainstem reflexes intact
Grade 3	Unresponsive to pain; spontaneous motor activity absent; brainstem reflexes depressed; motor tone, respirations, and temperature decreased
Grade 4	Unresponsive to pain; flaccid paralysis; brainstem reflexes and respirations absent; cardiovascular vital signs decreased

is distinguished from other depressant syndromes by muscarinic and nicotinic signs and symptoms (Table 459-1). Pronounced cardiovascular depression in the absence of significant CNS depression suggests a direct or peripherally acting sympatholytic. In contrast, in opioid and sedative-hypnotic poisoning, vital-sign changes are secondary to depression of CNS cardiovascular and respiratory centers (or consequent hypoxemia), and significant abnormalities in these parameters do not occur until there is a marked decrease in the level of consciousness (grade 3 or 4 physiologic depression; Table 459-2). Other clues that suggest the cause of physiologic depression include cardiac arrhythmias and conduction disturbances (due to antiarrhythmics, β-adrenergic antagonists, calcium channel blockers, digitalis glycosides, propoxyphene, and cyclic antidepressants), mydriasis (due to tricyclic antidepressants, some antiarrhythmics, meperidine, and diphenoxylate-atropine [Lomotil]), nystagmus (due to sedative-hypnotics), and seizures (due to cholinergic agents, propoxyphene, and cyclic antidepressants).

The Discordant Physiologic State The *discordant* physiologic state is characterized by mixed vital-sign and neuromuscular abnormalities, as observed in poisoning by asphyxiants, CNS syndromes, membrane-active agents, and anion-gap metabolic acidosis (AGMA) inducers (Table 459-1). In these conditions, manifestations of physiologic stimulation and physiologic depression occur together or at different times during the clinical course. For example, membrane-active agents can cause simultaneous coma, seizures, hypotension, and tachyarrhythmias. Alternatively, vital signs may be normal while the patient has an altered mental status or is obviously sick or clearly symptomatic. Early, pronounced vital-sign and mental-status changes suggest asphyxiant or membrane-active agent poisoning; the lack of such abnormalities suggests an AGMA inducer; and marked neuromuscular dysfunction without significant vital-sign abnormalities suggests a CNS syndrome. The *discordant* physiologic state may also be evident in patients poisoned with multiple agents.

The Normal Physiologic State A *normal* physiologic status and physical examination may be due to a nontoxic exposure, psychogenic illness, or poisoning by "toxic time-bombs": agents that are slowly absorbed, are slowly distributed to their sites of action, require metabolic activation, or disrupt metabolic processes (Table 459-1). Because so many medications have now been reformulated into once-a-day preparations for the patient's convenience and adherence, toxic time-bombs are increasingly common. Diagnosing a nontoxic exposure requires that the identity of the exposure agent be known or that a toxic time-bomb exposure be excluded and the time since exposure exceed the longest known or predicted interval between exposure and peak toxicity. Psychogenic illness (fear of being poisoned, mass hysteria) may also follow a nontoxic exposure and should be considered when symptoms are inconsistent with exposure history. Anxiety reactions resulting from a nontoxic exposure can cause mild physiologic stimulation (Table 459-2) and be indistinguishable from toxicologic causes without ancillary testing or a suitable period of observation.

LABORATORY ASSESSMENT

Laboratory assessment may be helpful in the differential diagnosis. Increased AGMA is most common in advanced methanol, ethylene glycol, and salicylate intoxication but can occur with any poisoning that results in hepatic, renal, or respiratory failure; seizures; or shock. The serum lactate concentration is more commonly low (less than the anion gap) in the former and high (nearly equal to the anion gap) in the latter. An abnormally low anion gap can be due to elevated blood levels of bromide, calcium, iodine, lithium, or magnesium. An increased osmolal gap—a difference of >10 mmol/L between serum osmolality (measured by freezing-point depression) and osmolality calculated from serum sodium, glucose, and blood urea nitrogen levels—suggests the presence of a low-molecular-weight solute such as acetone; an alcohol (benzyl, ethanol, isopropanol, methanol); a glycol (diethylene, ethylene, propylene); ether (ethyl, glycol); or an "unmeasured" cation (calcium, magnesium) or sugar (glycerol, mannitol, sorbitol). Ketosis suggests acetone, isopropyl alcohol, salicylate poisoning, or alcoholic ketoacidosis. Hypoglycemia may be due to poisoning with β-adrenergic blockers, ethanol, insulin, oral hypoglycemic agents, quinine, and salicylates, whereas hyperglycemia can occur in poisoning with acetone, β-adrenergic agonists, caffeine, calcium channel blockers, iron, theophylline, or *N*-3-pyridylmethyl-*N*′-*p*-nitrophenylurea (PNU [Vacor]). Hypokalemia can be caused by barium, β-adrenergic agonists, caffeine, diuretics, theophylline, or toluene; hyperkalemia suggests poisoning with an α-adrenergic agonist, a β-adrenergic blocker, cardiac glycosides, or fluoride. Hypocalcemia may be seen in ethylene glycol, fluoride, and oxalate poisoning. Prothrombin time and international normalized ratio are useful for risk stratification in cases of warfarin or rodenticide poisoning but are not to be relied on when evaluating overdose or complications from novel oral anticoagulant pharmaceuticals (direct thrombin inhibitors and direct factor Xa inhibitors).

The *electrocardiogram* (ECG) can be useful for rapid diagnostic purposes. Bradycardia and atrioventricular block may occur in patients poisoned by α-adrenergic agonists, antiarrhythmic agents, beta blockers, calcium channel blockers, cholinergic agents (carbamate and organophosphate insecticides), cardiac glycosides, lithium, or tricyclic antidepressants. QRS- and QT-interval prolongation may be caused by hyperkalemia, various antidepressants, and other membrane-active drugs (Table 459-1). Ventricular tachyarrhythmias may be seen in poisoning with cardiac glycosides, fluorides, membrane-active drugs, methylxanthines, sympathomimetics, antidepressants, and agents that cause hyperkalemia or potentiate the effects of endogenous catecholamines (e.g., chloral hydrate, aliphatic and halogenated hydrocarbons).

Radiologic studies may occasionally be useful. Pulmonary edema (adult respiratory distress syndrome [ARDS]) can be caused by poisoning with carbon monoxide, cyanide, an opioid, paraquat, phencyclidine, a sedative-hypnotic, or salicylate; by inhalation of irritant gases, fumes, or vapors (acids and alkali, ammonia, aldehydes, chlorine, hydrogen sulfide, isocyanates, metal oxides, mercury, phosgene, polymers); or by prolonged anoxia, hyperthermia, or shock. Aspiration pneumonia is common in patients with coma, seizures, and petroleum distillate aspiration. Chest x-ray is useful for identifying complications from metal fume fever or elemental mercury. The presence of radiopaque densities on abdominal x-rays or abdominal computed tomography (CT) scan suggests the ingestion of chloral hydrate, chlorinated hydrocarbons, heavy metals, illicit drug packets, iodinated compounds, potassium salts, enteric-coated tablets, or salicylates.

Toxicologic analysis of urine and blood (and occasionally of gastric contents and chemical samples) can sometimes confirm or rule out suspected poisoning. Interpretation of laboratory data requires

knowledge of the qualitative and quantitative tests used for screening and confirmation (enzyme-multiplied, fluorescence polarization, and radio-immunoassays; colorimetric and fluorometric assays; thin-layer, gas-liquid, or high-performance liquid chromatography; gas chromatography; mass spectrometry), their sensitivity (limit of detection) and specificity, the preferred biologic specimen for analysis, and the optimal time of specimen sampling. Personal communication with the hospital laboratory is essential to an understanding of institutional testing capabilities and limitations.

Rapid *qualitative* hospital-based urine tests for drugs of abuse are only screening tests that cannot confirm the exact identity of the detected substance and should not be considered diagnostic or used for forensic purposes. False-positive and false-negative results are common. A positive screen may result from other pharmaceuticals that interfere with laboratory analysis (e.g., fluoroquinolones commonly cause false-positive opiate screens). Confirmatory testing with gas chromatography/mass spectrometry can be requested, but it often takes weeks to obtain a reported result. A negative screening result may mean that the responsible substance is not detectable by the test used or that its concentration is too low for detection at the time of sampling. For instance, recent new drugs of abuse that often result in emergency department evaluation for unexpected complications, such as synthetic cannabinoids (spice), cathinones (bath salts), and opiate substitutes (kratom), are not detectable by hospital-based tests. In cases where a drug concentration is too low to be detected early during clinical evaluation, repeating the test at a later time may yield a positive result. Patients symptomatic from drugs of abuse often require immediate management based on the history, physical examination, and observed toxidrome without laboratory confirmation (e.g., apnea from opioid intoxication). When the patient is asymptomatic or when the clinical picture is consistent with the reported history, qualitative screening is neither clinically useful nor cost-effective. Thus, qualitative drug screens are of greatest value for the evaluation of patients with severe or unexplained toxicities, such as coma, seizures, cardiovascular instability, metabolic or respiratory acidosis, and nonsinus cardiac rhythms. In contrast to qualitative drug screens, *quantitative* serum tests are useful for evaluation of patients poisoned with acetaminophen **(Chap. 340)**, alcohols (including ethylene glycol and methanol), anticonvulsants, barbiturates, digoxin, heavy metals, iron, lithium, salicylate, and theophylline, as well as for the presence of carboxyhemoglobin and methemoglobin. The serum concentration in these cases guides clinical management, and results are often available within an hour.

The *response to antidotes* is sometimes useful for diagnostic purposes. Resolution of altered mental status and abnormal vital signs within minutes of IV administration of dextrose, naloxone, or flumazenil is virtually diagnostic of hypoglycemia, opioid poisoning, and benzodiazepine intoxication, respectively. The prompt reversal of dystonic (extrapyramidal) signs and symptoms following an IV dose of benztropine or diphenhydramine confirms a drug etiology. Although complete reversal of both central and peripheral manifestations of anticholinergic poisoning by physostigmine is diagnostic of this condition, physostigmine may cause some arousal in patients with CNS depression of any etiology.

TREATMENT

Poisoning and Drug Overdose

GENERAL PRINCIPLES

Treatment goals include support of vital signs, prevention of further poison absorption (decontamination), enhancement of poison elimination, administration of specific antidotes, and prevention of reexposure **(Table 459-3)**. Specific treatment depends on the identity of the poison, the route and amount of exposure, the time of presentation relative to the time of exposure, and the severity of poisoning. Knowledge of the offending agents' pharmacokinetics and pharmacodynamics is essential.

During the *pretoxic phase*, prior to the onset of poisoning, decontamination is the highest priority, and treatment is based solely on the history. The maximal potential toxicity based on the greatest possible exposure should be assumed. Since decontamination is more effective when accomplished soon after exposure and when the patient is asymptomatic, the initial history and physical examination should be focused and brief. It is also advisable to establish IV access and initiate cardiac monitoring, particularly in patients with potentially serious ingestions or unclear histories.

When an accurate history is not obtainable and a poison causing delayed toxicity (i.e., a toxic time-bomb) or irreversible damage is suspected, blood and urine should be sent for appropriate toxicologic screening and quantitative analysis. During poison absorption and distribution, blood levels may be greater than those in tissue and may not correlate with toxicity. However, high blood levels of agents whose metabolites are more toxic than the parent compound (acetaminophen, ethylene glycol, or methanol) may indicate the need for additional interventions (antidotes, dialysis). Most patients who remain asymptomatic or who become asymptomatic 6 h after ingestion are unlikely to develop subsequent toxicity and can be discharged safely. Longer observation will be necessary for patients who have ingested toxic time-bombs.

During the *toxic phase*—the interval between the onset of poisoning and its peak effects—management is based primarily on clinical and laboratory findings. *Effects after an overdose usually begin sooner, peak later, and last longer than they do after a therapeutic dose*. A drug's published pharmacokinetic profile in standard references such as the *Physician's Desk Reference* (PDR) is usually different from its toxicokinetic profile in overdose. Resuscitation and stabilization are the first priority. Symptomatic patients should have an IV line placed and should undergo oxygen saturation determination, cardiac monitoring, and continuous observation. Baseline laboratory, ECG, and x-ray evaluation may also be appropriate. Intravenous glucose (unless the serum level is documented to be normal), naloxone, and thiamine should be considered in patients with altered mental status, particularly those with coma or seizures. Decontamination should also be considered, but it is less likely to be effective during this phase than during the pretoxic phase.

TABLE 459-3 Fundamentals of Poisoning Management

Supportive Care	
Airway protection	Treatment of seizures
Oxygenation/ventilation	Correction of temperature abnormalities
Treatment of arrhythmias	Correction of metabolic derangements
Hemodynamic support	Prevention of secondary complications
Prevention of Further Poison Absorption	
Gastrointestinal decontamination	Decontamination of other sites
Gastric lavage	Eye decontamination
Activated charcoal	Skin decontamination
Whole-bowel irrigation	Body cavity evacuation
Dilution	
Endoscopic/surgical removal	
Enhancement of Poison Elimination	
Multiple-dose activated charcoal administration	Extracorporeal removal
Alteration of urinary pH	Hemodialysis
Chelation	Hemoperfusion
Hyperbaric oxygenation	Hemofiltration
	Plasmapheresis
	Exchange transfusion
Administration of Antidotes	
Neutralization by antibodies	Metabolic antagonism
Neutralization by chemical binding	Physiologic antagonism
Prevention of Reexposure	
Adult education	Notification of regulatory agencies
Child-proofing	Psychiatric referral

Measures that enhance poison elimination may shorten the duration and severity of the toxic phase. However, they are not without risk, which must be weighed against the potential benefit. Diagnostic certainty (usually via laboratory confirmation) is generally a prerequisite. Intestinal (gut) dialysis with repetitive doses of activated charcoal (see "Multiple-Dose Activated Charcoal," later) can enhance the elimination of selected poisons such as theophylline or carbamazepine. Urinary alkalinization may enhance the elimination of salicylates and a few other poisons. Chelation therapy can enhance the elimination of selected metals. Extracorporeal elimination methods are effective for many poisons, but their expense and risk make their use reasonable only in patients who would otherwise have an unfavorable outcome.

During the *resolution phase* of poisoning, supportive care and monitoring should continue until clinical, laboratory, and ECG abnormalities have resolved. Since chemicals are eliminated sooner from the blood than from tissues, blood levels are usually lower than tissue levels during this phase and again may not correlate with toxicity. This discrepancy applies particularly when extracorporeal elimination procedures are used. Redistribution from tissues may cause a rebound increase in the blood level after termination of these procedures (e.g., lithium). When a metabolite is responsible for toxic effects, continued treatment may be necessary in the absence of clinical toxicity or abnormal laboratory studies.

SUPPORTIVE CARE

The goal of supportive therapy is to maintain physiologic homeostasis until detoxification is accomplished and to prevent and treat secondary complications such as aspiration, bedsores, cerebral and pulmonary edema, pneumonia, rhabdomyolysis, renal failure, sepsis, thromboembolic disease, coagulopathy, and generalized organ dysfunction due to hypoxemia or shock.

Admission to an intensive care unit is indicated for the following: patients with severe poisoning (coma, respiratory depression, hypotension, cardiac conduction abnormalities, cardiac arrhythmias, hypothermia or hyperthermia, seizures); those needing close monitoring, antidotes, or enhanced elimination therapy; those showing progressive clinical deterioration; and those with significant underlying medical problems. Patients with mild to moderate toxicity can be managed on a general medical service, on an intermediate care unit, or in an emergency department observation area, depending on the anticipated duration and level of monitoring needed (intermittent clinical observation vs continuous clinical, cardiac, and respiratory monitoring). Patients who have attempted suicide require continuous observation and measures to prevent self-injury until they are no longer suicidal.

Respiratory Care Endotracheal intubation for protection against the aspiration of gastrointestinal contents is of paramount importance in patients with CNS depression or seizures as this complication can increase morbidity and mortality rates. Mechanical ventilation may be necessary for patients with respiratory depression or hypoxemia and for facilitation of therapeutic sedation or paralysis of patients in order to prevent or treat hyperthermia, acidosis, and rhabdomyolysis associated with neuromuscular hyperactivity. Since clinical assessment of respiratory function can be inaccurate, the need for oxygenation and ventilation is best determined by continuous pulse oximetry or arterial blood-gas analysis. The gag reflex is not a reliable indicator of the need for intubation. A patient with CNS depression may maintain airway patency while being stimulated but not if left alone. Drug-induced pulmonary edema is usually noncardiac rather than cardiac in origin, although profound CNS depression and cardiac conduction abnormalities suggest the latter. Measurement of pulmonary artery pressure may be necessary to establish the cause and direct appropriate therapy. Extracorporeal measures (membrane oxygenation, extracorporeal membrane oxygenation [ECMO], venoarterial perfusion, cardiopulmonary bypass) and partial liquid (perfluorocarbon) ventilation may be appropriate for severe but reversible respiratory failure. In the last decade, ECMO has been increasingly used for critically ill poisoned patients where standard resuscitative therapy or antidotes have not been helpful, but further research is still needed to determine the right toxicologic indications for this treatment strategy.

Cardiovascular Therapy Maintenance of normal tissue perfusion is critical for complete recovery to occur once the offending agent has been eliminated. Focused bedside echocardiography or measurement of central venous pressure may help prioritize therapeutic strategies. If hypotension is unresponsive to volume expansion and appropriate goal-directed antidotal therapy, treatment with norepinephrine, epinephrine, or high-dose dopamine may be necessary. Intraaortic balloon pump counterpulsation and venoarterial or cardiopulmonary perfusion techniques should be considered for severe but reversible cardiac failure. For patients with a return of spontaneous circulation after resuscitative treatment for cardiopulmonary arrest secondary to poisoning, therapeutic hypothermia should be used according to protocol. Bradyarrhythmias associated with hypotension generally should be treated as described in **Chaps. 244 and 245**. Glucagon, calcium, and high-dose insulin with dextrose may be effective in beta blocker and calcium channel blocker poisoning. Antibody therapy may be indicated for cardiac glycoside poisoning.

Supraventricular tachycardia associated with hypertension and CNS excitation is almost always due to agents that cause generalized physiologic excitation (Table 459–1). Most cases are mild or moderate in severity and require only observation or nonspecific sedation with a benzodiazepine. In severe cases or those associated with hemodynamic instability, chest pain, or ECG evidence of ischemia, specific therapy is indicated. When the etiology is sympathetic hyperactivity, treatment with a benzodiazepine should be prioritized. Further treatment with a combined alpha and beta blocker (labetalol), a calcium channel blocker (verapamil or diltiazem), or a combination of a beta blocker and a vasodilator (esmolol and nitroprusside) may be considered for cases refractory to high doses of benzodiazepines only when adequate sedation has been achieved but cardiac conduction or blood pressure abnormalities persist. Treatment with an α-adrenergic antagonist (phentolamine) alone may sometimes be appropriate. If the cause is anticholinergic poisoning, physostigmine alone can be effective. Supraventricular tachycardia without hypertension is generally secondary to vasodilation or hypovolemia and responds to fluid administration.

For ventricular tachyarrhythmias due to tricyclic antidepressants and other membrane-active agents (Table 459-1), sodium bicarbonate is indicated, whereas class IA, IC, and III antiarrhythmic agents are contraindicated because of similar electrophysiologic effects. Although lidocaine and phenytoin are historically safe for ventricular tachyarrhythmias of any etiology, sodium bicarbonate should be considered first for any ventricular arrhythmia suspected to have a toxicologic etiology. Intravenous lipid emulsion therapy has shown benefit for treatment of arrhythmias and hemodynamic instability from various membrane-active agents. Beta blockers can be hazardous if the arrhythmia is due to sympathetic hyperactivity. Magnesium sulfate and overdrive pacing (by isoproterenol or a pacemaker) may be useful in patients with torsades des pointes and prolonged QT intervals. Magnesium and anti-digoxin antibodies should be considered in patients with severe cardiac glycoside poisoning. Invasive (esophageal or intracardiac) ECG recording may be necessary to determine the origin (ventricular or supraventricular) of wide-complex tachycardias **(Chap. 246)**. If the patient is hemodynamically stable, however, it is reasonable to simply observe the patient rather than to administer another potentially proarrhythmic agent. Arrhythmias may be resistant to drug therapy until underlying acid-base, electrolyte, oxygenation, and temperature derangements are corrected.

Central Nervous System Therapies Neuromuscular hyperactivity and seizures can lead to hyperthermia, lactic acidosis, and rhabdomyolysis and should be treated aggressively. Seizures caused by excessive stimulation of catecholamine receptors (sympathomimetic or hallucinogen poisoning and drug withdrawal)

or decreased activity of GABA (isoniazid poisoning) or glycine (strychnine poisoning) receptors are best treated with agents that enhance GABA activity, such as benzodiazepine or barbiturates. Since benzodiazepines and barbiturates act by slightly different mechanisms (the former increases the frequency via allosteric modulation at the receptor and the latter directly increases the duration of chloride channel opening in response to GABA), therapy with both may be effective when neither is effective alone. Seizures caused by isoniazid, which inhibits the synthesis of GABA at several steps by interfering with the cofactor pyridoxine (vitamin B_6), may require high doses of supplemental pyridoxine. Seizures resulting from membrane destabilization (beta blocker or cyclic antidepressant poisoning) require GABA enhancers (benzodiazepines first, barbiturates second). Phenytoin is contraindicated in toxicologic seizures: Animal and human data demonstrate worse outcomes after phenytoin loading, especially in theophylline overdose. For poisons with central dopaminergic effects (methamphetamine, phencyclidine) manifested by psychotic behavior, a dopamine receptor antagonist, such as haloperidol or ziprasidone, may be useful. In anticholinergic and cyanide poisoning, specific antidotal therapy may be necessary. The treatment of seizures secondary to cerebral ischemia or edema or to metabolic abnormalities should include correction of the underlying cause. Neuromuscular paralysis is indicated in refractory cases. Electroencephalographic monitoring and continuing treatment of seizures are necessary to prevent permanent neurologic damage. Serotonergic receptor overstimulation in serotonin syndrome may be treated with cyproheptadine.

Other Measures Temperature extremes, metabolic abnormalities, hepatic and renal dysfunction, and secondary complications should be treated by standard therapies.

PREVENTION OF POISON ABSORPTION

Gastrointestinal Decontamination Whether or not to perform gastrointestinal decontamination and which procedure to use depends on the time since ingestion; the existing and predicted toxicity of the ingestant; the availability, efficacy, and contraindications of the procedure; and the nature, severity, and risk of complications. The efficacy of all decontamination procedures decreases with time, and data are insufficient to support or exclude a beneficial effect when they are used >1 h after ingestion. The average time from ingestion to presentation for treatment is >1 h for children and >3 h for adults. Most patients will recover from poisoning uneventfully with good supportive care alone, but complications of gastrointestinal decontamination, particularly aspiration, can prolong this process. Hence, gastrointestinal decontamination should be performed selectively, not routinely, in the management of overdose patients. It is clearly unnecessary when predicted toxicity is minimal or the time of expected maximal toxicity has passed without significant effect.

Activated charcoal has comparable or greater efficacy; has fewer contraindications and complications; and is less aversive and invasive than ipecac or gastric lavage. Thus, it is the preferred method of gastrointestinal decontamination in most situations. Activated charcoal suspension (in water) is given orally via a cup, straw, or small-bore nasogastric tube. The generally recommended dose is 1 g/kg body weight because of its dosing convenience, although in vitro and in vivo studies have demonstrated that charcoal adsorbs ≥90% of most substances when given in an amount equal to 10 times the weight of the substance. Palatability may be increased by adding a sweetener (sorbitol) or a flavoring agent (cherry, chocolate, or cola syrup) to the suspension. Charcoal adsorbs ingested poisons within the gut lumen, allowing the charcoal-toxin complex to be evacuated with stool. Charged (ionized) chemicals such as mineral acids, alkalis, and highly dissociated salts of cyanide, fluoride, iron, lithium, and other inorganic compounds are not well adsorbed by charcoal. In studies with animals and human volunteers, charcoal decreases the absorption of ingestants by an average of 73% when given within 5 min of ingestant administration, 51% when given at 30 min, and 36% when given at 60 min. For this reason, charcoal given before hospital arrival by prehospital emergency medical services (EMS) increases the potential clinical benefit. Side effects of charcoal include nausea, vomiting, and diarrhea or constipation. Charcoal may also prevent the absorption of orally administered therapeutic agents, so the timing and the dose administered need to be adjusted. Complications include mechanical obstruction of the airway, aspiration, vomiting, and bowel obstruction and infarction caused by inspissated charcoal. Charcoal is not recommended for patients who have ingested corrosives because it obscures endoscopy.

Gastric lavage should be considered for life-threatening poisons that cannot be treated effectively with other decontamination, elimination, or antidotal therapies (e.g., colchicine). Gastric lavage is performed by sequentially administering and aspirating ~5 mL of fluid per kilogram of body weight through a no. 40 French orogastric tube (no. 28 French tube for children). Except in infants, for whom normal saline is recommended, tap water is acceptable. The patient should be placed in Trendelenburg and left lateral decubitus positions to prevent aspiration (even if an endotracheal tube is in place). Lavage decreases ingestant absorption by an average of 52% if performed within 5 min of ingestion administration, 26% if performed at 30 min, and 16% if performed at 60 min. Significant amounts of ingested drug are recovered from <10% of patients. Aspiration is a common complication (occurring in up to 10% of patients), especially when lavage is performed improperly. Serious complications (esophageal and gastric perforation, tube misplacement in the trachea) occur in ~1% of patients. For this reason, the physician should personally insert the lavage tube and confirm its placement, and the patient must be cooperative during the procedure. Gastric lavage is contraindicated in corrosive or petroleum distillate ingestions because of the respective risks of gastroesophageal perforation and aspiration pneumonitis. It is also contraindicated in patients with a compromised unprotected airway and those at risk for hemorrhage or perforation due to esophageal or gastric pathology or recent surgery. Finally, gastric lavage is absolutely contraindicated in combative patients or those who refuse, as most published complications involve patient resistance to the procedure.

Syrup of ipecac, an emetogenic agent that was once the substance most commonly used for decontamination, no longer has a role in poisoning management. Even the American Academy of Pediatrics—traditionally the strongest proponent of ipecac—issued a policy statement in 2003 recommending that ipecac should no longer be used in poisoning treatment. Chronic ipecac use (by patients with anorexia nervosa or bulimia) has been reported to cause electrolyte and fluid abnormalities, cardiac toxicity, and myopathy.

Whole-bowel irrigation is performed by administering a bowel-cleansing solution containing electrolytes and polyethylene glycol (Golytely, Colyte) orally or by gastric tube at a rate of 2 L/h (0.5 L/h in children) until rectal effluent is clear. The patient must be in a sitting position. Although data are limited, whole-bowel irrigation appears to be as effective as other decontamination procedures in volunteer studies. It is most appropriate for those who have ingested foreign bodies, packets of illicit drugs, and agents that are poorly adsorbed by charcoal (e.g., heavy metals). This procedure is contraindicated in patients with bowel obstruction, ileus, hemodynamic instability, and compromised unprotected airways.

Cathartics are salts (disodium phosphate, magnesium citrate and sulfate, sodium sulfate) or saccharides (mannitol, sorbitol) that historically have been given with activated charcoal to promote the rectal evacuation of gastrointestinal contents. However, no animal, volunteer, or clinical data have ever demonstrated any decontamination benefit from cathartics. Abdominal cramps, nausea, and occasional vomiting are side effects. Complications of repeated dosing include severe electrolyte disturbances and excessive diarrhea. Cathartics are contraindicated in patients who have ingested corrosives and in those with preexisting diarrhea. Magnesium-containing cathartics should not be used in patients with renal failure.

Dilution (i.e., drinking water, another clear liquid, or milk at a volume of 5 mL/kg of body weight) is recommended only after the

ingestion of corrosives (acids, alkali). It may increase the dissolution rate (and hence absorption) of capsules, tablets, and other solid ingestants and should *not* be used in these circumstances.

Endoscopic or surgical removal of poisons may be useful in rare situations, such as ingestion of a potentially toxic foreign body that fails to transit the gastrointestinal tract, a potentially lethal amount of a heavy metal (arsenic, iron, mercury, thallium), or agents that have coalesced into gastric concretions or bezoars (heavy metals, lithium, salicylates, sustained-release preparations). Patients who become toxic from cocaine due to its leakage from ingested drug packets require immediate surgical intervention.

Decontamination of Other Sites Immediate, copious flushing with water, saline, or another available clear, drinkable liquid is the initial treatment for topical exposures (exceptions include alkali metals, calcium oxide, phosphorus). Saline is preferred for eye irrigation. A triple wash (water, soap, water) may be best for dermal decontamination. Inhalational exposures should be treated initially with fresh air or supplemental oxygen. The removal of liquids from body cavities such as the vagina or rectum is best accomplished by irrigation. Solids (drug packets, pills) should be removed manually, preferably under direct visualization.

ENHANCEMENT OF POISON ELIMINATION

Although the elimination of most poisons can be accelerated by therapeutic interventions, the pharmacokinetic efficacy (removal of drug at a rate greater than that accomplished by intrinsic elimination) and clinical benefit (shortened duration of toxicity or improved outcome) of such interventions are often more theoretical than proven. Accordingly, the decision to use such measures should be based on the actual or predicted toxicity and the potential efficacy, cost, and risks of therapy.

Multiple-Dose Activated Charcoal Repetitive oral dosing with charcoal can enhance the elimination of previously absorbed substances by binding them within the gut as they are excreted in the bile, are secreted by gastrointestinal cells, or passively diffuse into the gut lumen (*reverse absorption* or *enterocapillary exsorption*). Doses of 0.5–1 g/kg of body weight every 2–4 h, adjusted downward to avoid regurgitation in patients with decreased gastrointestinal motility, are generally recommended. Pharmacokinetic efficacy approaches that of hemodialysis for some agents (e.g., phenobarbital, theophylline). Multiple-dose therapy should be considered only for selected agents (theophylline, phenobarbital, carbamazepine, dapsone, quinine). Complications include intestinal obstruction, pseudo-obstruction, and nonocclusive intestinal infarction in patients with decreased gut motility. Because of electrolyte and fluid shifts, sorbitol and other cathartics are absolutely contraindicated when multiple doses of activated charcoal are administered.

Urinary Alkalinization Ion trapping via alteration of urine pH may prevent the renal reabsorption of poisons that undergo excretion by glomerular filtration and active tubular secretion. Since membranes are more permeable to nonionized molecules than to their ionized counterparts, acidic (low-pK_a) poisons are ionized and trapped in alkaline urine, whereas basic ones become ionized and trapped in acid urine. Urinary alkalinization (producing a urine pH ≥7.5 and a urine output of 3–6 mL/kg of body weight per hour by the addition of sodium bicarbonate to an IV solution) enhances the excretion of chlorophenoxyacetic acid herbicides, chlorpropamide, diflunisal, fluoride, methotrexate, phenobarbital, sulfonamides, and salicylates. Contraindications include congestive heart failure, renal failure, and cerebral edema. Acid-base, fluid, and electrolyte parameters should be monitored carefully. Although acid diuresis may make theoretical sense for some overdoses (amphetamines), it is *never* indicated and is potentially harmful.

Extracorporeal Removal Hemodialysis, charcoal or resin hemoperfusion, hemofiltration, plasmapheresis, and exchange transfusion are capable of removing any toxin from the bloodstream. Agents most amenable to enhanced elimination by dialysis have low molecular mass (<500 Da), high water solubility, low protein binding, small volumes of distribution (<1 L/kg of body weight), prolonged elimination (long half-life), and high dialysis clearance relative to total-body clearance. Molecular weight, water solubility, and protein binding do not limit the efficacy of the other forms of extracorporeal removal.

Dialysis should be considered in cases of severe poisoning due to carbamazepine, ethylene glycol, isopropyl alcohol, lithium, methanol, theophylline, salicylates, and valproate. Although hemoperfusion may be more effective in removing some of these poisons, it does not correct associated acid-base and electrolyte abnormalities, and most hospitals no longer have hemoperfusion cartridges readily available. Fortunately, recent advances in hemodialysis technology make it as effective as hemoperfusion for removing poisons such as caffeine, carbamazepine, and theophylline. Both techniques require central venous access and systemic anticoagulation and may result in transient hypotension. Hemoperfusion may also cause hemolysis, hypocalcemia, and thrombocytopenia. Peritoneal dialysis and exchange transfusion are less effective but may be used when other procedures are unavailable, contraindicated, or technically difficult (e.g., in infants). Exchange transfusion may be indicated in the treatment of severe arsine- or sodium chlorate–induced hemolysis, methemoglobinemia, and sulfhemoglobinemia. Although hemofiltration can enhance elimination of aminoglycosides, vancomycin, and metal-chelate complexes, the roles of hemofiltration and plasmapheresis in the treatment of poisoning are not yet defined.

Candidates for extracorporeal removal therapies include patients with severe toxicity whose condition deteriorates despite aggressive supportive therapy; those with potentially prolonged, irreversible, or fatal toxicity; those with dangerous blood levels of toxins; those who lack the capacity for self-detoxification because of liver or renal failure; and those with a serious underlying illness or complication that will adversely affect recovery.

Other Techniques The elimination of heavy metals can be enhanced by chelation, and the removal of carbon monoxide can be accelerated by hyperbaric oxygenation.

ADMINISTRATION OF ANTIDOTES

Antidotes counteract the effects of poisons by neutralizing them (e.g., antibody-antigen reactions, chelation, chemical binding) or by antagonizing their physiologic effects (e.g., activation of opposing nervous system activity, provision of a competitive metabolic or receptor substrate). Poisons or conditions with specific antidotes include acetaminophen, anticholinergic agents, anticoagulants, benzodiazepines, beta blockers, calcium channel blockers, carbon monoxide, cardiac glycosides, cholinergic agents, cyanide, drug-induced dystonic reactions, ethylene glycol, fluoride, heavy metals, hypoglycemic agents, isoniazid, membrane-active agents, methemoglobinemia, opioids, sympathomimetics, and a variety of envenomations. Intravenous lipid emulsion has been shown to be a successful antidote for poisoning from various anesthetics and membrane-active agents (e.g., cyclic antidepressants), but the exact mechanism of benefit is still under investigation. Antidotes can significantly reduce morbidity and mortality rates but are potentially toxic if used for inappropriate reasons. Since their safe use requires correct identification of a specific poisoning or syndrome, details of antidotal therapy are discussed with the conditions for which they are indicated **(Table 459-4)**.

PREVENTION OF REEXPOSURE

Poisoning is a preventable illness. Unfortunately, some adults and children are poison-prone, and recurrences are common. Unintentional polypharmacy poisoning has become especially common among adults with developmental delays, among the growing population of geriatric patients who are prescribed a large number of medications, and among adolescents and young adults experimenting with pharmaceuticals for recreational euphoria. Adults with unintentional exposures should be instructed regarding the safe use of medications and chemicals (according to labeling instructions). Confused patients may need assistance with the administration of

TABLE 459-4 Pathophysiologic Features and Treatment of Specific Toxic Syndromes and Poisonings

PHYSIOLOGIC CONDITION, CAUSES	EXAMPLES	MECHANISM OF ACTION	CLINICAL FEATURES	SPECIFIC TREATMENTS
Stimulated				
Sympathetics[a]				
Sympathomimetics	α_1-Adrenergic agonists (decongestants): phenylephrine, phenylpropanolamine β_2-Adrenergic agonists (bronchodilators): albuterol, terbutaline Nonspecific adrenergic agonists: amphetamines, cocaine, ephedrine	Stimulation of central and peripheral sympathetic receptors directly or indirectly (by promoting release or inhibiting reuptake of norepinephrine and sometimes dopamine)	Physiologic stimulation (Table 459-2). Reflex bradycardia can occur with selective α_1 agonists; β agonists can cause hypotension and hypokalemia.	Phentolamine, a nonselective α_1-adrenergic receptor antagonist, for severe hypertension due to α_1-adrenergic agonists; propranolol, a nonselective β blocker, for hypotension and tachycardia due to β_2 agonists; *either* labetalol, a β blocker with α-blocking activity, *or* phentolamine with esmolol, metoprolol, or another cardioselective β blocker for hypertension with tachycardia due to nonselective agents (β blockers, if used alone, can exacerbate hypertension and vasospasm due to unopposed α stimulation.); benzodiazepines; propofol
Ergot alkaloids	Ergotamine, methysergide, bromocriptine, pergolide	Stimulation and inhibition of serotonergic and α-adrenergic receptors; stimulation of dopamine receptors	Physiologic stimulation (Table 459-2); formication; vasospasm with limb (isolated or generalized), myocardial, and cerebral ischemia progressing to gangrene or infarction. Hypotension, bradycardia, and involuntary movements can also occur.	Nitroprusside or nitroglycerine for severe vasospasm; prazosin (an α_1 blocker), captopril, nifedipine, and cyproheptadine (a serotonin receptor antagonist) for mild-to-moderate limb ischemia; dopamine receptor antagonists (antipsychotics) for hallucinations and movement disorders
Methylxanthines	Caffeine, theophylline	Inhibition of adenosine synthesis and adenosine receptor antagonism; stimulation of epinephrine and norepinephrine release; inhibition of phosphodiesterase resulting in increased intracellular cyclic adenosine and guanosine monophosphate	Physiologic stimulation (Table 459-2); pronounced gastrointestinal symptoms and β agonist effects (see above). Toxicity occurs at lower drug levels in chronic poisoning than in acute poisoning.	Propranolol, a nonselective β blocker, or esmolol for tachycardia with hypotension; any β blocker for supraventricular or ventricular tachycardia without hypotension; elimination enhanced by multiple-dose charcoal, hemoperfusion, and hemodialysis. Indications for hemoperfusion or hemodialysis include unstable vital signs, seizures, and a theophylline level of 80–100 μg/mL after an acute overdose and 40–60 μg/mL with chronic exposure.
Monoamine oxidase inhibitors	Phenelzine, tranylcypromine, selegiline	Inhibition of monoamine oxidase resulting in impaired metabolism of endogenous catecholamines and exogenous sympathomimetic agents	Delayed or slowly progressive physiologic stimulation (Table 459-2); terminal hypotension and bradycardia in severe cases	Short-acting agents (e.g., nitroprusside, esmolol) for severe hypertension and tachycardia; direct-acting sympathomimetics (e.g., norepinephrine, epinephrine) for hypotension and bradycardia
Anticholinergics				
Antihistamines	Diphenhydramine, doxylamine, pyrilamine	Inhibition of central and postganglionic parasympathetic muscarinic cholinergic receptors. At high doses, amantadine, diphenhydramine, orphenadrine, phenothiazines, and tricyclic antidepressants have additional nonanticholinergic activity (see below).	Physiologic stimulation (Table 459-2); dry skin and mucous membranes, decreased bowel sounds, flushing, and urinary retention; myoclonus and picking activity. Central effects may occur without significant autonomic dysfunction.	Physostigmine, an acetylcholinesterase inhibitor (see below), for delirium, hallucinations, and neuromuscular hyperactivity. Contraindications include asthma and non-anticholinergic cardiovascular toxicity (e.g., cardiac conduction abnormalities, hypotension, and ventricular arrhythmias).
Antipsychotics	Chlorpromazine, olanzapine, quetiapine, thioridazine	Inhibition of α-adrenergic, dopaminergic, histaminergic, muscarinic, and serotonergic receptors. Some agents also inhibit sodium, potassium, and calcium channels.	Physiologic depression (Table 459-2), miosis, anticholinergic effects (see above), extrapyramidal reactions (see below), tachycardia	Sodium bicarbonate for ventricular tachydysrhythmias associated with QRS prolongation; magnesium, isoproterenol, and overdrive pacing for torsades des pointes. Avoid class IA, IC, and III antiarrhythmics.
Belladonna alkaloids	Atropine, hyoscyamine, scopolamine	Inhibition of central and postganglionic parasympathetic muscarinic cholinergic receptors	Physiologic stimulation (Table 459-2); dry skin and mucous membranes, decreased bowel sounds, flushing, and urinary retention; myoclonus and picking activity. Central effects may occur without significant autonomic dysfunction.	Physostigmine, an acetylcholinesterase inhibitor (see below), for delirium, hallucinations, and neuromuscular hyperactivity. Contraindications include asthma and non-anticholinergic cardiovascular toxicity (e.g., cardiac conduction abnormalities, hypotension, and ventricular arrhythmias).

(*Continued*)

TABLE 459-4 Pathophysiologic Features and Treatment of Specific Toxic Syndromes and Poisonings (Continued)

PHYSIOLOGIC CONDITION, CAUSES	EXAMPLES	MECHANISM OF ACTION	CLINICAL FEATURES	SPECIFIC TREATMENTS
Cyclic antidepressants	Amitriptyline, doxepin, imipramine	Inhibition of α-adrenergic, dopaminergic, GABA-ergic, histaminergic, muscarinic, and serotonergic receptors; inhibition of sodium channels (see membrane-active agents); inhibition of norepinephrine and serotonin reuptake	Physiologic depression (Table 459-2), seizures, tachycardia, cardiac conduction delays (increased PR, QRS, JT, and QT intervals; terminal QRS right-axis deviation) with aberrancy and ventricular tachydysrhythmias; anticholinergic toxidrome (see above)	Hypertonic sodium bicarbonate (or hypertonic saline) for ventricular tachydysrhythmias associated with QRS prolongation. Use of phenytoin is controversial. Avoid class IA, IC, and III antiarrhythmics. IV emulsion therapy may be beneficial in some cases.
Mushrooms and plants	*Amanita muscaria* and *A. pantherina*, henbane, jimson weed, nightshade	Inhibition of central and postganglionic parasympathetic muscarinic cholinergic receptors	Physiologic stimulation (Table 459-2); dry skin and mucous membranes, decreased bowel sounds, flushing, and urinary retention; myoclonus and picking activity. Central effects may occur without significant autonomic dysfunction.	Physostigmine, an acetylcholinesterase inhibitor (see below), for delirium, hallucinations, and neuromuscular hyperactivity. Contraindications include asthma and nonanticholinergic cardiovascular toxicity (e.g., cardiac conduction abnormalities, hypotension, and ventricular arrhythmias).
Depressed				
Sympatholytics				
α_2-Adrenergic agonists	Clonidine, guanabenz, tetrahydrozoline and other imidazoline decongestants, tizanidine and other imidazoline muscle relaxants	Stimulation of α_2-adrenergic receptors leading to inhibition of CNS sympathetic outflow. Activity at nonadrenergic imidazoline binding sites also contributes to CNS effects.	Physiologic depression (Table 459-2), miosis. Transient initial hypertension may be seen.	Dopamine and norepinephrine for hypotension; atropine for symptomatic bradycardia; naloxone for CNS depression (inconsistently effective)
Antipsychotics	Chlorpromazine, clozapine, haloperidol, risperidone, thioridazine	Inhibition of α-adrenergic, dopaminergic, histaminergic, muscarinic, and serotonergic receptors. Some agents also inhibit sodium, potassium, and calcium channels.	Physiologic depression (Table 459-2), miosis, anticholinergic effects (see above), extrapyramidal reactions (see below), tachycardia. Cardiac conduction delays (increased PR, QRS, JT, and QT intervals) with ventricular tachydysrhythmias, including torsades des pointes, can sometimes develop.	Sodium bicarbonate for ventricular tachydysrhythmias associated with QRS prolongation; magnesium, isoproterenol, and overdrive pacing for torsades des pointes. Avoid class IA, IC, and III antiarrhythmics.
β-Adrenergic blockers	Cardioselective (β_1) blockers: atenolol, esmolol, metoprolol Nonselective (β_1 and β_2) blockers: nadolol, propranolol, timolol Partial β agonists: acebutolol, pindolol α_1 Antagonists: carvedilol, labetalol Membrane-active agents: acebutolol, propranolol, sotalol	Inhibition of β-adrenergic receptors (class II antiarrhythmic effect). Some agents have activity at additional receptors or have membrane effects (see below).	Physiologic depression (Table 459-2), atrioventricular block, hypoglycemia, hyperkalemia, seizures. Partial agonists can cause hypertension and tachycardia. Sotalol can cause increased QT interval and ventricular tachydysrhythmias. Onset may be delayed after sotalol and sustained-release formulation overdose.	Glucagon for hypotension and symptomatic bradycardia. Atropine, isoproterenol, dopamine, dobutamine, epinephrine, and norepinephrine may sometimes be effective. High-dose insulin (with glucose and potassium to maintain euglycemia and normokalemia), electrical pacing, and mechanical cardiovascular support for refractory cases.
Calcium channel blockers	Diltiazem, nifedipine and other dihydropyridine derivatives, verapamil	Inhibition of slow (type L) cardiovascular calcium channels (class IV antiarrhythmic effect)	Physiologic depression (Table 459-2), atrioventricular block, organ ischemia and infarction, hyperglycemia, seizures. Hypotension is usually due to decreased vascular resistance rather than to decreased cardiac output. Onset may be delayed for ≥12 h after overdose of sustained-release formulations.	Calcium and glucagon for hypotension and symptomatic bradycardia. Dopamine, epinephrine, norepinephrine, atropine, and isoproterenol are less often effective but can be used adjunctively. High-dose insulin (with glucose and potassium to maintain euglycemia and normokalemia), IV lipid emulsion therapy, electrical pacing, and mechanical cardiovascular support for refractory cases.

(*Continued*)

TABLE 459-4 Pathophysiologic Features and Treatment of Specific Toxic Syndromes and Poisonings (Continued)

PHYSIOLOGIC CONDITION, CAUSES	EXAMPLES	MECHANISM OF ACTION	CLINICAL FEATURES	SPECIFIC TREATMENTS
Cardiac glycosides	Digoxin, endogenous cardioactive steroids, foxglove and other plants, toad skin secretions (Bufonidae spp.)	Inhibition of cardiac Na^+, K^+-ATPase membrane pump	Physiologic depression (Table 459-2); gastrointestinal, psychiatric, and visual symptoms; atrioventricular block with or without concomitant supraventricular tachyarrhythmia; ventricular tachyarrhythmias; hyperkalemia in acute poisoning. Toxicity occurs at lower drug levels in chronic poisoning than in acute poisoning.	Digoxin-specific antibody fragments for hemodynamically compromising dysrhythmias, Mobitz II or third-degree atrioventricular block, hyperkalemia (>5.5 meq/L; in acute poisoning only). Temporizing measures include atropine, dopamine, epinephrine, and external cardiac pacing for bradydysrhythmias and magnesium, lidocaine, or phenytoin, for ventricular tachydysrhythmias. Internal cardiac pacing and cardioversion can increase ventricular irritability and should be reserved for refractory cases.
Cyclic antidepressants	Amitriptyline, doxepin, imipramine	Inhibition of α-adrenergic, dopaminergic, GABA-ergic, histaminergic, muscarinic, and serotonergic receptors; inhibition of sodium channels (see membrane-active agents); inhibition of norepinephrine and serotonin reuptake	Physiologic depression (Table 459-2), seizures, tachycardia, cardiac conduction delays (increased PR, QRS, JT, and QT intervals; terminal QRS right-axis deviation) with aberrancy and ventricular tachydysrhythmias; anticholinergic toxidrome (see above)	Hypertonic sodium bicarbonate (or hypertonic saline) for ventricular tachydysrhythmias associated with QRS prolongation. Use of phenytoin is controversial. Avoid class IA, IC, and III antiarrhythmics. IV emulsion therapy may be beneficial in some cases.
Cholinergics				
Acetylcholinesterase inhibitors Muscarinic agonists Nicotinic agonists	Carbamate insecticides (aldicarb, carbaryl, propoxur) and medicinals (neostigmine, physostigmine, tacrine); nerve gases (sarin, soman, tabun, VX); organophosphate insecticides (diazinon, chlorpyrifos-ethyl, malathion) Bethanechol, mushrooms (*Boletus, Clitocybe, Inocybe* spp.), pilocarpine Lobeline, nicotine (tobacco)	Inhibition of acetylcholinesterase leading to increased synaptic acetylcholine at muscarinic and nicotinic cholinergic receptor sites Stimulation of CNS and postganglionic parasympathetic cholinergic (muscarinic) receptors Stimulation of preganglionic sympathetic and parasympathetic and striated muscle (neuromuscular junction) cholinergic (nicotine) receptors	Physiologic depression (Table 459-2). Muscarinic signs and symptoms: seizures, excessive secretions (lacrimation, salivation, bronchorrhea and wheezing, diaphoresis), and increased bowel and bladder activity with nausea, vomiting, diarrhea, abdominal cramps, and incontinence of feces and urine. Nicotinic signs and symptoms: hypertension, tachycardia, muscle cramps, fasciculations, weakness, and paralysis. Death is usually due to respiratory failure. Cholinesterase activity in plasma and red cells is <50% of normal in acetylcholinesterase inhibitor poisoning.	Atropine for muscarinic signs and symptoms; 2-PAM, a cholinesterase reactivator, for nicotinic signs and symptoms due to organophosphates, nerve gases, or an unknown anticholinesterase
Sedative-hypnotics[b]				
Anticonvulsants Barbiturates Benzodiazepines	Carbamazepine, ethosuximide, felbamate, gabapentin, lamotrigine, levetiracetam, oxcarbazepine, phenytoin, tiagabine, topiramate, valproate, zonisamide Short-acting: butabarbital, pentobarbital, secobarbital Long-acting: phenobarbital, primidone Ultrashort-acting: estazolam, midazolam, temazepam, triazolam Short-acting: alprazolam, flunitrazepam, lorazepam, oxazepam Long-acting: chlordiazepoxide, clonazepam, diazepam, flurazepam Pharmacologically related agents: zaleplon, zolpidem	Potentiation of the inhibitory effects of GABA by binding to the neuronal GABA–A chloride channel receptor complex and increasing the frequency or duration of chloride channel opening in response to GABA stimulation. Baclofen and, to some extent, GHB act at the GABA–B receptor complex. Meprobamate, its metabolite carisoprodol, felbamate, and orphenadrine antagonize NDMA excitatory receptors. Ethosuximide, valproate, and zonisamide decrease conduction through T-type calcium channels. Valproate decreases GABA degradation, and tiagabine blocks GABA reuptake. Carbamazepine, lamotrigine, oxcarbazepine, phenytoin, topiramate, valproate, and zonisamide slow the rate of recovery of inactivated sodium channels. Some agents also have α_2 agonist, anticholinergic, and sodium channel–blocking activity (see above and below).	Physiologic depression (Table 459-2), nystagmus. Delayed absorption can occur with carbamazepine, phenytoin, and valproate. Myoclonus, seizures, hypertension, and tachyarrhythmias can occur with baclofen, carbamazepine, and orphenadrine. Tachyarrhythmias can also occur with chloral hydrate. AGMA, hypernatremia, hyperosmolality, hyperammonemia, chemical hepatitis, and hypoglycemia can be seen in valproate poisoning. Carbamazepine and oxcarbazepine may produce hyponatremia from SIADH.	Benzodiazepines, barbiturates, or propofol for seizures. Hemodialysis and hemoperfusion may be indicated for severe poisoning by some agents (see "Extracorporeal Removal," in text). See above and below for treatment of anticholinergic and sodium channel (membrane)–blocking effects.

(*Continued*)

TABLE 459-4 Pathophysiologic Features and Treatment of Specific Toxic Syndromes and Poisonings (Continued)

PHYSIOLOGIC CONDITION, CAUSES	EXAMPLES	MECHANISM OF ACTION	CLINICAL FEATURES	SPECIFIC TREATMENTS
GABA precursors	γ-Hydroxybutyrate (sodium oxybate; GHB), γ-butyrolactone (GBL), 1,4-butanediol	Stimulation at GABA receptor complex increases chloride channel opening	Physiologic depression (Table 459-2)	Goal-directed supportive care
Muscle relaxants	Baclofen, carisoprodol, cyclobenzaprine, etomidate, metaxalone, methocarbamol, orphenadrine, propofol, tizanidine and other imidazoline muscle relaxants	Baclofen acts at GABA-B receptor complex; Stimulation of α2-adrenergic receptors inhibits CNS sympathetic outflow. Activity at nonadrenergic imidazoline binding sites also contributes to CNS effects. The others have centrally-acting and various other unknown mechanisms of action	Physiologic depression (Table 459-2)	Goal-directed supportive care; benzodiazepines and barbiturates for seizures
Other agents	Chloral hydrate, ethchlorvynol, glutethimide, meprobamate, methaqualone, methyprylon			
Discordant				
Asphyxiants				
Cytochrome oxidase inhibitors	Cyanide, hydrogen sulfide	Inhibition of mitochondrial cytochrome oxidase, with consequent blockage of electron transport and oxidative metabolism. Carbon monoxide also binds to hemoglobin and myoglobin and prevents oxygen binding, transport, and tissue uptake. (Binding to hemoglobin shifts the oxygen dissociation curve to the left.)	Signs and symptoms of hypoxemia with initial physiologic stimulation and subsequent depression (Table 459-2); lactic acidosis; normal PO_2 and calculated oxygen saturation but decreased oxygen saturation by co-oximetry. (That measured by pulse oximetry is falsely elevated but is less than normal and less than the calculated value.) Headache and nausea are common with carbon monoxide. Sudden collapse may occur with cyanide and hydrogen sulfide exposure. A bitter almond breath odor may be noted with cyanide ingestion, and hydrogen sulfide smells like rotten eggs.	High-dose oxygen; IV hydroxocobalamin or IV sodium nitrite and sodium thiosulfate (Lilly cyanide antidote kit) for coma, metabolic acidosis, and cardiovascular dysfunction in cyanide poisoning or victims from a fire; ECMO
Methemoglobin inducers	Aniline derivatives, dapsone, local anesthetics, nitrates, nitrites, nitrogen oxides, nitro- and nitrosohydrocarbons, phenazopyridine, primaquine-type antimalarials, sulfonamides	Oxidation of hemoglobin iron from ferrous (Fe^{2+}) to ferric (Fe^{3+}) state prevents oxygen binding, transport, and tissue uptake. (Methemoglobinemia shifts oxygen dissociation curve to the left.) Oxidation of hemoglobin protein causes hemoglobin precipitation and hemolytic anemia (manifesting as Heinz bodies and "bite cells" on peripheral-blood smear).	Signs and symptoms of hypoxemia with initial physiologic stimulation and subsequent depression (Table 459-2), gray-brown cyanosis unresponsive to oxygen at methemoglobin fractions >15–20%, headache, lactic acidosis (at methemoglobin fractions >45%), normal PO_2 and calculated oxygen saturation but decreased oxygen saturation and increased methemoglobin fraction by co-oximetry (Oxygen saturation by pulse oximetry may be falsely increased or decreased but is less than normal and less than the calculated value.)	High-dose oxygen; IV methylene blue for methemoglobin fraction >30%, symptomatic hypoxemia, or ischemia (contraindicated in G6PD deficiency); exchange transfusion and hyperbaric oxygen for severe or refractory cases

(*Continued*)

TABLE 459-4 Pathophysiologic Features and Treatment of Specific Toxic Syndromes and Poisonings (Continued)

PHYSIOLOGIC CONDITION, CAUSES	EXAMPLES	MECHANISM OF ACTION	CLINICAL FEATURES	SPECIFIC TREATMENTS
AGMA inducers	Ethylene glycol	Ethylene glycol causes CNS depression and increased serum osmolality. Metabolites (primarily glycolic acid) cause AGMA, CNS depression, and renal failure. Precipitation of oxalic acid metabolite as calcium salt in tissues and urine results in hypocalcemia, tissue edema, and crystalluria.	Initial ethanol-like intoxication, nausea, vomiting, increased osmolar gap, calcium oxalate crystalluria; delayed AGMA, back pain, renal failure; coma, seizures, hypotension, ARDS in severe cases	Sodium bicarbonate to correct acidemia; thiamine, folinic acid, magnesium, and high-dose pyridoxine to facilitate metabolism; ethanol or fomepizole for AGMA, crystalluria or renal dysfunction, ethylene glycol level >3 mmol/L (20 mg/dL), and ethanol-like intoxication or increased osmolal gap if level not readily obtainable; hemodialysis for persistent AGMA, lack of clinical improvement, and renal dysfunction; hemodialysis also useful for enhancing ethylene glycol elimination and shortening duration of treatment when ethylene glycol level is >8 mmol/L (50 mg/dL).
	Iron	Hydration of ferric (Fe^{3+}) ion generates H^+. Non-transferrin-bound iron catalyzes formation of free radicals that cause mitochondrial injury, lipid peroxidation, increased capillary permeability, vasodilation, and organ toxicity.	Initial nausea, vomiting, abdominal pain, diarrhea; AGMA, cardiovascular and CNS depression, hepatitis, coagulopathy, and seizures in severe cases. Radiopaque iron tablets may be seen on abdominal x-ray.	Whole-bowel irrigation for large ingestions; endoscopy and gastrostomy if clinical toxicity and large number of tablets are still visible on x-ray; IV hydration; sodium bicarbonate for acidemia; IV deferoxamine for systemic toxicity, iron level >90 µmol/L (500 µg/dL)
	Methanol	Methanol causes ethanol-like CNS depression and increased serum osmolality. Formic acid metabolite causes AGMA and retinal toxicity.	Initial ethanol-like intoxication, nausea, vomiting, increased osmolar gap; delayed AGMA, visual (clouding, spots, blindness) and retinal (edema, hyperemia) abnormalities; coma, seizures, cardiovascular depression in severe cases; possible pancreatitis	Gastric aspiration for recent ingestion; sodium bicarbonate to correct acidemia; high-dose folinic acid or folate to facilitate metabolism; ethanol or fomepizole for AGMA, visual symptoms, methanol level >6 mmol/L (20 mg/dL), and ethanol-like intoxication or increased osmolal gap if level not readily obtainable; hemodialysis for persistent AGMA, lack of clinical improvement, and renal dysfunction; hemodialysis also useful for enhancing methanol elimination and shortening duration of treatment when methanol level is >15 mmol/L (50 mg/dL)
	Salicylate	Increased sensitivity of CNS respiratory center to changes in and stimulates respiration. Uncoupling of oxidative phosphorylation, inhibition of Krebs cycle enzymes, and stimulation of carbohydrate and lipid metabolism generate unmeasured endogenous anions and cause AGMA.	Initial nausea, vomiting, hyperventilation, alkalemia, alkaluria; subsequent alkalemia with both respiratory alkalosis and AGMA and paradoxical aciduria; late acidemia with CNS and respiratory depression; cerebral and pulmonary edema in severe cases. Hypoglycemia, hypocalcemia, hypokalemia, and seizures can occur.	IV hydration and supplemental glucose; sodium bicarbonate to correct acidemia; urinary alkalinization for systemic toxicity; hemodialysis for coma, cerebral edema, seizures, pulmonary edema, renal failure, progressive acid-base disturbances or clinical toxicity, salicylate level >7 mmol/L (100 mg/dL) following acute overdose
CNS syndromes				
Extrapyramidal reactions	Antipsychotics (see above), some cyclic antidepressants and antihistamines	Decreased CNS dopaminergic activity with relative excess of cholinergic activity	Akathisia, dystonia, parkinsonism	Oral or parenteral anticholinergic agent such as benztropine or diphenhydramine
Isoniazid		Interference with activation and supply of pyridoxal-5-phosphate, a cofactor for glutamic acid decarboxylase, which converts glutamic acid to GABA, results in decreased levels of this inhibitory CNS neurotransmitter; complexation with and depletion of pyridoxine itself; inhibition of nicotine adenine dinucleotide–dependent lactate and hydroxybutyrate dehydrogenases, resulting in substrate accumulation	Nausea, vomiting, agitation, confusion; coma, respiratory depression, seizures, lactic and ketoacidosis in severe cases	High-dose IV pyridoxine (vitamin B_6) for agitation, confusion, coma, and seizures; diazepam or barbiturates for seizures

(*Continued*)

TABLE 459-4 Pathophysiologic Features and Treatment of Specific Toxic Syndromes and Poisonings (Continued)

PHYSIOLOGIC CONDITION, CAUSES	EXAMPLES	MECHANISM OF ACTION	CLINICAL FEATURES	SPECIFIC TREATMENTS
Lithium		Interference with cell membrane ion transport, adenylate cyclase and Na^+, K^+-ATPase activity, and neurotransmitter release	Nausea, vomiting, diarrhea, ataxia, choreoathetosis, encephalopathy, hyperreflexia, myoclonus, nystagmus, nephrogenic diabetes insipidus, falsely elevated serum chloride with low anion gap, tachycardia; coma, seizures, arrhythmias, hyperthermia, and prolonged or permanent encephalopathy and movement disorders in severe cases; delayed onset after acute overdose, particularly with delayed-release formulations. Toxicity occurs at lower drug levels in chronic poisoning than in acute poisoning.	Whole-bowel irrigation for large ingestions; IV hydration; hemodialysis for coma, seizures, encephalopathy or neuromuscular dysfunction (severe, progressive, or persistent), peak lithium level >4 meq/L following acute overdose
Serotonin syndrome	Amphetamines, cocaine, dextromethorphan, meperidine, MAO inhibitors, selective serotonin (5-HT) reuptake inhibitors, tricyclic antidepressants, tramadol, triptans, tryptophan	Promotion of serotonin release, inhibition of serotonin reuptake, or direct stimulation of CNS and peripheral serotonin receptors (primarily 5-HT-1a and 5-HT-2), alone or in combination	Altered mental status (agitation, confusion, mutism, coma, seizures), neuromuscular hyperactivity (hyperreflexia, myoclonus, rigidity, tremors), and autonomic dysfunction (abdominal pain, diarrhea, diaphoresis, fever, flushing, labile hypertension, mydriasis, tearing, salivation, tachycardia). Complications include hyperthermia, lactic acidosis, rhabdomyolysis, and multisystem organ failure.	Discontinue the offending agent(s); benzodiazepines for agitation or signs of stimulation; the serotonin receptor antagonist cyproheptadine may be helpful in severe cases.
Membrane-active agent	Amantadine, antiarrhythmics (class I and III agents; some β blockers), antipsychotics (see above), antihistamines (particularly diphenhydramine), carbamazepine, local anesthetics (including cocaine), opioids (meperidine, propoxyphene), orphenadrine, quinoline antimalarials (chloroquine, hydroxychloroquine, quinine), cyclic antidepressants (see above)	Blockade of fast sodium membrane channels prolongs phase 0 (depolarization) of the cardiac action potential, which prolongs QRS duration and promotes reentrant (monomorphic) ventricular tachycardia. Class Ia, Ic, and III antiarrhythmics also block potassium channels during phases 2 and 3 (repolarization) of the action potential, prolonging the JT interval and promoting early afterdepolarizations and polymorphic (torsades des pointes) ventricular tachycardia. Similar effects on neuronal membrane channels cause CNS dysfunction. Some agents also block α-adrenergic and cholinergic receptors or have opioid effects (see above and **Chap. 456**).	QRS and JT prolongation (or both) with hypotension, ventricular tachyarrhythmias, CNS depression, seizures; anticholinergic effects with amantadine, antihistamines, carbamazepine, disopyramide, antipsychotics, and cyclic antidepressants (see above); opioid effects with meperidine and propoxyphene **(see Chap. 456)**; cinchonism (hearing loss, tinnitus, nausea, vomiting, vertigo, ataxia, headache, flushing, diaphoresis), and blindness with quinoline antimalarials	Hypertonic sodium bicarbonate (or hypertonic saline) for cardiac conduction delays and monomorphic ventricular tachycardia; lidocaine for monomorphic ventricular tachycardia (except when due to class Ib antiarrhythmics); magnesium, isoproterenol, and overdrive pacing for polymorphic ventricular tachycardia; physostigmine for anticholinergic effects (see above); naloxone for opioid effects **(see Chap. 456)**; extracorporeal removal for some agents (see text).

[a]See above and **Chap. 457**. [b]See above and **Chap. 456**.

Abbreviations: AGMA, anion-gap metabolic acidosis; ARDS, adult respiratory distress syndrome; CNS, central nervous system; ECMO, extracorporeal membrane oxygenation; GABA, γ-aminobutyric acid; GBL, γ-butyrolactone; GHB, γ-hydroxybutyrate; G6PD, glucose-6-phosphate dehydrogenase; MAO, monoamine oxidase; NDMA, *N*-methyl-D-aspartate; 2-PAM, pralidoxime; SIADH, syndrome of inappropriate antidiuretic hormone secretion.

their medications. Errors in dosing by health care providers may require educational efforts. Patients should be advised to avoid circumstances that result in chemical exposure or poisoning. Appropriate agencies and health departments (e.g., Occupational Health and Safety Administration [OSHA]) should be notified in cases of environmental or workplace exposure. The best approach to young children and patients with intentional overdose (deliberate self-harm or attempted suicide) is to limit their access to poisons. In households where children live or visit, alcoholic beverages, medications, household products (automotive, cleaning, fuel, pet-care, and toiletry products), inedible plants, and vitamins should be kept out of reach or in locked or child-proof cabinets. Depressed, bipolar, or psychotic patients should undergo psychiatric assessment, disposition, and follow-up. They should be given prescriptions for a limited supply of drugs with a limited number of refills and should be monitored for compliance and response to therapy.

SPECIFIC TOXIC SYNDROMES AND POISONINGS

Table 459-4 summarizes the pathophysiology, clinical features, and treatment of toxidromes and poisonings that are common, produce life-threatening toxicity, or require unique therapeutic interventions. In all cases, treatment should include attention to the general principles discussed above and, in particular, supportive care. Poisonings not covered in this chapter are discussed in specialized texts.

Alcohol, cocaine, hallucinogen, and opioid poisoning and alcohol and opioid withdrawal are discussed in Chaps. 453, 456, and

457; nicotine addiction is discussed in Chap. 454; acetaminophen poisoning is discussed in Chap. 340; the neuroleptic malignant syndrome is discussed in Chap. 435; and heavy metal poisoning is discussed in Chap. 458.

GLOBAL CONSIDERATIONS

Risks of poisoning in the United States and throughout the world are in transition. Patterns of travel, immigration, and internet consumerism should always be considered in patients suspected of poisoning or overdose without a clear etiology. Immigrants into various countries may have underlying poisoning from various metals from work or the environment where they previously lived; herbal remedies, food products, and cosmetics imported from overseas or ordered from the internet may be contaminated with metals, toxic plants, or other pharmaceutical contaminants; and new drugs of abuse that originate in one part of the world quickly circulate due to the ease afforded by the internet. Expanding the history at the time of evaluation, recruiting the assistance of global health specialists, and ordering expanded laboratory panels may be indicated. For instance, during the COVID-19 pandemic, poisoning from household cleaning substances and novel untested therapies increased worldwide.

460 Disorders Caused by Venomous Snakebites and Marine Animal Exposures

Erik Fisher, Alex Chen, Charles Lei

This chapter outlines general principles for the evaluation and management of victims of envenomation and poisoning by venomous snakes and marine animals. Because the incidence of serious bites and stings is relatively low in developed nations, there is a paucity of relevant clinical research; as a result, therapeutic decision-making often is based on anecdotal information.

VENOMOUS SNAKEBITE

EPIDEMIOLOGY

The venomous snakes of the world belong to the families Viperidae (subfamily Viperinae: Old World vipers; subfamily Crotalinae: New World and Asian pit vipers), Elapidae (including cobras, coral snakes, sea snakes, kraits, and all Australian venomous snakes), Lamprophiidae (subfamily Atractaspidinae: burrowing asps), and Colubridae (a large family in which most species are nonvenomous). Most snakebites occur in developing countries with temperate and tropical climates in which populations subsist on agriculture and fishing (Fig. 460-1). Recent estimates indicate that somewhere between 1.2 million and 5.5 million snakebites occur worldwide each year, with 421,000–1,200,000 envenomations and 81,000–138,000 deaths. Such wide-ranging estimates reflect the challenges of collecting accurate data in the regions most affected by venomous snakes; many victims in these areas either do not seek medical attention or have insufficient access to antivenom, and reporting and record-keeping are generally poor.

SNAKE ANATOMY/IDENTIFICATION

The typical snake venom delivery apparatus consists of bilateral venom glands situated behind the eyes and hollow anterior maxillary fangs. In viperids, these fangs are long and highly mobile; they are retracted against the roof of the mouth when the snake is at rest, then brought to an upright position when about to strike. In elapids, the fangs are fixed in an erect position and smaller in size, which can lead to fewer distinct wounds after an envenomation. Colubrids do not possess venom glands but have homologous structures known as Duvernoy's glands. Approximately 20–25% of pit viper bites and higher percentages of other snakebites (up to 75% for sea snakes) are "dry" bites, in which no venom is released.

Differentiating between venomous and nonvenomous snake species can be challenging. Identifying venomous snakes by color pattern can be misleading, as many nonvenomous snakes have color patterns that closely mimic those of venomous snakes found in the same region. Viperids are characterized by triangular heads (a feature shared with many harmless snakes), elliptical pupils (also seen in some nonvenomous snakes, such as boas and pythons), and enlarged maxillary fangs; pit vipers also possess heat-sensing organs (pits) on each side of the head that assist with locating prey and aiming strikes. Rattlesnakes possess a series of interlocking hollow keratin plates (the rattle) on the tip of the tail that emits a buzzing sound when vibrated rapidly; this sound serves as a warning signal to perceived threats.

VENOMS AND CLINICAL MANIFESTATIONS

Snake venoms consist of highly complex mixtures of enzymes, polypeptides, glycoproteins, and other constituents. Venom components may vary greatly depending on the species, age, and geographic location of the snake. Snake venoms can cause local tissue necrosis, affect the coagulation pathway at various steps, impair organ function, or act at the neuromuscular junction to cause paralysis.

After an envenomation, the time to symptom onset and clinical presentation can be quite variable depending on the species involved, the anatomic location of the bite, and the amount of venom injected. Envenomations by most viperids and some elapids cause progressive local pain, soft-tissue swelling, and ecchymosis (Fig. 460-2). Hemorrhagic or serum-filled vesicles and bullae may develop at the bite site over a period of hours to days. In serious bites, tissue loss can be significant (Fig. 460-3). Systemic findings are variable and can include generalized fatigue, nausea, changes in taste, mouth numbness, tachycardia or bradycardia, hypotension, muscle fasciculations, pulmonary edema, renal dysfunction, and spontaneous hemorrhage. Envenomations by neurotoxic elapids, such as kraits (*Bungarus* species), many Australian elapids (e.g., death adders [*Acanthophis* species] and tiger snakes [*Notechis* species]), and some cobras (*Naja* species), as well as some viperids (e.g., the South American rattlesnake [*Crotalus durissus*], Mojave rattlesnake [*Crotalus scutulatus*], and certain Indian Russell's vipers [*Daboia russelii*]), cause neurologic dysfunction. Early findings may consist of nausea and vomiting, headache, paresthesias or numbness, and altered mental status. Victims may develop cranial nerve abnormalities (e.g., ptosis, difficulty swallowing), followed by peripheral motor weakness. Severe envenomation may result in diaphragmatic paralysis and lead to death from respiratory failure and aspiration. Sea snake envenomation results in local pain (variable), generalized myalgias, trismus, rhabdomyolysis, and progressive flaccid paralysis; these manifestations can be delayed for several hours.

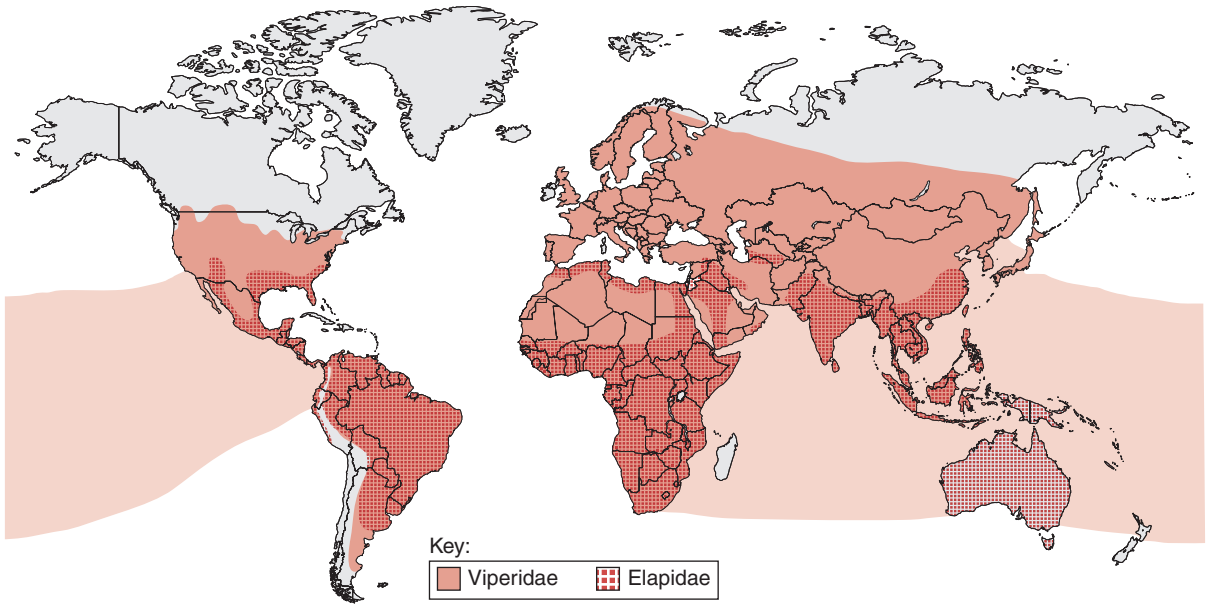

FIGURE 460-1 Geographic distribution of venomous snakes.

TREATMENT

Venomous Snakebite

FIELD MANAGEMENT

The most important aspect of prehospital care of a person bitten by a venomous snake is rapid transport to a medical facility equipped to provide supportive management (airway, breathing, and circulation) and antivenom therapy. Any jewelry or tight-fitting clothing near the bite should be removed to avoid constriction from anticipated soft-tissue swelling. Although wound care should not delay transport, the wound should be cleaned with soap and running water then covered with a sterile dressing. It is reasonable to apply a splint to the bitten extremity to limit movement and assist with positioning. If possible, the extremity should be maintained in a neutral position of comfort at approximately heart level. Attempting to capture and transport the offending snake is not advised; instead, digital photographs taken from a safe distance may assist with snake identification and treatment decisions.

Most of the first-aid measures recommended in the past are of little benefit and may worsen outcomes. Incising and/or applying

A

B

FIGURE 460-2 Northern Pacific rattlesnake (*Crotalus oreganus oreganus*) envenomations. *A.* Moderately severe envenomation. Note edema and early ecchymosis 2 h after a bite to the finger. ***B.*** Severe envenomation. Note extensive ecchymosis 5 days after a bite to the ankle. *(Courtesy of Robert Norris, with permission.)*

suction to the bite site should be avoided, as these measures exacerbate local tissue damage, increase the risk of infection, and have not been shown to be effective. Venom sequestration devices (e.g., lympho-occlusive bandages or tourniquets) are not advised, as they may intensify local tissue damage by restricting the spread of potentially necrotizing venom. Tourniquet use can result in loss of function, ischemia, and limb amputation, even in the absence of envenomation. In developing countries, victims should be encouraged to seek immediate treatment at a medical facility equipped with antivenom instead of consulting traditional healers and thus incurring significant delays in reaching appropriate care.

Elapid envenomations that are primarily neurotoxic and have no significant effects on local tissue may be managed with pressure-immobilization, in which the entire bitten limb is immediately wrapped with a bandage and then immobilized. This technique is meant to restrict lymphatic drainage and has been shown to delay the systemic absorption of venom from predominantly neurotoxic species. For pressure-immobilization to be effective, the wrap pressure should not exceed 40–70 mmHg in upper-extremity application and 55–70 mmHg in lower-extremity application. As an estimate, the bandage should be snug enough to apply pressure but loose enough for a finger to slip underneath. Additionally, the victim must be carried out of the field because walking generates muscle-pumping activity that—regardless of the anatomic site of the bite—will disperse venom into the systemic circulation. Pressure-immobilization should be used only in cases in which the offending snake is reliably identified and known to be primarily neurotoxic, the rescuer is skilled in pressure-wrap application, the necessary supplies are readily available, and the victim can be fully immobilized and carried to medical care—a rare combination of conditions, particularly in the regions of the world where such bites are most common.

HOSPITAL MANAGEMENT

Initial hospital management should focus on the victim's airway, breathing, and circulation. Patients with bites to the face or neck may require early endotracheal intubation to prevent loss of airway patency caused by rapid soft-tissue swelling. Vital signs, cardiac rhythm, oxygen saturation, and urine output should be closely monitored. Two large-bore IV lines should be established in unaffected extremities. Because of the potential for coagulopathy, venipuncture attempts should be minimized and noncompressible sites (e.g., subclavian vein) avoided. Early hypotension may be caused by bradykinin-potentiating factors, which lead to vasodilation and pooling of blood in the pulmonary and splanchnic vascular beds. Additionally, systemic bleeding, hemolysis, and loss of intravascular volume into the soft tissues may play important roles in hypotension. Fluid resuscitation with isotonic saline (20–40 mL/kg IV) should be initiated if there is any evidence of hemodynamic instability. Vasopressors (e.g., norepinephrine, epinephrine) should be considered if venom-induced shock persists after aggressive volume resuscitation and antivenom administration (see below), as the victim may be experiencing anaphylaxis to the venom components or the antivenom itself.

A thorough history (including the time of the bite and any symptoms of envenomation) should be obtained and a complete physical examination performed, with a focus on the neurovascular status of the site of envenomation. For envenomation of a limb, palpation of axillary or inguinal lymph nodes can provide information about lymphatic spread. Bandages or wraps applied in the field should be removed as soon as possible, with cognizance that the release of such ligatures may result in hypotension or dysrhythmias when stagnant acidotic blood containing venom is released into the systemic circulation. To objectively evaluate the progression of local envenomation, the leading edge of swelling, ecchymosis, and tenderness should be marked and limb circumference should be measured at three points (e.g., at the bite site, the joint proximal, and the joint distal) every 15 min until the local-tissue effects have stabilized. Once stabilized, measurements can be taken every 1–2 h. During this period of observation, the bitten extremity should be positioned at approximately heart level. Victims of neurotoxic envenomation should be monitored closely for evidence of cranial nerve dysfunction (e.g., ptosis) that may precede more overt signs of impending airway compromise (e.g., difficulty swallowing, respiratory insufficiency) necessitating endotracheal intubation and mechanical ventilation.

Blood should be drawn for laboratory evaluation as soon as possible. Important studies include a complete blood count to determine the degree of hemorrhage or hemolysis and to detect thrombocytopenia; blood type and cross-matching; assessment of renal and hepatic function; coagulation studies such as prothrombin time and fibrinogen level; measurement of fibrin degradation products such as D-dimer; measurement of creatine kinase for suspected rhabdomyolysis; and testing of urine for blood or myoglobin. In developing regions, the 20-min whole-blood clotting test can be used to diagnose coagulopathy when access to laboratory tests is limited. To perform this test, 1–2 mL of venous blood are placed in a clean, dry glass receptacle (e.g., a test tube) and left undisturbed for 20 min. The sample is then inverted. If the blood is still liquid and a clot has not formed, coagulopathy is present. There have been some recent studies examining the utility of thromboelastography (TEG) in detecting venom-induced consumptive coagulopathy. In vitro studies have shown that TEG may be more sensitive than conventional coagulation studies in detecting coagulopathy at lower venom concentrations; however, it remains to be seen if this bears any clinical significance. At this time, there is insufficient evidence to suggest routine use of TEG. Electrocardiography and chest radiography may be helpful in severe envenomations or when there is significant comorbidity. After antivenom therapy (see below), laboratory values should be rechecked every 6 h until clinical stability is achieved.

The mainstay of treatment of a venomous snakebite resulting in significant envenomation is prompt administration of specific antivenom. Antivenoms are produced by injecting animals (generally horses or sheep) with venoms from medically important snakes. Once the stock animals develop antibodies to the venoms, their serum is harvested and the antibodies are isolated for antivenom preparation. The goal of antivenom administration is to allow antibodies (or antibody fragments) to bind and deactivate circulating venom components before they can attach to target tissues and cause deleterious effects. Antivenoms may be monospecific (directed against a particular snake species) or polyspecific (covering several species in a geographic region). Unless the species are known to have homologous venoms, antivenoms rarely offer cross-protection against snake species other than those used in their production. Thus, antivenom selection must be specific for the offending snake; if the antivenom chosen does not contain antibodies to that snake's venom components, it will provide no benefit and may lead to unnecessary complications (see below). In the United States, assistance in finding appropriate antivenom can be obtained from a regional poison control center, which can be reached by telephone 24 h a day at (800) 222-1222.

For victims of bites by viperids or cytotoxic elapids, indications for antivenom administration include significant progressive local findings (e.g., soft-tissue swelling that crosses a joint, involves more than half the bitten limb, or is rapidly spreading; extensive blistering or bruising; severe pain) and any evidence of systemic envenomation (e.g., systemic symptoms or signs, laboratory abnormalities). Caution must be used when determining the significance of isolated pain or soft-tissue swelling after the bite of an unidentified snake because the saliva of some relatively harmless species can cause mild discomfort or edema at the bite site; in such bites, antivenoms are useless and potentially harmful. Antivenoms have limited efficacy in preventing local-tissue damage caused by necrotizing venoms, as venom components bind to local tissues very quickly. Nevertheless, antivenom should be administered as soon as the need for it is identified to limit further tissue damage and systemic

effects. Antivenom administration after bites by neurotoxic elapids is indicated at the first sign of neurotoxicity (e.g., cranial nerve dysfunction, peripheral neuropathy). In general, antivenom is effective only in reversing active venom toxicity; it is of little benefit in reversing effects that have already been established (e.g., renal failure, established paralysis) and will improve only with time and other supportive therapies.

Specific comments related to the management of venomous snakebites in the United States and Canada appear in **Table 460-1.** The package insert for the selected antivenom should be consulted regarding species covered, method of administration, starting dose, and need (if any) for redosing. Whenever possible, it is advisable for health care providers to seek advice from experts in snakebite management regarding indications for and dosing of antivenom.

Antivenom should be administered only by the IV route, and the infusion should be started slowly, with the treating clinician at the bedside ready to immediately intervene at the first signs of an acute adverse reaction. In the absence of an adverse reaction, the rate of infusion can be increased gradually until the full starting dose has been administered (over a total period of ~1 h). Further antivenom may be necessary if the patient's acute clinical condition worsens or fails to stabilize or if venom effects recur. The decision to administer further antivenom to a stabilized patient should be based on clinical evidence of the persistent circulation of unbound venom components. For viperid bites, antivenom administration should generally be continued until the victim shows definite improvement (e.g., reduced pain, stabilized vital signs, restored coagulation). Neurotoxicity from elapid bites may be more difficult to reverse with antivenom. Once neurotoxicity is established and endotracheal intubation is required, further doses of antivenom are unlikely to be beneficial. In such cases, the victim must be maintained on mechanical ventilation until recovery, which may take days to weeks.

Adverse reactions to antivenom administration include early (anaphylaxis) and late (serum sickness) hypersensitivity reactions. Clinical manifestations of early hypersensitivity may include tachycardia, rigors, vomiting, urticaria, dyspnea, laryngeal edema, bronchospasm, and hypotension. Although recommended by some antivenom manufacturers, skin testing for potential early hypersensitivity is neither sensitive nor specific and is of no benefit. The quality of antivenoms is highly variable worldwide; rates of acute anaphylactic reactions to some of these products exceed 50%. More recent data on North American snakebites suggest that the incidence of anaphylaxis to Crotalidae Polyvalent Immune Fab (CroFab®) (Ovine) (BTG International Inc., West Conshohocken, PA) antivenom may be closer to 1.1%. There is some evidence supporting routine pretreatment with low-dose SC epinephrine (0.25 mg of 1:1000 aqueous solution) to prevent acute anaphylactic reactions after antivenom infusion. Although widely practiced, prophylactic use of antihistamines and glucocorticoids has not proved beneficial. Modest expansion of the patient's intravascular volume with crystalloids may blunt episodes of acute hypotension during antivenom infusion. Epinephrine and airway equipment should always be immediately available. If the patient develops an anaphylactic reaction to antivenom, the infusion should be stopped temporarily and the reaction treated immediately with IM epinephrine (0.01 mg/kg up to 0.5 mg), an IV antihistamine (e.g., diphenhydramine, 1 mg/kg up to 50 mg), and a glucocorticoid (e.g., hydrocortisone, 2 mg/kg up to 100 mg). Once the reaction has been controlled, if the severity of the envenomation warrants additional antivenom, the dose should be restarted as soon as possible at a slower rate (5–10 mL/h) and titrated upward as tolerated. In rare cases of refractory hypotension, a concomitant IV infusion of epinephrine may be initiated and titrated to clinical effect while antivenom is administered. The patient must be monitored very closely during such therapy, preferably in an emergency department or intensive care setting. Serum sickness typically develops 1–2 weeks after antivenom administration and may present as myalgias, arthralgias, fever, chills, urticaria, lymphadenopathy, or renal or neurologic dysfunction. Treatment for serum sickness consists of systemic glucocorticoids (e.g., oral prednisone, 1–2 mg/kg daily) until all symptoms have resolved, with a subsequent taper over 1–2 weeks. Oral antihistamines and analgesics may provide additional relief of symptoms.

Blood products are rarely necessary in the management of an envenomated patient. The venoms of many snake species can deplete coagulation factors and cause a decrease in platelet count or hematocrit. Nevertheless, these components usually rebound within hours after administration of adequate antivenom. If the need for blood products is thought to be great (e.g., a dangerously low platelet count in a hemorrhaging patient), these products should be given only after adequate antivenom administration to avoid fueling ongoing consumptive coagulopathy.

Rhabdomyolysis should be managed in standard fashion with IV fluids and close monitoring of urine output. Victims who develop acute renal failure should be evaluated by a nephrologist and referred for hemodialysis or peritoneal dialysis as needed. Such renal failure is usually due to acute tubular necrosis and is frequently reversible. If bilateral cortical necrosis occurs, however, the prognosis for renal recovery is less favorable, and long-term dialysis with possible renal transplantation may be necessary.

Most snake envenomations involve subcutaneous deposition of venom. On occasion, venom can be injected more deeply into muscle compartments, particularly if the offending snake was large and the bite occurred on the hand, forearm, or anterior compartment of the lower leg. Intramuscular swelling of the affected extremity may be accompanied by severe pain, decreased strength, altered sensation, cyanosis, and apparent pulselessness—signs suggesting a muscle compartment syndrome. If there is clinical concern that subfascial muscle edema may be impeding tissue perfusion, intracompartmental pressures should be measured by a minimally invasive technique (e.g., with a wick catheter or digital readout device). If the intracompartmental pressure is high (>30–40 mmHg), the extremity should be kept elevated while antivenom is administered. If the intracompartmental pressure remains elevated after 1 h of such therapy, a surgical consultation should be obtained for possible fasciotomy. Although evidence from animal studies suggests that fasciotomy may actually worsen myonecrosis, compartmental decompression may still be necessary to preserve neurologic function. Fortunately, the incidence of compartment syndrome is very low after a snakebite, with fasciotomies required in <1% of cases. Nevertheless, vigilance is essential.

Acetylcholinesterase inhibitors (e.g., edrophonium and neostigmine) may promote neurologic improvement in patients bitten by snakes with postsynaptic neurotoxins. Snakebite victims with objective evidence of neurologic dysfunction may receive a test dose of acetylcholinesterase inhibitors, as outlined in **Table 460-2.** If they exhibit improvement, additional doses of long-acting neostigmine can be administered as needed. Acetylcholinesterase inhibitors are not a substitute for endotracheal intubation or the administration of appropriate antivenom when available.

Care of the bite wound includes simple cleansing with soap and water; application of a dry, sterile dressing; and splinting of the affected extremity with padding between the digits. Once antivenom therapy has been initiated, the extremity should be elevated above heart level to reduce swelling. Patients should receive tetanus immunization as appropriate. Prophylactic antibiotics are generally unnecessary after bites by North American snakes because the incidence of secondary infection is low. In some regions, secondary bacterial infection is more common and the consequences are serious; as such, prophylactic treatment with broad-spectrum antibiotics may be appropriate. Antibiotics may also be considered if misguided first-aid efforts included incision or mouth suction of the bite site. Pain control may be achieved with acetaminophen or opioid analgesics. Salicylates and nonsteroidal anti-inflammatory agents should be avoided because of their potential effects on blood clotting.

TABLE 460-1 Management of Venomous Snakebites in the United States and Canada[a]

Pit Viper Bites: Rattlesnakes (*Crotalus* and *Sistrurus* spp.), Cottonmouth Water Moccasins (*Agkistrodon piscivorus*), and Copperheads (*Agkistrodon contortrix*)

- Stabilize airway, breathing, and circulation.
- Institute monitoring (vital signs, cardiac rhythm, and oxygen saturation).
- Establish two large-bore IV lines.
  - If patient is hypotensive, administer normal saline bolus (20–40 mL/kg IV).
- Take thorough history and perform complete physical examination.
- Identify offending snake (if possible).
- Measure and record circumference of bitten extremity every 15 min until swelling has stabilized. Can take measurements every 1 h once stabilized.
- Order laboratory studies (CBC, blood type and cross-matching, metabolic panel, PT/INR/PTT, fibrinogen level, FDP, CK, urinalysis).
  - If normal, repeat CBC and coagulation studies every 4 h until it is clear that no systemic envenomation has occurred.
  - If abnormal, repeat every 6 h after antivenom administration until swelling has stabilized (see below).
- Determine severity of envenomation.
  - None: fang marks only ("dry" bite)
  - Mild: local findings only (e.g., pain, ecchymosis, nonprogressive swelling)
  - Moderate: swelling that is clearly progressing, systemic symptoms or signs, and/or laboratory abnormalities
  - Severe: neurologic dysfunction, respiratory distress, and/or cardiovascular instability/shock
- Contact regional poison control center.
- Locate and administer antivenom as indicated: Crotalidae Polyvalent Immune Fab (CroFab®) (Ovine) (BTG International Inc., West Conshohocken, PA) or Crotalidae Immune F(ab')2 (Anavip®) (Equine) (Instituto Bioclon S.A de C.V., Tlalpan CDMX, Mexico).
  - Starting dose:
    - Based on severity of envenomation
      - None or mild: none
      - Moderate: CroFab® (4–6 vials), Anavip® (10 vials)
      - Severe: CroFab® (6 vials), Anavip® (10 vials)
    - Dilute reconstituted vials in 250 mL of normal saline.
    - Infuse IV over 1 h (with medical provider in close attendance).
      - Start at rate of 25–50 mL/h for first 10 min.
      - If there is no allergic reaction, increase rate to 250 mL/h.
  - If there is an acute reaction to antivenom:
    - Stop infusion.
    - Treat with standard doses of epinephrine (IM or IV; latter route only in setting of severe hypotension), antihistamines (IV), and glucocorticoids (IV).
    - When reaction is controlled, restart antivenom as soon as possible (at rate of 5–10 mL/h; titrate up as tolerated).
  - Monitor clinical status over 1 h.
    - Stabilized or improved: Admit to hospital.
    - Progressing or unimproved: Repeat starting dose. Continue this pattern until patient's condition is stabilized or improved. Admit to ICU if possible.
- Blood products are rarely needed; if required, they should be given only after antivenom administration.
- Provide tetanus immunization as needed.
- Prophylactic antibiotics are unnecessary unless prehospital care included incision or mouth suction.
- Pain management: Administer acetaminophen and/or opioids as needed; avoid salicylates and nonsteroidal anti-inflammatory agents.
- Admit patient to hospital. (If there is no evidence of envenomation, monitor for 8–12 h before discharge.)
  - Give additional antivenom: CroFab® (2 vials every 6 h for 3 additional doses), Anavip® (4 vials for recurrent coagulopathy).
  - Monitor for evidence of rising intracompartmental pressures (see text).
  - Provide wound care (see text).
  - Start physical therapy (see text).
- At discharge, warn patient of possible recurrent coagulopathy and symptoms/signs of serum sickness. Schedule repeat laboratory testing to monitor for recurrent coagulopathy.

Coral Snake Bites: Eastern coral snake (*Micrurus fulvius*), Texas coral snake (*Micrurus tener*), and Sonoran coral snake (*Micruroides euryxanthus*)

- Stabilize airway, breathing, and circulation.
- Institute monitoring (vital signs, cardiac rhythm, and oxygen saturation).
- Establish two large-bore IV lines and initiate normal saline infusion.
- Take thorough history and perform complete physical examination.
- Identify offending snake (if possible).
- Laboratory studies are unlikely to be helpful.
- Contact regional poison control center.
- Locate and administer antivenom as indicated: Antivenin (*Micrurus fulvius*) (Equine) (commonly referred to as North American Coral Snake Antivenin; Pfizer Inc., Philadelphia, PA).[b]
  - Refer to antivenom package insert.
  - Dilute 3–5 reconstituted vials in 250–500 mL of normal saline.
  - Infuse IV over 1 h (with medical provider in close attendance).
  - If signs of envenomation progress despite initial dosing, repeat starting dose; up to 10 vials total may be required.

(*Continued*)

TABLE 460-1 Management of Venomous Snakebites in the United States and Canada[a] (Continued)

- If there is an acute adverse reaction to antivenom:
  - Stop infusion.
  - Treat with standard doses of epinephrine (IM or IV; latter route only in setting of severe hypotension), antihistamines (IV), and glucocorticoids (IV).
  - When reaction is controlled, restart antivenom as soon as possible (at rate of 5–10 mL/h; titrate up as tolerated).
- If there is evidence of neurologic dysfunction (e.g., any cranial nerve abnormalities):
  - Administer trial of acetylcholinesterase inhibitors (see Table 460-2).
  - If there is evidence of difficulty swallowing or breathing, proceed with endotracheal intubation and ventilatory support (may be required for days to weeks).
- Provide tetanus immunization as needed.
- Prophylactic antibiotics are unnecessary unless prehospital care included incision or mouth suction.
- Admit patient to hospital (ICU) even if there is no evidence of envenomation; monitor for at least 24 h.

[a]These recommendations are specific to the care of victims of venomous snakebites in the United States and Canada and should not be applied to bites in other regions of the world. [b]At the time of this writing, Lot L67530 of Antivenin had an extended expiration date of January 31, 2020.

Abbreviations: CBC, complete blood count; CK, creatine kinase; FDP, fibrin degradation products; ICU, intensive care unit; PT/INR/PTT, prothrombin time/international normalized ratio/partial thromboplastin time.

Wound care in the days after the bite should include careful aseptic debridement of clearly necrotic tissue once coagulopathy has been fully reversed. Intact serum-filled vesicles or hemorrhagic blebs should be left undisturbed. If ruptured, they should be debrided with sterile technique. Any debridement of damaged muscle should be conservative because there is evidence that such muscle may recover to a significant degree after antivenom therapy.

Physical therapy should be started as soon as possible to assist the patient in returning to a functional state. The incidence of long-term loss of function (e.g., reduced range of motion, impaired sensory function) is unclear.

Any patient with signs of envenomation should be observed in the hospital for at least 24 h. In North America, a patient with an apparently "dry" viperid bite should be closely monitored for at least 8–12 h before discharge, as significant toxicity occasionally develops after a delay of several hours. The onset of systemic symptoms commonly is delayed for a number of hours after bites by certain elapids (including coral snakes, *Micrurus* species), some non–North American viperids (e.g., the hump-nosed pit viper [*Hypnale hypnale*]), and sea snakes. Patients bitten by these snakes should be observed in the hospital for at least 24 h. Admission to an intensive care setting is advised for patients with progressive clinical findings despite initial antivenom administration; those bitten in the head, neck, or other high-risk sites; and those who develop an acute hypersensitivity reaction to antivenom.

At hospital discharge, victims of venomous snakebites should be warned about symptoms and signs of wound infection, antivenom-related serum sickness, and potential long-term sequelae, such as pituitary insufficiency from Russell's viper (*D. russelii*) bites. If coagulopathy developed in the acute stages of envenomation, it can recur during the first 2–3 weeks after the bite as venom antigens may have longer half-lives than their corresponding antivenoms; in such cases, victims should be warned to avoid elective surgery or activities posing a high risk of trauma during this period. Repeat laboratory tests (e.g., complete blood count, prothrombin time, fibrinogen level) should be scheduled to monitor for recurrent coagulopathy. Outpatient analgesic treatment, wound management, and physical therapy should be provided.

TABLE 460-2 Use of Acetylcholinesterase Inhibitors in Envenomations by Neurotoxic Snakes and Cone Snails

1. Patients with clear, objective evidence of neurotoxicity (e.g., ptosis or inability to maintain upward gaze) should receive a test dose of edrophonium (if available) or neostigmine.
   a. Pretreat with atropine: 0.6 mg IV (children, 0.02 mg/kg with a minimum of 0.1 mg)
   b. Treat with:
      Edrophonium: 10 mg IV (children, 0.25 mg/kg)
      or
      Neostigmine: 0.02 mg/kg IV or IM (children, 0.04 mg/kg)
2. If objective improvement is evident after 30 min, treat with:
   a. Neostigmine: 0.5 mg IV, IM, or SC (children, 0.01 mg/kg) every 1 h as needed
   b. Atropine: 0.6 mg as IV continuous infusion over 8 h (children, 0.02 mg/kg over 8 h)
3. Closely monitor airway and perform endotracheal intubation if needed.

MORBIDITY AND MORTALITY

The overall mortality rates for victims of venomous snakebites are low in regions with rapid access to medical care and appropriate antivenoms. In the United States, for example, the mortality rate is <1% for victims who receive antivenom. Eastern and western diamondback rattlesnakes (*Crotalus adamanteus* and *Crotalus atrox*, respectively) are responsible for the majority of snakebite deaths in the United States. Snakes responsible for a large number of deaths in other countries include cobras (*Naja* species), carpet and saw-scaled vipers (*Echis* species), Russell's vipers (*D. russelii*), large African vipers (*Bitis* species), lancehead pit vipers (*Bothrops* species), and tropical rattlesnakes (*C. durissus*).

The incidence of morbidity—defined as permanent functional loss in a bitten extremity—is difficult to estimate but is substantial. Morbidity may be due to muscle, nerve, or vascular injury or to scar contracture. Such morbidity can have devastating consequences for victims in the developing world when they lose the ability to work and provide for their families. In the United States, functional loss tends to be more common and severe after rattlesnake bites than after bites by copperheads (*Agkistrodon contortrix*) or water moccasins (*Agkistrodon piscivorus*).

GLOBAL CONSIDERATIONS

In May 2019, the World Health Organization announced a comprehensive strategy to control and prevent snake envenomations worldwide, with the goal to reduce the number of deaths and cases of disability from snakebites by 50% by 2030. This strategy has been developed around four central tenets: empowering and engaging communities, ensuring safe and effective treatments, strengthening health systems, and improving partnerships, coordination, and resources. In many developing countries where snakebites are common, limited access to medical care and antivenoms contributes to high rates of morbidity and mortality. Recent data show that 6.85 billion people live within the regions inhabited by snakes, with >10% of people living >1 h from an urban center. Often, the available antivenoms are inappropriate and ineffective against the venoms of medically important indigenous snakes. In those regions, further research is necessary to determine the actual impact of venomous snakebites and the specific antivenoms needed in terms of both quantity and spectrum of coverage. Appropriate antivenoms must be available at the most likely first point of medical contact for patients (e.g., primary health centers) in order to minimize the common practice of referring victims to more distant, higher levels of care for the initiation of antivenom therapy. Just as important as getting the correct antivenoms into underserved regions

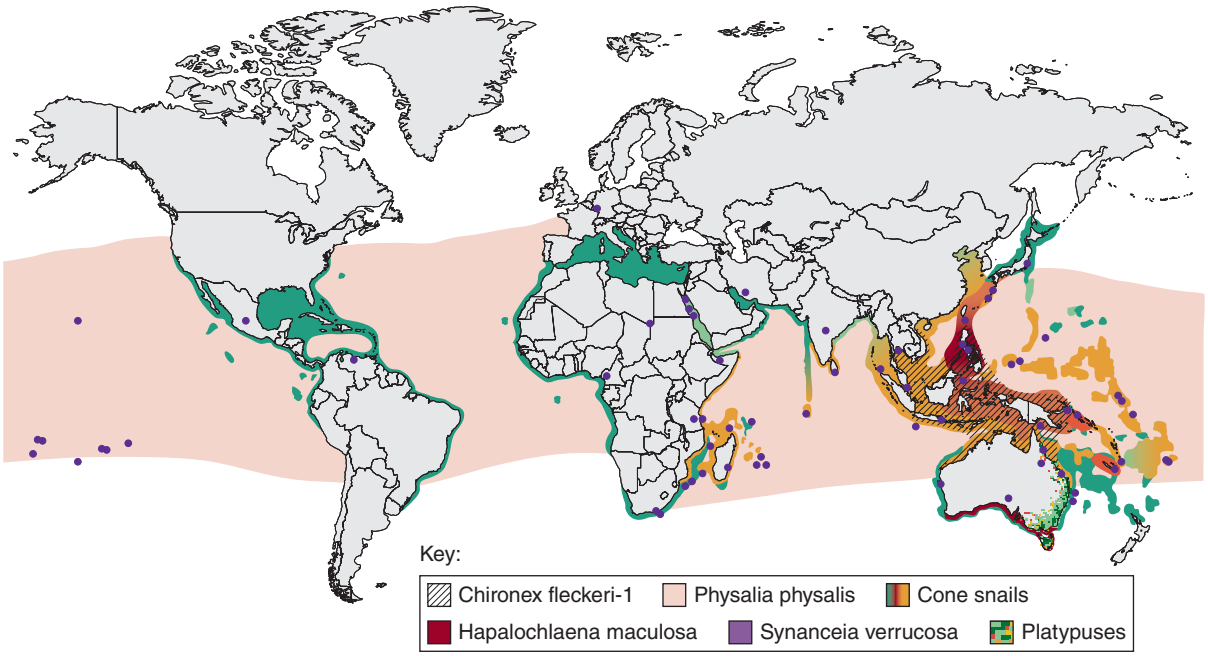

FIGURE 460-4 Geographic distribution of venomous marine animals.

is the need to educate populations about snakebite prevention and train medical care providers in proper management approaches. Local protocols written with significant input from experienced providers in the region of concern should be developed and distributed. Those who care for snakebite victims in these often-remote clinics must have the skills and confidence required to begin antivenom treatment (and to treat possible reactions) as soon as possible when indicated.

MARINE ENVENOMATIONS

The global incidence of marine envenomation is likely underestimated, as the majority of cases are mild. Much of the management of envenomation by marine animals is supportive, but a few specific antivenoms are available. This section provides general guidance, and patient management should be tailored to the practice patterns and known prevalence of specific venomous species in the region (Fig. 460-4).

INVERTEBRATES

Cnidarians Cnidarians, such as hydroids, fire coral, jellyfish, Portuguese men-of-war, and sea anemones, possess thousands of specialized stinging organelles called *cnidocysts* (a term that encompasses nematocysts, ptychocysts, and spirocysts) distributed along their tentacles. Nematocysts contain a coiled hollow thread bathed in venom that is discharged when provoked by mechanical stimuli, osmotic changes, or other chemical stimuli (Fig. 460-5). The venom contains enzymes (phospholipases, metalloproteases), pore-forming toxins, neurotoxins, and nonprotein bioactive substances, such as tetramine, 5-hydroxytryptamine, histamine, and serotonin. Venom flows through the hollow thread into the victim's skin. Cnidocysts that possess barbs on the ends of their threads can penetrate human skin; thus, only a subset of cnidarians are toxic to humans.

Victims usually report immediate burning, pruritus, paresthesias, and painful throbbing with radiation. The skin becomes reddened, darkened, edematous, and blistered and may show signs of superficial necrosis. A minority of victims develop systemic toxicity affecting the cardiovascular, respiratory, gastrointestinal, and nervous systems, especially following stings from anemones, *Physalia* species, and scyphozoans. Anaphylaxis and secondary infection with marine bacteria can also occur.

Hundreds of deaths have been reported, many of them caused by *Chironex fleckeri, Stomolophus nomurai, Physalia physalis*, and *Chiropsalmus quadrumanus*. Irukandji syndrome is a potentially fatal condition associated with envenomation by the Australian jellyfish *Carukia barnesi* and *Malo* species. Symptoms generally manifest within 30 min and include hypertension; tachycardia; severe chest, abdominal, and back pain; nausea and vomiting; and headache. In the most serious cases, victims may develop cerebral hemorrhage, cerebral edema, cardiomyopathy, pulmonary edema, and systemic hypotension. Massive release of endogenous catecholamines induced by venom components appears to be the underlying cause of this syndrome.

Initial management should focus on removing the victim from the water and decontaminating the skin. Drowning is a common cause of death after significant *Cnidarian* envenomation. Once the victim

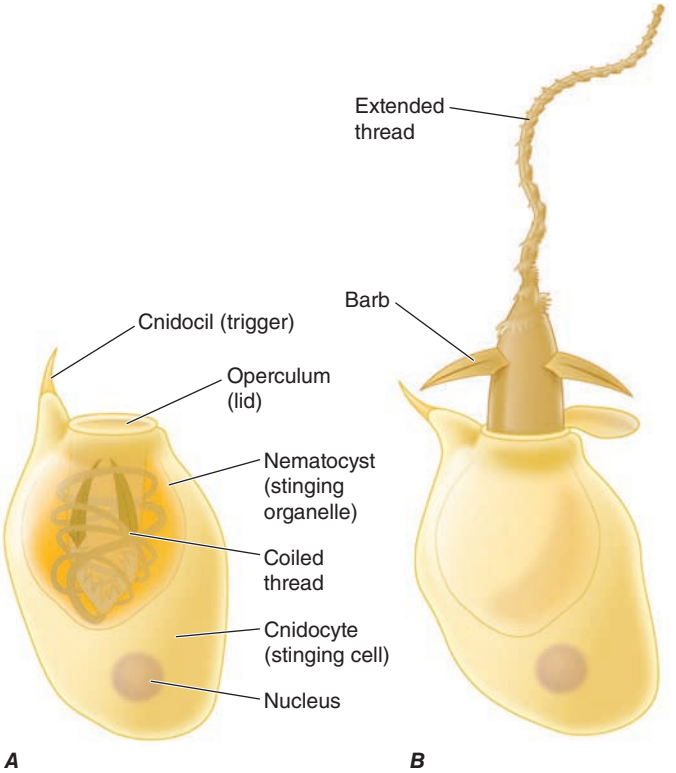

FIGURE 460-5 Schematic of a nematocyst. *A.* Undischarged. Note coiled hollow thread bathed in venom. ***B.*** Discharged.

is on land or a boat, the skin should be decontaminated with saline or seawater. Providers wearing protective equipment should carefully remove any adherent tentacles. Vinegar (5% acetic acid) appears to be useful for relieving pain caused by a large number of species, especially in the Indo-Pacific region where *C. fleckeri* and *C. barnesi* are common. In that region, decontamination with vinegar should be followed by hot water immersion up to 45°C (113°F). Vinegar may increase nematocyst discharge in *P. physalis* and *C. quinquecirrha*, species common in the United States. Victims in the United States should be decontaminated with seawater and then have affected areas immersed in hot water. Alternatively, vinegar may be tested on a small area of affected skin to assess effects before performing complete decontamination. If hot water is unavailable, commercial (chemical) cold packs or ice packs applied over a thin dry cloth or plastic membrane can be effective in alleviating pain, but do not denature venom components. In general, rubbing leads to further stinging by adherent cnidocysts and should be avoided.

After decontamination, topical application of a local anesthetic, antihistamine, or glucocorticoid may be helpful for symptom control. Persistent severe pain may be treated with opioid analgesics. Muscle spasms may respond to IV diazepam (2–5 mg, titrated upward as necessary). An antivenom is available from Seqirus (an affiliate of Commonwealth Serum Laboratories) for stings from the box jellyfish found in Australian and Indo-Pacific waters. Recent studies have raised questions about the efficacy of the antivenom, and there are no reports of survival directly attributable to its administration. Use of the antivenom is still recommended when it is available but should not replace aggressive supportive care (see "Sources of Antivenoms and Other Assistance," below). Adverse reactions to the antivenom include early (anaphylaxis) and late (serum sickness) hypersensitivity reactions. Acute allergic reactions should be treated with systemic antihistamines, glucocorticoids, and epinephrine when appropriate. Delayed serum sickness is relatively common, typically occurs 5–10 days after antivenom administration, and generally responds well to 5 days of oral glucocorticoids.

Treatment of Irukandji syndrome may require administration of opioid analgesics and aggressive treatment of hypertension. Appropriate antihypertensive agents include phentolamine, nicardipine, nitroprusside, nitroglycerin, and IV magnesium sulfate. Beta-adrenergic antagonists should be avoided due to the risk of worsening hypertension from unopposed alpha-adrenergic effects. All victims with systemic reactions should be observed for at least 6–8 h for rebound from any therapy and should be monitored for cardiac arrhythmias.

Safe Sea (Nidaria Technology Ltd.), a "jellyfish-safe" sunblock applied to the skin before an individual enters the water, inactivates the recognition and discharge mechanisms of nematocysts; it may prevent or diminish the effects of coelenterate stings. Whenever possible, a dive skin or wetsuit should be worn when entering ocean waters.

Sea Sponges Many sponges produce irritants known as crinotoxins. Touching a sea sponge may result in allergic contact dermatitis. Irritant dermatitis may result if the sponge's spicules of silica or calcium carbonate penetrate the skin. Affected skin should be dried and adhesive tape, a commercial facial peel, or a thin layer of rubber cement used to remove embedded spicules. Vinegar should then be applied immediately, with repeated application for 10–30 min three or four times a day thereafter. Corticosteroid cream or oral antihistamines may provide additional symptomatic relief. Systemic corticosteroids should be reserved for severe allergic reactions (such as severe vesiculation) or erythema multiforme. Mild reactions generally subside within 7 days. Severe envenomation can lead to fevers, chills, and muscle spasms. Desquamation of affected skin has also been described and can occur up to 2 months after exposure. Outpatient wound care is essential to monitor for secondary infection.

Annelid Worms Annelid worms (bristleworms) are covered with chitinous spines capable of penetrating human skin and producing dermal symptoms similar to those of *Cnidarian* envenomation, including pain, prickling, urticaria, and discoloration. Pain usually subsides within hours, but urticaria can persist for days and discoloration for weeks **(Fig. 460-6)**. Victims should be instructed not to scratch as it may fracture the spines, complicating their removal and increasing the risk of secondary infection. Visible bristles should be removed with forceps, adhesive tape, rubber cement, or a commercial facial peel. Soaking the affected skin in vinegar may provide additional relief. Severe inflammation can be treated with systemic antihistamines or corticosteroids.

FIGURE 460-6 Rash on the hand of a diver from the spines of a bristleworm. *(Courtesy of Paul Auerbach, with permission.)*

Sea Urchins Venomous sea urchins possess either hollow, venom-filled, calcified spines or pincer-like, flexible pedicellariae with venom glands. The venom contains bradykinin-like substances, steroid glycosides, hemolysins, proteases, serotonin, and cholinergic substances. Envenomation causes immediate onset of severe pain, edema, and erythema. If multiple spines penetrate the skin, the patient may develop systemic symptoms, including nausea, vomiting, numbness, muscular paralysis, and respiratory distress. Synovitis and arthritis have been reported after joint-space penetration. Retained spines can cause the formation of painful granulomas.

The affected part should be immersed in hot water up to 45°C (113°F). Embedded spines should be removed with care as they may fracture and leave remnants lodged in the victim. Soft-tissue radiography, ultrasonography, or MRI can be used to evaluate for the presence of retained fragments. Surgical removal may be necessary, especially if the spines are in close proximity to vital structures (e.g., joints, neurovascular bundles). Granulomas from retained spines are amenable to excision or intralesional injection with triamcinolone hexacetonide. Arthritis from joint penetration has been treated with synovectomy.

Starfish The crown-of-thorns starfish (*Acanthaster planci*) produces viscous venom that coats the surface of its spines **(Fig. 460-7)**. The venom contains saponins with hemolytic, myotoxic, hepatotoxic, and anticoagulant properties. Skin puncture causes immediate pain, bleeding, and local edema. Multiple punctures may result in reactions such

FIGURE 460-7 Spines on the crown-of-thorns sea star (*Acanthaster planci*). *(Courtesy of Paul Auerbach, with permission.)*

as local muscle paralysis. The spines fracture easily and retained fragments may cause granulomatous lesions and synovitis. Envenomated persons benefit from acute immersion therapy in hot water, local anesthesia, wound cleansing, imaging, and possible exploration to remove spines and foreign material. The hemolytic and hepatotoxic components are less heat labile than other venom constituents; hot water immersion may not prevent systemic toxicity.

Sea Cucumbers Sea cucumbers excrete holothurin (a cantharidin-like liquid toxin) from their anus. This toxin is then concentrated in the tentacular organs that are projected when the animal is threatened. Underwater, holothurin induces minimal contact dermatitis but can cause significant corneal and conjunctival irritation should ocular contact occur. A severe reaction can lead to blindness. Skin should be decontaminated with vinegar. The eyes should be anesthetized with 1–2 drops of 0.5% proparacaine and irrigated copiously with normal saline, with subsequent slit-lamp examination to identify corneal defects.

Cone Snails Cone snails use a detachable dartlike tooth to inject conotoxins into victims. Numerous conotoxins have been identified including some that interfere with neuronal and cardiac ion channels and others that antagonize neuromuscular acetylcholine receptors. Punctures result in small, painful wounds followed by local ischemia, cyanosis, and numbness. Syncope, dysphagia, dysarthria, ptosis, blurred vision, and pruritus also have been documented. Some envenomations induce paralysis leading to respiratory failure. Cardiac dysrhythmias have also been reported. Pressure-immobilization (see "Octopuses," below), hot-water soaks, and local anesthetics have been successful for localized symptoms. Respiratory failure may necessitate mechanical ventilation. Cardiac dysrhythmias should be treated with electrical cardioversion as ion channel-blocking antidysrhythmic medications may worsen the dysrhythmia. No antivenom is available. Edrophonium has been recommended as therapy for paralysis if an edrophonium test is positive (see Table 460-2).

Octopuses Serious envenomations and deaths have followed bites of Australian blue-ringed octopuses (*Hapalochlaena maculosa* and *Hapalochlaena lunulata*). The classic blue rings appear only when the animal is threatened. These species are not aggressive and human envenomations have typically occurred when handling the octopus. Their salivary glands contain symbiotic bacteria that produce tetrodotoxin, a potent sodium channel blocker that inhibits transmissions in the peripheral nervous system. The bite is minimally painful but oral and facial numbness develop within minutes of a serious envenomation. Mild weakness can rapidly progress to total flaccid paralysis. Mentation is typically unaffected. The venom can also cause peripheral vasodilation leading to profound hypotension. Deaths from these envenomations are due to respiratory failure or vasodilatory shock and hypoperfusion.

Immediately after envenomation, a wide circumferential pressure-immobilization bandage should be applied over a gauze pad placed directly over the sting. The dressing should be applied at venous-lymphatic pressure with the preservation of distal arterial pulses, and the limb should be splinted. The bandage can be released when the victim has been transported to a medical facility. There is no antidote and treatment is supportive. Respiratory failure may necessitate mechanical ventilation. Appropriate analgesia and sedation are critical as mental status is generally unaffected even in cases of complete paralysis. Hypotension should be treated with crystalloid and vasopressors if needed. In animal studies, phenylephrine and norepinephrine were more effective than dopamine or epinephrine for treatment of vasodilatory shock. Recovery usually occurs within 24–48 h and long-term sequelae are uncommon unless related to hypoxia or hypoperfusion. Tetrodotoxin is also found in the flesh of fish in the order Tetraodontiformes, which contains a number of "pufferfish" including blowfish, globefish, and balloonfish. The toxin can be absorbed orally when these fish are consumed. Fugu, a traditional Japanese delicacy, is a reported source of poisoning. When properly prepared by a licensed chef, fugu is meant to contain a sufficient dose of tetrodotoxin to cause mild perioral paresthesia without systemic toxicity. When larger doses of the toxin are consumed due to improper preparation, symptoms are similar to envenomation by the blue-ringed octopus.

VERTEBRATES

As for all penetrating injuries, first-aid care should be provided and tetanus immunization administered when indicated. Victims should be monitored for secondary infection by aquatic bacteria such as *Vibrio* species and *Aeromonas hydrophila*. Risk of infection is much higher if spines and needles remain embedded.

Stingrays A stingray injury is both an envenomation and a traumatic wound. Stingrays possess serrated spines with venom glands that can easily penetrate human skin. The venom contains serotonin, 5′-nucleotidase, and phosphodiesterase. Victims experience severe pain, bleeding, and edema at the site of injury that peak within 30–60 min and may persist for up to 2 days. Penetrating injuries to the thorax and heart as well as lacerations to major vessels (especially of the lower extremity) have been reported. The wound often becomes ischemic in appearance and heals poorly, with adjacent soft-tissue swelling and prolonged disability. Systemic effects of the venom include weakness, diaphoresis, nausea, vomiting, diarrhea, hypotension, dysrhythmias, syncope, seizures, muscle cramps, fasciculations, and paralysis. While the venom effects can be fatal in rare cases, most deaths are attributable to the traumatic injury.

Stonefish Stonefish (*Synanceia* species) are members of the Scorpaenidae family and generally considered the most venomous bony fish in the world. Their venom contains pore-forming toxins, proteases, hyaluronidase, 5'-nucleotidase, acetylcholinesterase, and cardiac calcium channel-blockers. The venom is delivered through 12 or 13 dorsal, 2 pelvic, and 3 anal spines when provoked by mechanical stimuli. Victims experience immediate, intense pain that peaks within 90 min, local edema, and wound cyanosis. Local symptoms most often resolve within 12 h but can persist for days. Signs of systemic toxicity include abdominal pain, vomiting, delirium, seizures, paralysis, respiratory distress, dysrhythmias, and congestive heart failure. An antivenom from Seqirus (see "Sources of Antivenoms and Other Assistance," below) can be used in cases of severe envenomation but should not replace supportive care.

Lionfish Also members of the family Scorpaenidae, lionfish (*Pterois* species) are much less toxic to humans than stonefish. The venom is delivered by curved dorsal spines and contains heat-labile, high-molecular-weight proteins. Reported symptoms include localized pain, blistering, edema, sensory changes (paresthesia, anesthesia, or hyperesthesia), and necrosis (rare).

Platypuses The platypus is a venomous mammal. The male has a keratinous spur on each hind limb that is connected to a venom gland within the upper thigh. Skin puncture causes soft-tissue edema and pain that may last for days to weeks. Care is supportive and should focus on appropriate analgesia and wound care. Hot water immersion does not appear to be beneficial.

TREATMENT

Marine Vertebrate Stings

The stings of all marine vertebrates are treated in a similar fashion. Antivenom is currently available only for stonefish and severe scorpionfish envenomations. The affected part should be immersed immediately in hot water up to 45°C (113°F) for 30–90 min or until there is significant pain relief. Recurrent pain may respond to repeated hot water treatment. Systemic opioids as well as wound infiltration or regional nerve block with local anesthetics can help alleviate pain and facilitate wound exploration and debridement. Advanced imaging (in particular, ultrasound or MRI) may be helpful in identification of retained foreign bodies. After exploration and debridement, the wound should be irrigated vigorously with

warm, sterile saline. Bleeding is generally controlled with local pressure. Most wounds should be left open to heal by secondary intention or treated by delayed primary closure. Early primary repair is occasionally preferred for cosmetic reasons but increases the risk of wound infection. Tetanus immunization should be provided as appropriate. Antibiotic treatment should be considered for serious wounds and for envenomations in immunocompromised hosts. The initial antibiotics should cover *Staphylococcus* and *Streptococcus* species. If the victim is immunocompromised, if a wound is primarily repaired, or if an infection develops, antibiotic coverage should be broadened to include *Vibrio* species for wounds sustained in salt water or *Aeromonas* species for wounds sustained in freshwater.

APPROACH TO THE PATIENT

Marine Envenomations

It is useful to be familiar with the local marine fauna and to recognize patterns of injury.

Coelenterate (marine invertebrate) stings sometimes create diagnostic skin patterns. A diffuse urticarial rash on exposed skin is often indicative of exposure to fragmented hydroids or larval anemones. A linear, whiplike print pattern appears where a jellyfish tentacle has contacted the skin. In the case of the box jellyfish, a crosshatched appearance, followed by development of dark purple coloration within a few hours of the sting, heralds skin necrosis. An encounter with fire coral causes immediate pain, erythema, and swelling in the pattern of contact, similar to but more severe than the imprint left by exposure to an intact feather hydroid. Seabather's eruption, caused by thimble jellyfish and larval anemones, is a diffuse, intensely pruritic rash consisting of clusters of erythematous macules or papules that follow the pattern of bathing attire (Fig. 460-8). Toxic sponges create a burning and painful red rash on exposed skin, which may blister and later desquamate. Virtually all marine stingers cause cutaneous inflammation; thus, local erythema, swelling, and adenopathy are fairly nonspecific.

A large puncture wound or jagged laceration (particularly on the lower extremity) that is more painful than one would expect from the size and configuration of the wound is likely to be a stingray envenomation. Smaller puncture wounds, sometimes associated with purple or dark discoloration, represent the activity of a sea urchin or starfish. Stony corals cause rough abrasions and, in rare instances, lacerations or puncture wounds.

FIGURE 460-8 Erythematous, papular rash typical of seabather's eruption caused by thimble jellyfish and larval anemones. *(Courtesy of Paul Auerbach, with permission.)*

SOURCES OF ANTIVENOMS AND OTHER ASSISTANCE

In the United States, assistance in locating a specific antivenom can be obtained from a regional poison control center (800-222-1222). Divers Alert Network, a nonprofit organization designed to assist in the care of injured divers, also may help with the treatment of marine injuries. The network can be reached at *www.diversalertnetwork.org* or by telephone 24 h a day at 919-684-9111. The antivenoms for box jellyfish (*C. fleckeri*) and stonefish or severe scorpionfish envenomations are made in Australia by Seqirus (63 Poplar Road, Parkville, Victoria, Australia 3052; *www.seqirus.com.au*; 61-3-9389-2000). When administering the box jellyfish antivenom, time is of the essence. For cardiac or respiratory decompensation, a minimum of 1 ampule and up to 6 ampules consecutively should be given IV, preferably in a 1:10 dilution with normal saline. For stonefish or severe scorpionfish envenomation, 1 ampule of specific antivenom should be administered IM for every one or two punctures, to a maximum of 3 ampules.

MARINE POISONINGS

HISTAMINE (SCOMBROID) FISH POISONING

Histamine fish poisoning, most often referred to as scombroid or pseudoallergenic fish poisoning, may be the most common type of seafood poisoning worldwide. It was originally described after consumption of scombroid (mackerel-like) fish (including albacore, bluefin, and yellowfin tuna; mackerel; saury; needlefish; wahoo; skipjack; and bonito), but is now more commonly reported with consumption of nonscombroid fish (including dolphinfish, kahawai, sardine, black marlin, pilchard, anchovy, herring, amberjack, Australian ocean salmon, and bluefish).

Under conditions of inadequate preservation or refrigeration, the amino acid L-histidine in the musculature of these fish undergoes decarboxylation to histamine, histamine phosphate, and histamine hydrochloride by *Morganella morganii*, *Escherichia coli*, *Proteus* species, and *Klebsiella* species. Histamine levels of 20–50 mg/100 g are noted in toxic fish, with levels >400 mg/100 g on occasion. Toxic levels can be reached with as few as 12 h of inadequate refrigeration. The pathophysiology of this intoxication remains unclear, as large doses of oral histamine do not reproduce the condition. It has been proposed that other biogenic amines such as cadaverine and putrescine may inhibit the metabolism of histamine. Another potential mechanism is the induction of mast cell degranulation by an unidentified toxin. However, affected individuals may have normal levels of mast cell–derived prostaglandins, which argues against this mechanism.

The toxin or toxins involved are heat stable and are not destroyed by cooking or freezing. Affected fish may have a sharply metallic or peppery taste, although more often they are normal in appearance, color, and flavor. Not all persons who eat a contaminated fish necessarily become ill, perhaps because of uneven distribution of decay within the fish.

Symptoms develop within 15–90 min of ingestion. Most cases are mild, with tingling of the lips and mouth, mild abdominal discomfort, and nausea. The more severe and commonly described presentation includes intense, sharply demarcated flushing of the face, neck, and upper trunk, pruritus, urticaria, and angioedema. This syndrome may progress to bronchospasm, nausea, vomiting, diarrhea, epigastric pain, abdominal cramps, dysphagia, headache, palpitations, tachycardia, dizziness, hypotension, and cardiogenic shock. Without treatment, the symptoms generally resolve within 8–12 h. Because of blockade of gastrointestinal tract histaminase, the reaction may be more severe in a person who is concurrently ingesting isoniazid.

TREATMENT

Scombroid Poisoning

Therapy is directed at reversing the histamine effect with systemic antihistamines. In case literature, H2 receptor antagonists (e.g., cimetidine, ranitidine) appear to further decrease the severity and duration of illness when added to H1 receptor antagonists

(e.g., diphenhydramine, hydroxyzine). If bronchospasm is severe, an inhaled bronchodilator (e.g., albuterol) can be used. In rare cases, parenteral epinephrine may be needed. The use of activated charcoal is not recommended. Protracted nausea and vomiting may be controlled with antiemetics (e.g., ondansetron, prochlorperazine). Hypotension should be treated with IV fluids. It is important to inform the patient that the symptoms are related to eating improperly refrigerated fish and are not due to a fish allergy.

CIGUATERA

Epidemiology and Pathogenesis Ciguatera poisoning is the most common nonbacterial food poisoning associated with fish in the United States and accounts for approximately half of all cases. Florida and Hawaii account for 90% of reported U.S. cases, although, with transportation of imported fish worldwide, all clinicians need to be aware of ciguatera. The poisoning almost exclusively involves carnivorous, bottom-dwelling reef fish native to the Indian Ocean, the South Pacific, and the Caribbean Sea. More than 500 different fish species have been implicated in ciguatera poisoning, but the most common are barracuda, snapper, moray eel, grouper, sea bass, and Spanish mackerel. Global estimates of incidence vary widely from 20,000–500,000 cases per year; it is suspected that a large majority of cases go unreported. Ciguatoxins are produced primarily by the bottom-dwelling, photosynthetic marine dinoflagellate *Gambierdiscus toxicus*. These lipophilic toxins bioaccumulate in the marine food chain when large carnivorous fish consume the grazing fish that feed on these dinoflagellates. Ciguatoxins are heat stable and unaffected by freezing, drying, cooking, or gastric acid. The toxins do not affect the odor, taste, or appearance of the fish, making identification and prevention difficult. Ciguatoxins are potent activators of neuronal sodium channels but may also have other effects such as antagonism of voltage-gated potassium channels. Toxins are found in the highest concentrations in the fish's skin, head, and viscera; therefore, consumption of these portions should be avoided.

Clinical Manifestations Symptoms can develop within 15–30 min of ingestion but more commonly in 2–6 h. Most victims develop symptoms within 12 h of ingestion, and virtually all are afflicted within 24 h. Numerous ciguatoxins have been identified, and their relative abundance in different species of fish and geographic regions likely explains the wide array of reported symptoms (Table 460-3). Early symptoms include nausea, vomiting, diarrhea, abdominal cramps, headache, and diaphoresis. Neurologic manifestations include vertigo, dysesthesia, paresthesia, visual disturbance, dysgeusia, and reversal of hot and cold temperature discrimination. Some victims describe a sensation of loose teeth. Bradycardia, hypotension, and orthostasis have also been reported. Gastrointestinal symptoms generally resolve after 24–48 h but neurologic manifestations may persist for days to weeks.

TABLE 460-3 Representative Symptoms and Signs of Ciguatera Poisoning

SYSTEM	SYMPTOMS/SIGNS
Gastrointestinal	Abdominal pain, nausea, vomiting, diarrhea
Neurologic	Paresthesias, pruritus, tongue and throat numbness or burning, sensation of "carbonation" during swallowing, odontalgia or dental dysesthesias, dysphagia, tremor, fasciculations, athetosis, meningismus, aphonia, ataxia, vertigo, pain and weakness in the lower extremities, visual blurring, transient blindness, hyporeflexia, seizures, coma
Dermatologic	Conjunctivitis, maculopapular rash, skin vesiculations, dermographism
Cardiovascular	Bradycardia, heart block, hypotension, central respiratory failure[a]
Other	Chills, dysuria, dyspnea, dyspareunia, fatigue, nasal congestion and dryness, insomnia, hypersalivation, diaphoresis, headache, arthralgias, myalgias

[a]Tachycardia and hypertension may occur after potentially severe transient bradycardia and hypotension. Death is rare.

More severe reactions tend to occur on repeat exposure. Persons who have ingested parrotfish (scaritoxin) may develop classic ciguatera poisoning as well as a "second-phase" syndrome (after a delay of 5–10 days) of disequilibrium with ataxia, dysmetria, and resting or kinetic tremor. This syndrome may persist for 2–6 weeks.

Diagnosis Ciguatera poisoning is a clinical diagnosis. The toxin can be detected by liquid chromatography and tandem mass spectrometry, and fish suspected of contamination can be tested using a ciguatoxin-specific enzyme immunoassay, but these techniques are generally not available in most health care institutions. The differential diagnosis of ciguatera includes paralytic shellfish poisoning, eosinophilic meningitis, type E botulism, organophosphate insecticide poisoning, tetrodotoxin poisoning, and psychogenic hyperventilation.

TREATMENT

Ciguatera Poisoning

Therapy is supportive and based on symptoms. Volume losses from vomiting and diarrhea should be treated with crystalloids and electrolyte repletion. Hypotension may rarely be unresponsive to fluids and require vasopressors. Symptomatic bradyarrhythmias generally respond well to atropine (0.5 mg IV, up to 2 mg). Problematic orthostasis can be treated with direct alpha-adrenergic agonists (e.g., phenylephrine). IV infusion of mannitol may be beneficial in moderate or severe cases in fluid-replete patients; however, the efficacy of this therapy has not been definitively proven. An initial IV dose of mannitol at 1 g/kg may be given over 45–60 min. If symptoms are alleviated, a second dose may be given within 3–4 h and a third dose the next day. Care must be taken to avoid dehydration. The mechanism of the drug's benefit against ciguatera poisoning is unclear but may be due to decreased sodium conductance across neuronal cell membranes. Hyperosmotic water-drawing action is another proposed mechanism but no changes in neuronal cell edema have been observed in vitro. Amitriptyline (25 mg orally twice a day) reportedly alleviates pruritus and dysesthesias and may decrease rates of subsequent development of chronic nerve symptoms. Gabapentin and pregabalin have shown some efficacy in the treatment of long-term nerve pain in case reports, but evidence from controlled trials is lacking.

During recovery from ciguatera poisoning, the victim should exclude the following from the diet for 6 months: fish (fresh or preserved), fish sauces, shellfish, shellfish sauces, alcoholic beverages, nuts, and nut oils. Consumption of fish in ciguatera-endemic regions should be avoided.

PARALYTIC SHELLFISH POISONING

Paralytic shellfish poisoning is induced by ingestion of filter-feeding organisms, including clams, oysters, scallops, mussels, chitons, limpets, starfish, and sand crabs. The most common agent is saxitoxin, produced by dinoflagellates in the genera *Alexandrium*, *Gonyaulax*, and *Pyrodinium*. These unicellular phytoplankton form the foundation of the food chain for many filter-feeding organisms and the toxin accumulates in their tissues. In the United States, paralytic shellfish poisoning is acquired primarily from seafood harvested in the Northeast, the Pacific Northwest, and Alaska. During algal blooms ("red tides") in the summer months, these planktonic species can release massive amounts of toxic metabolites into the water and cause mortality in bird and marine populations. The paralytic shellfish toxins are water soluble as well as heat and acid stable; ordinary cooking or freezing does not destroy them. Contaminated seafood looks, smells, and tastes normal. Saxitoxin appears to block sodium conductance, inhibiting neuromuscular transmission at the axonal and muscle membrane levels. A toxin concentration of >75 μg/100 g of foodstuff is considered hazardous to humans. During an algal bloom, the concentration of saxitoxin in shellfish can exceed 9000 μg/100 g. A mouse bioassay that identifies saxitoxin in suspected shellfish is currently in use. Saxitoxin can be detected in body fluids by high-performance liquid chromatography, but this method is generally not available in the clinical setting.

Intraoral and perioral paresthesia can occur within minutes to a few hours after ingestion of contaminated shellfish and can progress rapidly to involve the neck and distal extremities. Other neurologic symptoms can include headache, vertigo, ataxia, diffuse muscle weakness, hyperreflexia, and cranial neuropathies such as dysarthria, dysphagia, dysphonia, and transient vision loss. Gastrointestinal symptoms can include nausea, vomiting, diarrhea, and abdominal pain. Flaccid paralysis and respiratory insufficiency may follow 2–12 h after ingestion. In the absence of hypoxia, the victim often remains alert but paralyzed. Up to 12% of patients may die.

TREATMENT

Paralytic Shellfish Poisoning

Treatment is supportive and based on symptoms. If the victim seeks medical attention within the first few hours after ingestion, activated charcoal (50–100 g) can be administered in the absence of vomiting. Gastric lavage and cathartics have been attempted but there is no evidence of benefit and most authors recommend against their use.

The most serious concern is respiratory paralysis. The victim should be closely observed for respiratory distress for at least 24 h in a hospital. With prompt recognition of respiratory failure and establishment of ventilatory support, anoxic myocardial and brain injury may be prevented. If the patient survives for 18 h, the prognosis is good for a complete recovery.

AMNESIC SHELLFISH POISONING

Amnesic shellfish poisoning occurs when humans consume shellfish containing domoic acid. Marine diatoms of the genera *Nitzschia* and *Pseudonitzchia* produce the toxin, which can bioaccumulate in filter feeders during algal blooms. Clams, mussels, oysters, anchovies, and Dungeness crabs have all been found to cause amnesic shellfish poisoning. Domoic acid is an excitotoxic amino acid capable of binding to kainate and AMPA-type glutamate receptors in the central nervous system. Uncontrolled calcium influx into neurons stimulated by domoic acid binding causes neurodegeneration and apoptosis. The toxin is heat stable and is not affected by cooking or freezing. Shellfish can be tested for domoic acid by mouse bioassay and high-performance liquid chromatography (HPLC). The regulatory limit for domoic acid in shellfish is 20 parts per million. An enzyme-linked immunoassay has been developed to detect domoic acid in human body fluids but is generally not available in clinical laboratories.

Most victims will report symptoms within 5 h of ingesting contaminated shellfish but delayed onset of up to 40 h has been reported. Symptoms include nausea, vomiting, diarrhea, abdominal cramps, and a variety of neurologic manifestations, such as severe headache, memory loss, seizures, hemiparesis, ophthalmoplegia, grimacing, purposeless chewing, agitation, emotional lability, and coma. Cardiac dysrhythmias, hypotension, and pulmonary edema have also been reported. Postmortem examination of brain tissue has shown neuronal necrosis or cell loss and astrocytosis, most prominently in the hippocampus and amygdala. Several months after the primary intoxication, victims may still display chronic residual memory deficits and motor or sensory neuropathy.

TREATMENT

Amnesic Shellfish Poisoning

Therapy is supportive and based on symptoms. IV fluids and antiemetics may be used for severe nausea, vomiting, and diarrhea. Domoic acid neurotoxicity is primarily seizure mediated; anticonvulsive therapy using GABA agonists (e.g., benzodiazepines, propofol, or barbiturates) should be instituted early. However, some patients without clinically evident seizure activity have developed neurologic sequelae.

DIARRHETIC SHELLFISH POISONING

Diarrhetic shellfish poisoning occurs with consumption of shellfish containing the lipophilic compound okadaic acid. This toxin inhibits serine and threonine protein phosphatases, with consequent protein accumulation and continued secretion of fluid by intestinal cells leading to diarrhea. Shellfish acquire these toxins by feeding on dinoflagellates, particularly of the genera *Dinophysis* and *Prorocentrum*.

Symptoms include diarrhea, nausea, vomiting, abdominal pain, and chills. Onset typically occurs between 30 min and 12 h after ingestion of contaminated shellfish. The illness is usually self-limited; most patients recover in 3–4 days and only a few require hospitalization. Treatment is supportive and focused on hydration. Toxins can be detected in food samples by a mouse bioassay, an immunoassay, and fluorometric HPLC.

Acknowledgment

Kirsten B. Hornbeak and Robert L. Norris contributed to this chapter in the prior edition and material from that chapter has been retained here. We would like to dedicate this chapter to the late Dr. Paul S. Auerbach, who was a contributing author for the previous seven editions of Harrison's Principles of Internal Medicine. Dr. Auerbach had a tremendous impact on the field of emergency medicine and founded the subspecialty of wilderness medicine. Dr. Auerbach was a wonderful teacher, mentor, and friend, and will be deeply missed.

461 Ectoparasite Infestations and Arthropod Injuries

Richard J. Pollack, Scott A. Norton

Ectoparasites include arthropods and creatures from other phyla that infest the skin or hair of animals; the host animals provide them with sustenance and shelter. The ectoparasites may remain superficially on the skin or hair, attached by mouthparts and specialized claws. Other ectoparasites may penetrate the skin and reside in the epidermis, dermis, or subcutis. Ectoparasites may inflict direct mechanical injury, consume blood or nutrients, induce hypersensitivity reactions, inoculate toxins, transmit pathogens, create openings in the skin for secondary bacterial infection, and incite fear or disgust. Human beings are the sole or obligate hosts for only a few kinds of ectoparasites but serve as facultative, dead-end, or paratenic (accidental) hosts for many others. Of the organisms discussed in this chapter, only scabies mites (the *hominis* variety) and human-infesting lice are obligate parasites of humans.

Arthropods that are capable of ectoparasitism or that can otherwise cause injury include insects (such as lice, fleas, bed bugs, wasps, ants, bees, and diverse kinds of flies), arachnids (spiders, scorpions, mites, and ticks), and myriapods (millipedes and centipedes). Several arthropods can cause uncomfortable reactions when they or their setae and exudates contact skin, mucous membranes, and ocular tissues.

Certain nematodes (helminths), such as the hookworms **(Chap. 231)**, are ectoparasitic in that they penetrate and migrate through the skin. Infrequently encountered ectoparasites in other phyla include the pentastomes (armillifers or tongue worms) and leeches.

Arthropods may cause injury when they attempt to take a blood meal or as they defend themselves by biting, stinging, or exuding venoms. Papular urticaria and other lesions caused by arthropod bites and stings are so diverse and variable (depending upon the host's health status and prior exposure to the arthropod's saliva, venom, or other exudates) that it is difficult to identify the precise causative organism without a bona fide specimen and taxonomic expertise. Specimens of the presumably offending arthropod should, whenever possible, be sampled (ideally by medical personnel) directly (when taken from the patient) or indirectly by the use of traps or other monitoring devices in the patient's home or workplace. Samples sent to laboratorians for evaluation should be properly fixed, preserved, and packaged. Information on the patient's travel history, occupation and avocation, and exposure to animals—pets and pests—often helps the clinician and parasitologist resolve the cause.

SCABIES

The human itch mite, *Sarcoptes scabiei* var. *hominis*, is an obligate human ectoparasite and a common cause of itchy dermatosis, affecting ~250 million persons worldwide. Gravid female mites (~0.3 mm in length) burrow superficially within the stratum corneum, depositing several eggs per day. Six-legged larvae mature to eight-legged nymphs and then to adults. Gravid adult females emerge to the surface of the skin about 8 days later and then (re)invade the skin of the same or another host. Newly fertilized female mites are transferred from person to person mainly by direct skin-to-skin contact; transfer is facilitated by crowding, poor hygiene, and close physical contact with other persons. Generally, scabies mites die within a day or so in the absence of a suitable host. Transmission via sharing of contaminated bedding or clothing occurs less frequently than is often thought. In the United States, scabies may account for up to 5% of visits to dermatologists. Outbreaks are known to occur in preschools, hospitals, nursing homes, prisons, and other institutional residences.

The itching and rash associated with scabies derive from a sensitization reaction to mites and their secretions/excretions. A person's initial infestation typically remains asymptomatic for up to 6 weeks before the onset of intense pruritus, but a reinfestation produces a hypersensitivity reaction without delay. Burrows become surrounded by inflammatory infiltrates composed of eosinophils, lymphocytes, and histiocytes. Infested individuals often feel generalized pruritus, not just in the most heavily involved areas. Hyperinfestation with thousands of mites, a condition known as *crusted scabies* (formerly termed *Norwegian scabies*), may result from glucocorticoid use, immunodeficiency (including that due to HIV/AIDS), and neurologic or psychiatric illnesses that limit the itch and/or the scratch response.

Pruritus typically intensifies at night and after hot showers. Classic burrows are often difficult to find because they are few in number and may be obscured by excoriations. Burrows appear as dark wavy lines in the upper epidermis and are 3–15 mm long. Scabietic lesions are most common on the volar wrists and along the digital web spaces. In males, the penis and scrotum almost invariably become involved. Small papules and vesicles, often accompanied by eczematous plaques, pustules, or nodules, appear symmetrically at those sites and within intertriginous areas, around the navel and belt line, in the axillae, and on the buttocks and upper thighs. Except in infants, the face, scalp, neck, palms, and soles are usually spared. Crusted scabies often resembles psoriasis: both are characterized by widespread thick keratotic crusts, scaly plaques, and dystrophic nails. Characteristic burrows are not seen in crusted scabies, and patients usually do not itch, although their infestations are highly contagious and have been responsible for outbreaks of common scabies in hospitals.

Scabies should be considered in patients with pruritus and symmetric superficial, excoriated, papulovesicular skin lesions in characteristic locations, particularly if there is a history of direct and prolonged contact with an infested person. Burrows should be sought and unroofed with a sterile needle or scalpel blade, and the scrapings should be examined microscopically for mites, eggs, and fecal pellets. Examination of biopsied skin samples (including those obtained by superficial cyanoacrylate biopsy) or scrapings, dermatoscopic imaging of papulovesicular lesions, and microscopic inspection of clear cellophane tape lifted from lesions also may be diagnostic. In the absence of identifiable mites or eggs, a clinical diagnosis is based on a history of pruritus, a physical examination, and an epidemiologic link. Unrelated skin diseases are frequently misdiagnosed as scabies, particularly in presumed "outbreak" situations. *Sarcoptes* mites of other mammals may cause transient irritation, but they do not reside or reproduce in human hosts. In some aboriginal communities, household dogs may serve as reservoirs for human scabies mites.

TREATMENT

Scabies

The four scabicides approved by the U.S. Food and Drug Administration (FDA)—permethrin, crotamiton, spinosad, and lindane—are topical and available solely by prescription. Permethrin cream (5%) is less toxic than 1% lindane preparations and is effective against lindane-resistant infestations. Scabicides are applied thinly but thoroughly from the jawline down after bathing, with careful application to interdigital spaces, the navel, and under the nails, and are removed 6–14 h later with soap and water. Treatment of crusted scabies is difficult and may require preapplication of a keratolytic agent such as 6% salicylic acid and then of scabicides to the skin's entire surface, including the scalp, face, and ears. Repeated treatments or the sequential use of several agents may be necessary. Ivermectin, which is approved by the FDA for the treatment of two nematodal diseases, has not been approved for the treatment of scabies; however, a single oral dose (200 μg/kg) is effective in otherwise healthy persons. Patients with crusted scabies require three to seven doses of ivermectin over 8–30 days, along with topical permethrin and possibly a keratolytic compound.

Within 1 day of effective treatment, scabies infestations become noncommunicable, but the pruritic hypersensitivity dermatitis induced by dead mites and their detritus frequently persists for weeks. Unnecessary retreatment with topical agents may provoke contact dermatitis, especially from repeated applications of permethrin cream. Topical emollients, menthol and methyl salicylate products, calamine lotion, and oral antihistamines relieve itching

during treatment. Topical glucocorticoids may calm pruritus that lingers after effective treatment. To prevent reinfestations, bedding and clothing should be washed and dried on high heat or heat-pressed, and other environmental surfaces or fomites should be cleaned. Close contacts of confirmed cases, even if asymptomatic, should be treated simultaneously.

Scabies infestations often lead to secondary bacterial infections, usually with *Staphylococcus aureus* or *Streptococcus pyogenes* (or both). Consequences of these superinfections include impetigo, cellulitis, invasive bacterial infections, poststreptococcal glomerulonephritis, and possibly acute rheumatic fever.

CHIGGERS AND OTHER BITING MITES

Chiggers are the larvae of trombiculid (harvest) mites that normally feed on mice and other small vertebrates in grassy or brush-covered sites in tropical, subtropical, and (less frequently) temperate areas during warm months. They reside on low vegetation and attach themselves to passing vertebrate hosts. While feeding, larvae secrete saliva with proteolytic enzymes to create a tube-like invagination in the host's skin; this *stylostome* allows the mite to imbibe tissue fluids. The saliva is highly antigenic and causes small (usually <1 cm in diameter) but exceptionally pruritic papular, urticarial, or pustulovesicular lesions. In persons previously sensitized to salivary antigens, the papules develop within hours of attachment. While attached, mites appear as minute (~0.5-mm diameter) red dots on the skin. Generally, lesions have a hemorrhagic base and are slightly elevated, resembling vasculitic papules. Scratching invariably destroys the body of a mite, but itching and burning often persist for weeks. The rash is common on the ankles and in areas where circumferentially tight clothing obstructs the further wanderings of the mites. Repellents are useful for preventing chigger bites. Chiggers (*Leptotrombidium* species) serve as vectors for *Orientia tsutsugamushi*, the agent of scrub typhus in the eastern half of Asia and the Indomalayan and Australasian regions. Endemic foci of scrub typhus were recently identified in southern Chile and in East Africa, far outside the traditional endemic region.

Many kinds of mites associated with peridomestic birds and rodents are particularly bothersome when they invade homes and bite people. In North America, the northern fowl mite, chicken mite, tropical rat mite, and house mouse mite normally feed on poultry, other birds, and small mammals. After their natural hosts leave the nest or die, the mites disperse and may invade homes. Although the mites are rarely seen because of their small size, their bites can be painful and pruritic. House mouse mites (*Liponyssoides sanguineus*) serve as vectors for the agent of rickettsialpox, *Rickettsia akari*, an uncommon disease characterized by mild fevers, an eschar at the bite site, and a papulovesicular eruption. Rickettsialpox **(Chap. 187)** has been recognized mainly in large northern temperate cities. Once confirmed as the cause of a skin disorder, rodent- and bird-associated mites are best eliminated by exclusion of their animal hosts, removal of the nests, and cleaning and treatment of the nesting area with appropriate acaricides.

Pyemotes and other mites that infest grain, straw, cheese, hay, oak leaf galls, or other products occasionally produce similar episodes of rash and discomfort and may produce a unique dermatologic "comet sign" lesion—a paisley-shaped urticarial plaque **(Fig. 461-1)**.

Diagnosis of mite-induced dermatitides (including those caused by chiggers) relies on confirmation of the mite's identity or elicitation of a history of exposure to the mite's source. Because the mites do not reside on humans, treatment of the patient with acaricides (e.g., permethrin) is discouraged. Oral antihistamines or topical steroids may reduce mite-induced pruritus temporarily.

The mites that cause house dust–related allergic conditions neither bite nor infest humans.

TICK BITES AND TICK PARALYSIS

Ticks attach superficially to skin and usually feed painlessly; blood is their only food. Their salivary secretions are biologically active (intended to prevent blood coagulation while the tick feeds) and can produce local reactions, induce fevers, and cause paralysis in addition to transmitting diverse pathogens. The two main families of ticks are the hard (ixodid) ticks and soft (argasid) ticks. Because no ticks are obligate parasites on humans, all tick-borne diseases (bacterial, viral, and protozoal) are zoonoses.

Generally, soft ticks feed quickly, attaching for <1 h, and then drop off. Because of this rapid feeding behavior, the ticks are not carried widely by animal or bird hosts. Soft tick–associated infections usually have fairly focal distributions. When a soft tick finishes the blood meal on a human and drops off, red macules may develop at the bite site. Some species in Africa, the western United States, and Mexico produce painful hemorrhagic lesions.

Hard ticks are much more common than are soft ticks, and they transmit most of the tick-borne infections that are familiar to physicians and patients. Hard ticks attach to the host and feed for several days to >1 week, with the exact duration depending upon the tick's species and stage of development. At the site of hard-tick bites, small areas of induration, often purpuric, develop and may be surrounded by an erythematous rim. A necrotic eschar, called a *tâche noire* ("black spot"), occasionally develops. Chronic nodules (persistent tick-bite granulomas) can be several centimeters in diameter and may linger for months after the feeding tick has been removed. These granulomas can be treated with injected intralesional glucocorticoids or by simple local excision. Tick-induced fever, unassociated with transmission of any pathogen, is often accompanied by headache, nausea, and malaise but usually resolves ≤36 h after the tick is removed. Salivary antigens of certain ticks, particularly the Lone Star tick, *Amblyomma americanum*, may induce antibodies to galactose-α-1,3-galactose (alpha-gal) that result in mammalian meat allergy–alpha-gal syndrome.

Tick paralysis, an acute ascending flaccid paralysis that resembles Guillain-Barré syndrome, is believed to be caused by one or more toxins in tick saliva that block neuromuscular transmission and decrease nerve conduction. This rare complication has followed the bites of >60 species of ticks. It is reported worldwide, but most cases arise in the Rocky Mountain region, in the northwestern United States and southeastern Canada, and on the east coast of Australia. In North America, dog and wood ticks (*Dermacentor* species) are most commonly involved. Weakness begins symmetrically in the lower extremities ≤6 days after the tick's attachment, ascends symmetrically during several days, and may culminate in complete paralysis of the extremities and cranial nerves. Deep tendon reflexes are diminished or absent, but sensory examination and findings on lumbar puncture are typically normal. Diagnosis depends on finding the tick, which is often hidden beneath scalp hair. Removal of the tick generally leads to improvement within a few hours and complete recovery after several days, although the patient's condition may continue to deteriorate for a full day. Failure to remove the tick may lead to dysarthria, dysphagia, and ultimately death from aspiration or respiratory paralysis. An antiserum to the saliva of *Ixodes holocyclus*, the usual cause of tick paralysis in Australia, effectively reverses paralysis caused by these ticks.

Removal of hard ticks during the first 36 h of attachment generally prevents transmission of the agents of Lyme disease, babesiosis, anaplasmosis, and ehrlichiosis, although tick-borne viruses may be transmitted more quickly. Ticks should be removed by traction with fine-tipped forceps placed firmly around the tick's mouthparts where they enter the skin. Careful handling (to avoid rupture of ticks) and use of gloves may avert accidental contamination with pathogens contained in tick fluids. Use of occlusive dressings, heat, or various substances (in an attempt to induce the tick to detach) merely delays tick removal. Afterward, the site of attachment should be disinfected. Tick mouthparts sometimes remain in the skin but generally are shed spontaneously within days without the need for surgical removal. Current guidelines from the Centers for Disease Control and Prevention suggest that, rather than awaiting the onset of erythema migrans, the results of tick testing, or seroconversion to antigens diagnostic for Lyme disease, physicians may appropriately administer prophylaxis—a single oral dose of doxycycline (200 mg) within 72 h of tick removal—to adult patients with bites thought to be associated with *Ixodes scapularis* (deer ticks) in Lyme disease–endemic areas. Whereas prophylactic

FIGURE 461-1 Comet signs in individuals with known or suspected mite-bite reactions, likely due to *Pyemotes* species. Note central punctum at bite site, surrounded by edematous erythema. Linear or serpiginous "comet tails" emanate from the central site. *Pyemotes*-induced comet tails generally do not follow typical patterns of ascending lymphatic drainage.

antibiotic treatment may have value in preventing Lyme disease, it is not recommended as a means to prevent other tick-borne infections.

The Asian longhorned tick (*Haemaphysalis longicornis*) is a newly invasive species in the United States, first detected in the northeastern states in 2017. Although it carries several pathogens to domestic animals, wildlife, and humans in its natural range (northeastern Asia), it has not yet been implicated in disease transmission in the United States.

LOUSE INFESTATION (PEDICULIASIS AND PTHIRIASIS)

Three kinds of biting lice are obligate blood-feeding ectoparasites of human beings. These include the human head and body lice that represent distinct genetic clades of *Pediculus humanus*, and the pubic ("crab") lice (*Pthirus pubis*). Nymphs and adults of these lice feed at least once a day, ingesting human blood exclusively, and they partition ecologically on the host. Head lice infest mainly the hair of the scalp, body lice the clothing, and pubic lice mainly the hair of the pubis. The saliva of lice produces a pruritic morbilliform or urticarial rash in some sensitized persons. Female head and pubic lice cement their eggs (nits) firmly to hair, whereas female body lice cement their eggs to clothing, particularly to threads along clothing seams. After ~10 days of development within the egg, a nymph emerges. Empty eggs may remain affixed for months or years thereafter.

Body lice are acquired by direct contact with an infested person or that individual's recently used clothing or bedding. These lice venture for just minutes to the skin to feed, but otherwise sequester on clothing. They generally succumb in ≤2 days if separated from their host. Body lice tend to be limited to a small proportion of indigent persons or others who have relevant exposure and lack the wherewithal or desire to change or appropriately launder their clothing and bedding. Body lice, as well as the pathogens they transmit, may become increasingly prevalent after societal upheaval and disasters. These lice are vectors for the agents of louse-borne (epidemic) typhus **(Chap. 187)**, louse-borne relapsing fever **(Chap. 185)**, and trench fever **(Chap. 172)**. Chronic infestations result in a postinflammatory hyperpigmentation and thickening of the skin known as *vagabond's disease*.

Head lice are acquired mainly by direct head-to-head contact rather than via fomites such as shared headgear, bed linens, and grooming implements. The prevalence of head lice varies widely as a function of age, geography, and cultural habits. In North America, the prevalence is greatest (~1%) among 6- to 10-year-old children and is considerably lower among persons of other ages. Infestations can be far more prevalent elsewhere. Generally, an infested person hosts 10 or fewer head lice. Chronically infested persons tend to be asymptomatic, and some may host >100 lice. Pruritus, due mainly to hypersensitivity to the louse's saliva, usually is transient and mild and is most evident around the posterior hairline. Head lice removed from a person succumb to desiccation and starvation within ~1 day. Head lice are generally considered unimportant as natural vectors for any pathogens.

The crab or pubic louse is transmitted mainly by sexual contact. These lice occur predominantly on pubic hair and less frequently on axillary or facial hair, including the eyelashes. Children and adults may acquire pubic lice by sexual or close nonsexual contact. Intensely pruritic, bluish macules ~3 mm in diameter (*maculae ceruleae*) develop at the site of bites. Blepharitis commonly accompanies infestations of the eyelashes.

Pediculiasis is often suspected upon the detection of presumed nits firmly cemented to hairs or in clothing or on the basis of pruritus. Often, objects presumed to be louse eggs are, instead, pseudo-nits composed of debris and hair-associated fungi. Hatched and dead eggs remain firmly affixed to scalp hair for months. Such relicts are frequently misconstrued to be signs of an active louse infestation. Confirmation of a louse infestation, therefore, should rely on the discovery of a live louse.

TREATMENT

Louse Infestation

Body lice usually are eliminated by bathing and by changing to laundered clothes. Application of topical pediculicides from head to foot may be necessary for hirsute patients. Clothes and bedding are effectively deloused by heating in a clothes dryer at ≥55°C (≥131°F) for 30 min or by heat-pressing. Emergency mass delousing of persons and clothing may be warranted during periods of civil strife and after natural disasters to reduce the risk of pathogen transmission by body lice.

Head lice and their eggs may be removed with a fine-toothed louse or nit comb, but this effort can be difficult and time-consuming and often fails to eradicate the lice. Treatment of newly identified, active infestations traditionally relies on a 10-min topical application of ~1% permethrin or pyrethrins, with a second application ~10 days later. Lice persisting after this treatment may be resistant to pyrethroids. Chronic infestations may be treated for ≤12 h with 0.5% malathion. Lindane is applied for just 4 min but seems less effective and may pose a greater risk of adverse reactions, particularly when misused. Resistance of head lice to permethrin, malathion, and lindane is well documented. Newer FDA-approved topical pediculicides contain benzyl alcohol, dimethicone, spinosad, and ivermectin. Although children infested by head lice—or those who simply have remnant nits from a prior infestation—are frequently isolated or excluded from school, this practice increasingly is considered to be unjustified, ineffective, and counterproductive.

Pubic louse infestations are treated with topical pediculicides, except for eyelid infestations (*pthiriasis palpebrum*), which generally respond to a coating of petrolatum applied for 3–4 days.

MYIASIS (FLY INFESTATION)

Myiasis refers to infestations by fly larvae (maggots) that invade living or necrotic tissues or body cavities and produce different clinical syndromes, depending on the species of fly.

In forested parts of Central and South America, larvae of the human botfly (*Dermatobia hominis*) produce furuncular (boil-like) dermal and subcutaneous nodules ≤3 cm in diameter. A gravid adult female botfly captures a mosquito or another bloodsucking insect and deposits her eggs on its abdomen. When the carrier insect attacks a human or another mammalian host (often cattle) several days later, the warmth and moisture of the host's skin stimulate the eggs to hatch. The emerging larvae, ~1 mm long, promptly penetrate intact skin. After 6–12 weeks of development, mature larvae emerge from the skin and drop to the ground to pupate and then become adults.

The African tumbu fly (*Cordylobia anthropophaga*) deposits its eggs on damp sand, leaf litter, or drying laundry, particularly items contaminated by urine or sweat. Larvae hatch from eggs upon contact with a host's body and penetrate the skin, producing boil-like lesions from which mature larvae emerge ~9–10 days later. Furuncular myiasis is suggested by uncomfortable lesions with a central breathing pore that emit bubbles when submerged in water. A sensation of movement under the patient's skin may cause severe emotional distress.

Larvae that cause furuncular myiasis may be induced to emerge if the air pore is coated with petrolatum or another occlusive substance. Removal may be facilitated by injection of a local anesthetic (or sterile injectable saline) into the subjacent tissue to uplift the larva through the breathing pore. Surgical excision is sometimes necessary because upward-pointing spines of some species hold the larvae firmly in place.

Other fly larvae cause nonfuruncular myiasis. Larvae of the horse botfly (*Gasterophilus intestinalis*) emerge from eggs, usually deposited on the hairs of a horse's front legs. Direct contact with a person's bare hands or legs may result in the larvae's hatching from the eggs and invading skin. After penetrating human skin, these larvae rarely mature but instead may migrate for weeks in the dermis. The resulting pruritic and serpiginous eruption resembles cutaneous larva migrans caused by canine or feline hookworms (Chap. 231). Larvae of rabbit and rodent botflies (*Cuterebra* species) occasionally cause cutaneous or tracheopulmonary myiasis.

Certain flies are attracted to blood and pus, laying their eggs on open or draining sores. Newly hatched larvae enter wounds or diseased skin. Larvae of several types of green bottle flies (*Lucilia* species) usually remain superficial and confined to necrotic tissue. Specially raised, sterile "surgical maggots" are sometimes used deliberately for wound debridement. Larvae of screwworm flies (*Cochliomyia*) and flesh flies (*Wohlfahrtia* species) invade viable tissues more deeply and produce large suppurating lesions. Larvae that infest wounds also may enter body cavities such as the mouth, nose, ears, sinuses, anus, vagina, and lower urinary tract, particularly in unconscious or otherwise debilitated patients. The consequences range from harmless colonization to destruction of the nose, meningitis, and deafness. Treatment involves removal of maggots and debridement of tissue.

Larvae of the sheep botfly, *Oestrus ovis*, and other flies responsible for furuncular and wound myiasis also may cause ophthalmomyiasis. Sequelae include nodules in the eyelid, retinal detachment, and destruction of the globe. Most instances in which maggots are found in human feces result from deposition of eggs or larvae by flies on recently passed stools, not from an intestinal maggot infestation.

PENTASTOMIASIS

Pentastomids (tongue worms), an obscure type of crustacean, inhabit the respiratory passages of reptiles and carnivorous mammals. Human infestation by *Linguatula serrata* is common in the Middle East and results from the consumption of encysted larval stages in raw liver or lymph nodes of sheep and goats, which are true intermediate hosts for the tongue worms. In areas where raw sheep and goat liver are served, larvae migrate to the nasopharynx and produce an acute self-limiting syndrome—known as *halzoun* in Lebanon and *marrara* in Sudan—characterized by rapid onset (within <12 h) of pain and itching of the throat and ears, coughing, hoarseness, dysphagia, and dyspnea. Severe edema may cause obstruction that requires tracheostomy. In addition, ocular invasion has been described. Diagnostic larvae measuring ≤10 mm in length appear in copious nasal discharge or vomitus.

Another type of tongue worm, *Armillifer armillatus*, infects people who consume its eggs in contaminated food or drink or after handling the definitive host, the African python. Larvae encyst in various organs, usually the liver or peritoneum, but rarely cause symptoms. Cysts may require surgical removal as they enlarge during worm molting, but they usually are encountered as an incidental finding at autopsy. Parasite-induced lesions may be misinterpreted as a malignancy, with the correct diagnosis confirmed histopathologically. Cutaneous larva migrans–type syndromes of other pentastomes have been reported from Southeast Asia and Central America.

LEECH INFESTATIONS

Medically important leeches are annelid worms that attach to their hosts with chitinous cutting jaws and draw blood through muscular suckers. Medicinal leeches (Europe: *Hirudo medicinalis* and other *Hirudo* species; Asia: *Hirudinaria manillensis*; North America: *Macrobdella*

decora) are still used occasionally for medical purposes to reduce venous congestion in surgical flaps or replanted body parts. This practice has been complicated by intractable bleeding, wound infections, myonecrosis, and sepsis due to *Aeromonas hydrophila*, which colonizes the gullets of commercially available leeches.

Ubiquitous aquatic leeches that parasitize fish, frogs, and turtles readily attach to human skin—most often the nasal mucosa—and avidly suck blood. Attachment is usually painless, and the leeches will detach themselves when satiated with a blood meal. Hirudin, a powerful anticoagulant secreted by the leech, causes continued bleeding after the leech has detached. Healing of a leech-bite wound is slow, and secondary bacterial infections are not uncommon. Several kinds of aquatic leeches in Africa, Asia, and southern Europe can enter the mouth, nose, and genitourinary tract and attach to mucosal surfaces at sites as deep as the esophagus and trachea. Leeches may detach on exposure to gargled saline or may be removed by forceps or medical suction.

Arboreal land leeches, which live amid rain forest vegetation, are attracted by heat and can drop from a leaf onto one's skin. Externally attached leeches generally drop off after they have engorged, but removal is hastened by gentle scraping aside of the anterior and posterior suckers the leech uses for attachment and feeding. Some authorities dispute the wisdom of removing leeches with alcohol, salt, vinegar, insect repellent, a flame or heated instrument, or applications of other noxious substances.

SPIDER BITES

Of the >30,000 recognized species of spiders, only ~100 defend themselves aggressively and have fangs sufficiently long to penetrate human skin. The venom that some spiders use to immobilize and digest their prey can cause necrosis of the skin and systemic toxicity. Whereas the bites of most spiders may be painful but not harmful, envenomations by recluse or fiddleback spiders (*Loxosceles* species) and widow spiders (*Latrodectus* species) may be life-threatening. Identification of the offending spider is important because specific treatments exist for bites of widow spiders. Except when the patient actually observes a spider immediately associated with the bite or fleeing from the site, painful noduloulcerative and other lesions reported as spider-bite reactions are most often due to other injuries or to infections with bacteria, particularly methicillin-resistant *S. aureus* (MRSA).

Recluse Spider Bites and Necrotic Arachnidism Brown recluse spiders (*Loxosceles reclusa*) live mainly in the southcentral United States and have close relatives in Central and South America, Africa, the Mediterranean basin, and the Middle East. Recluse spiders are not aggressive toward humans and bite only if threatened or pressed against the skin. They generally dwell beneath rocks and logs or in caves and animal burrows. They invade homes and seek dark and undisturbed hiding spots in closets, garages, crawl spaces, and attics; under furniture and rubbish in storage rooms; and in folds of clothing. Despite their impressive abundance in some homes, these spiders rarely bite humans. Bites tend to occur while the victim is donning clothing in which the spider has hidden itself and are sustained primarily on the hands, arms, neck, and lower abdomen.

Whereas a bite by a brown recluse spider may cause minor injury with edema and erythema, envenomation can cause severe necrosis of skin and subcutaneous tissue and, more rarely, systemic hemolysis. Initially, the bite is painless or may produce a stinging sensation. Within a few hours, the site becomes painful and pruritic, with central induration surrounded by a pale ischemic zone that itself is encircled by a zone of erythema. In most cases, the lesion resolves without treatment in just a few days. In severe cases, the erythema spreads, and the center of the lesion becomes hemorrhagic or necrotic with an overlying bulla. A black eschar forms and sloughs several weeks later, leaving an ulcer that eventually may create a depressed scar. Healing usually takes place in ≤3 months. Local complications include injury to nerves and secondary bacterial infection. Fever, chills, weakness, headache, nausea, vomiting, myalgia, arthralgia, morbilliform eruption, and leukocytosis may develop ≤72 h after the bite. Reports of deaths attributed to bites of North American brown recluse spiders have not been verified.

The Mediterranean recluse spider (*Loxosceles rufescens*) is a widely invasive species in urban areas of both the Old and New Worlds. The dorsal surfaces of *L. rufescens* and *L. reclusa* are adorned with a fiddle-shaped pattern. *L. rufescens* is warier than *L. reclusa*, is less likely to bite, and rarely causes necrosis. Misidentification of this spider may create spurious reports of *L. reclusa* activity outside the known range of that species.

TREATMENT

Recluse Spider Bites

Initial management includes rest, ice, compression, and elevation (RICE). Analgesics, antihistamines, antibiotics, and tetanus prophylaxis should be administered if indicated. Early debridement or surgical excision of the wound without closure delays healing. Routine use of antibiotics or dapsone lacks utility. Patients should be monitored closely for signs of hemolysis, renal failure, and other systemic complications.

Widow Spider Bites The black widow spider, common in the southeastern United States, measures ≤1 cm in body length and 5 cm in leg span and is shiny black with a red hourglass marking on the ventral abdomen. Other dangerous *Latrodectus* species occur elsewhere in temperate and subtropical parts of the world. The bites of the female widow spiders are notorious for their potent neurotoxins.

Widow spiders spin their webs under stones, logs, plants, or rock piles and in dark spaces in barns, garages, and outhouses. Bites are most common in the summer and early autumn and occur when a web is disturbed or a spider is trapped or provoked. The initial bite is perceived as a sharp pinprick or may go unnoticed. Fang-puncture marks are uncommon. The venom that is injected does not produce local necrosis, and some persons experience no other symptoms.

α-Latrotoxin, the most active component of the venom, binds irreversibly to presynaptic nerve terminals and causes release and eventual depletion of acetylcholine, norepinephrine, and other neurotransmitters from those terminals. Painful cramps may spread within 60 min from the bite site to large muscles of the extremities and trunk. Extreme rigidity of the abdominal muscles and excruciating pain may suggest peritonitis, but the abdomen is not tender on palpation and surgery is not warranted. The pain begins to subside during the first 12 h but may recur during several days or weeks before resolving spontaneously. A wide range of other sequelae may include salivation, diaphoresis, vomiting, hypertension, tachycardia, labored breathing, anxiety, headache, weakness, fasciculations, paresthesia, hyperreflexia, urinary retention, uterine contractions, and premature labor. Rhabdomyolysis and renal failure have been reported, and respiratory arrest, cerebral hemorrhage, or cardiac failure may end fatally, especially in very young, elderly, or debilitated persons.

TREATMENT

Widow Spider Bites

Treatment consists of RICE and tetanus prophylaxis. Hypertension that does not respond to analgesics and antispasmodics (e.g., benzodiazepines or methocarbamol) requires specific antihypertensive medication. The efficacy and safety of antivenin (i.e., antivenom) made from equine immunoglobulins are controversial for bites of the black widow and the closely related Australian redback spider because of concerns about potential anaphylaxis or serum sickness. Antivenins made from monoclonal antibodies are in development.

Tarantulas and Other Spiders Tarantulas are large hairy spiders of which 30 species are found in the United States, mainly in the Southwest. Several species of tarantulas that have become popular household pets are usually imported from Central or South America. Tarantulas bite persons only when threatened and usually cause no more harm than a

bee sting, but on occasion, the venom causes deep pain and swelling. Several species of tarantulas are covered with urticating hairs that are brushed off in the thousands when a threatened spider rubs its hind legs across its dorsal abdomen. These hairs can penetrate human skin and produce pruritic papules that may persist for weeks. Failure to wear gloves or to wash the hands after handling the Chilean Rose tarantula, a popular pet spider, has resulted in transfer of hairs to the eye with subsequent devastating ocular inflammation. Treatment of bites includes local washing and elevation of the bitten area, tetanus prophylaxis, and analgesic administration. Antihistamines and topical or systemic glucocorticoids are given for exposure to urticating hairs.

Atrax robustus, a funnel-web spider of Australia, and *Phoneutria* species, the South American banana spiders, are among the most dangerous spiders in the world because of their aggressive behavior and potent neurotoxins. Envenomation by *A. robustus* causes a rapidly progressive neuromotor syndrome that can be fatal within 2 h. The bite of a banana spider causes severe local pain followed by profound systemic symptoms and respiratory paralysis that can lead to death within 2–6 h. Specific antivenins for use after bites by each of these spiders are available. Yellow sac spiders (*Cheiracanthium* species) are common in homes worldwide. Their bites, though painful, generally lead to only minor erythema, edema, and pruritus.

SCORPION STINGS

Scorpions are arachnids that feed on arthropods and other small animals. They paralyze their prey and defend themselves by injecting venom from a stinger on the tip of the tail. Painful but relatively harmless scorpion stings need to be distinguished from the potentially lethal envenomations that are produced by ~30 of the ~1000 known species and that cause >5000 deaths worldwide each year. Scorpions are nocturnal and remain hidden during the day in crevices or burrows or under wood, loose bark, or rocks. They occasionally enter houses and tents and may hide in shoes, clothing, or bedding. Scorpions sting humans only when threatened.

Of the 40 or so scorpion species in the United States, only bark scorpions (*Centruroides sculpturatus*/*C. exilicauda*) in the Southwest produce venom that is potentially lethal to humans. This venom contains neurotoxins that cause sodium channels to remain open. Such envenomations usually are associated with little swelling, but prominent pain, paresthesia, and hyperesthesia can be accentuated by tapping on the affected area (the *tap test*). These symptoms soon spread to other locations; dysfunction of cranial nerves and hyperexcitability of skeletal muscles develop within hours. Patients present with restlessness, blurred vision, abnormal eye movements, profuse salivation, lacrimation, rhinorrhea, slurred speech, difficulty in handling secretions, diaphoresis, nausea, and vomiting. Muscle twitching, jerking, and shaking may be mistaken for a seizure. Complications include tachycardia, arrhythmias, hypertension, hyperthermia, rhabdomyolysis, and acidosis. Symptoms progress to maximal severity in ~5 h and subside within a day or two, although pain and paresthesia can last for weeks. Fatal respiratory arrest is most common among young children and the elderly.

Envenomations by *Leiurus quinquestriatus* in the Middle East and North Africa, by *Mesobuthus tamulus* in India, by *Androctonus* species along the Mediterranean littoral and in North Africa and the Middle East, and by *Tityus serrulatus* in Brazil cause massive release of endogenous catecholamines with hypertensive crises, arrhythmias, pulmonary edema, and myocardial damage. Acute pancreatitis occurs with stings of *Tityus trinitatis* in Trinidad, and central nervous toxicity complicates stings of *Parabuthus* and *Buthotus* scorpions of South Africa.

In Iran and adjacent countries, *Hemiscorpius lepturus* causes the most scorpion envenomations. Its stings are relatively asymptomatic at first, but its cytotoxic venom causes pain, hemolysis, and tissue necrosis after the first day. Systemic complications include hemoglobinuria and subsequent acute kidney injury.

Stings of most other species cause immediate sharp local pain followed by edema, ecchymosis, and a burning sensation. Symptoms typically resolve within a few hours, and skin does not slough. Allergic reactions to the venom sometimes develop.

TREATMENT

Scorpion Stings

Identification of the offending scorpion helps to determine the course of treatment. Stings of nonlethal species require at most ice packs, analgesics, or antihistamines. Because most victims experience only local discomfort, they can be managed at home with instructions to return to the emergency department if signs of cranial-nerve or neuromuscular dysfunction develop. Aggressive supportive care and judicious use of antivenom can reduce or eliminate deaths from more severe envenomations. Keeping the patient calm and applying pressure dressings and cold packs to the sting site are measures that decrease the absorption of venom. A continuous IV infusion of midazolam controls the agitation, flailing, and involuntary muscle movements produced by scorpion stings. Close monitoring during treatment with this drug and other sedatives or narcotics is necessary for persons with neuromuscular symptoms because of the risk of respiratory arrest. Hypertension and pulmonary edema respond to nifedipine, nitroprusside, hydralazine, or prazosin. Dangerous bradydysrhythmia can be controlled with atropine.

Commercially prepared antivenins are available in several countries for some of the most dangerous scorpion species. An FDA-approved *C. sculpturatus* IgG $F(ab')_2$ antivenin in horse serum is available. IV administration of antivenin rapidly reverses cranial-nerve dysfunction and muscular symptoms.

HYMENOPTERA STINGS

Bees, wasps, hornets, yellow jackets, and ants (all of the insect order Hymenoptera) sting in defense or to subdue their prey. Their venoms contain a wide array of amines, peptides, and enzymes that cause local and systemic reactions. Although the toxic effect of multiple stings can be fatal to a human, nearly all of the ≥100 deaths due to hymenopteran stings in the United States each year result from type 1, immediate-type allergic reactions.

Bee and Wasp Stings The stinger of the honeybee (*Apis mellifera*) is unique in being barbed. The stinging apparatus and attached venom sac tear loose from the honeybee's body, and muscular contractions of the venom sac continue to infuse venom into the skin. Other kinds of bees, ants, and wasps have smooth stinging mechanisms and can sting numerous times in succession. Generally, a person sustains just one sting from a bee or social wasp unless a nest was disturbed. Africanized honeybees (now present in South and Central America and the southern and western United States) respond to minimal intrusions more aggressively. The sting of an Africanized bee contains less venom than that of its non-Africanized relatives, but victims tend to sustain far more stings and thus receive a far greater overall volume of venom. Most patients who report having sustained a "bee sting" are more likely to have encountered stinging wasps instead.

The venoms of different kinds of hymenopterans are biochemically and immunologically distinct. Direct toxic effects are mediated by mixtures of low-molecular-weight compounds such as serotonin, histamine, acetylcholine, and several kinins. Polypeptide toxins in honeybee venom include mellitin, which damages cell membranes; mast cell–degranulating protein, which causes histamine release; the neurotoxin apamin; and the anti-inflammatory compound adolapin. Enzymes in venom include hyaluronidase and phospholipases. There appears to be little cross-sensitization between the venoms of honeybees and wasps.

Uncomplicated hymenopteran stings cause immediate pain, a wheal-and-flare reaction, and local edema, all of which usually subside in a few hours. Multiple stings can lead to vomiting, diarrhea, generalized edema, dyspnea, hypotension, and non-anaphylactic circulatory collapse. Rhabdomyolysis and intravascular hemolysis may cause renal failure. Death from the direct (nonallergic) effects of venom has followed stings of several hundred honeybees. Stings to the tongue or mouth may induce life-threatening edema of the upper airways.

Large local reactions accompanied by erythema, edema, warmth, and tenderness that spread ≥10 cm around the sting site over 1–2 days are not uncommon. These reactions may resemble bacterial cellulitis but are caused by hypersensitivity rather than by secondary infection. Such reactions tend to recur on subsequent exposure but are seldom accompanied by anaphylaxis and are not prevented by venom immunotherapy.

An estimated 0.4–4.0% of the U.S. population exhibits clinical immediate-type hypersensitivity to hymenopteran stings, and 15% may have asymptomatic sensitization manifested by positive skin tests. Persons who experience severe allergic reactions are likely to have similar or more severe reactions after subsequent stings by the same or closely related species. Mild anaphylactic reactions to insect stings, as to other causes, consist of nausea, abdominal cramping, generalized urticaria or angioedema, and flushing. Serious reactions, including upper airway edema, bronchospasm, hypotension, and shock, may be rapidly fatal. Severe reactions usually begin within 10 min of the sting and only rarely develop after 5 h.

TREATMENT

Bee and Wasp Stings

Honeybee stingers embedded in the skin should be removed as soon as possible to limit the quantity of venom delivered. The stinger and venom sac may be scraped off with a blade, a fingernail, or the edge of a credit card or may be removed with forceps. The site should be cleansed and disinfected and ice packs applied to slow the spread of venom. Elevation of the affected site and administration of oral analgesics, oral antihistamines, and topical calamine lotion help relieve symptoms.

Anaphylactic reactions to bee or wasp venom can be a life-threatening emergency that requires prompt life-saving actions. If the individual carries a bee-sting kit, then a subcutaneous injection of epinephrine hydrochloride (0.3 mL of a 1:1000 dilution) should be considered, with treatment repeated every 20–30 min as necessary. A tourniquet may slow the spread of venom. The patient should be transferred to a hospital emergency room where treatment for profound shock, if required, can be administered safely. Such treatment may entail the use of IV epinephrine and other vasopressors, intubation or provision of supplemental oxygen, fluid resuscitation, use of bronchodilators, and parenteral administration of antihistamines. Patients should be observed for 24 h for recurrent anaphylaxis, renal failure, or coagulopathy.

Persons with a history of allergy to insect stings should carry an anaphylaxis kit with a preloaded syringe containing epinephrine for self-administration. These patients should seek medical attention immediately after using the kit.

Prophylactic immunotherapy may greatly reduce the risk of life-threatening reactions to bee and wasp stings. Repeated injections of purified venom produce a blocking IgG antibody response to venom and reduce the incidence of recurrent anaphylaxis. Honeybee, wasp, and yellow jacket venoms are commercially available for desensitization and for skin testing. Results of skin tests and venom-specific radioallergosorbent tests (RASTs) aid in the selection of patients for immunotherapy and guide the design of such treatment.

STINGING ANTS

Stinging ants are an important medical problem in the United States. Imported fire ants (*Solenopsis* species) infest southern states from Texas to North Carolina, with colonies now established in California, New Mexico, Arizona, and Virginia. Slight disturbances of their mound nests have provoked massive outpourings of ants and as many as 10,000 stings on a single person. Elderly and immobile persons are at high risk for attacks when fire ants invade dwellings.

Fire ants attach to skin with powerful mandibles and rotate their bodies while repeatedly injecting venom with posteriorly situated stingers. The alkaloid venom consists of cytotoxic and hemolytic piperidines and several proteins with enzymatic activity. The initial wheal-and-flare reaction, burning, and itching resolve in ~30 min, and a sterile pustule develops within 24 h. The pustule ulcerates over the next 48 h and then heals in ≥1 week. Large areas of erythema and edema lasting several days are not uncommon and, in extreme cases, may compress nerves and blood vessels. Anaphylaxis occurs in <2% of victims; seizures and mononeuritis have been reported. Stings are treated with ice packs, topical glucocorticoids, and oral antihistamines. Pustules should be cleansed and then covered with bandages and antibiotic ointment to prevent bacterial infection. Epinephrine administration and supportive measures are indicated for anaphylactic reactions. Fire ant whole-body extracts are available for skin testing and immunotherapy, which appear to lower the rate of anaphylactic reactions.

European fire (red) ants (*Myrmica rubra*) have recently become public health pests in the northeastern United States and southern Canada. The western United States is home to harvester ants (*Pogonomyrmex* species). The painful local reaction that follows harvester ant stings often extends to lymph nodes and may be accompanied by anaphylaxis. The bullet or conga ant (*Paraponera clavata*) of South America is known locally as *hormiga veinticuatro* ("24-hour ant"), a designation that refers to the 24 h of throbbing, excruciating pain following a sting that delivers the potent paralyzing neurotoxin poneratoxin.

DIPTERAN (FLY AND MOSQUITO) BITES

In the process of feeding on vertebrate blood and tissue fluids, adults of certain fly species inflict painful bites, inject saliva that may cause vasodilation and produce local allergic reactions, and may transmit diverse pathogenic agents. Bites of mosquitoes (culicids), tiny "no-see-um" midges (ceratopogonids), and sand flies (phlebotomines) typically produce a wheal and a pruritic papule. Small humpbacked black flies (simuliids) lacerate skin, resulting in a lesion with serosanguineous discharge that is often painful and pruritic. Regional lymphadenopathy, fever, or anaphylaxis occasionally ensues. The widely distributed deerflies and horseflies as well as the tsetse flies of Africa are stout flies that attack during the day and produce large and painful bleeding punctures. House flies (*Musca domestica*) do not consume blood but use rasping mouthparts to scarify skin and feed upon tissue fluids and salt. Beyond direct injury from bites of any kind of fly, risks include transmission of diverse pathogens and secondary bacterial infection of the lesion.

TREATMENT

Fly and Mosquito Bites

Treatment of fly bites is symptom based. Topical application of antipruritic agents, glucocorticoids, or antiseptic lotions may relieve itching and pain. Allergic reactions may require oral antihistamines. Antibiotics may be necessary for the treatment of large bite wounds that become secondarily infected.

FLEA BITES

Common human-biting fleas include the dog and cat fleas (*Ctenocephalides* species) and the rat flea (*Xenopsylla cheopis*), which infest their respective hosts and their nests and resting sites. Sensitized persons develop erythematous pruritic papules (*papular urticaria*) and occasionally vesicles and bacterial superinfection at the site of the bite. Symptom-based treatment consists of antihistamines, topical glucocorticoids, and topical antipruritic agents.

Flea infestations are eliminated by removal and treatment of animal nests, frequent cleaning of pet bedding, and application of contact and systemic insecticides to pets and the dwelling. Flea infestations in the home may be abated or prevented if pets are regularly treated with veterinary antiparasitic agents, insect growth regulators, or chitin inhibitors.

Tunga penetrans, like other fleas, is a wingless, laterally flattened insect that feeds on blood. Also known as the chigoe flea, sand flea,

or jigger (not to be confused with the chigger), it occurs in tropical regions of Africa and the Americas. Adult female chigoes live in sandy soil and burrow under the skin, usually between toes, under nails, or on the soles of bare feet. Gravid chigoes engorge on the host's blood and grow from pinpoint to pea size during a 2-week interval. They produce lesions that resemble a white pustule with a central black depression and that may be pruritic or painful. Occasional complications include tetanus, bacterial infections, and autoamputation of toes (*ainhum*). Tungiasis is treated by removal of the intact flea with a sterile needle or scalpel, tetanus vaccination, and topical application of antibiotics.

HEMIPTERAN/HETEROPTERAN (TRUE BUG) BITES

Most true bugs feed on plants, but some are predaceous or feed on blood. In order to feed or to defend themselves, they may inflict bites that produce allergic reactions and are sometimes painful. Bites of the cone-nose or "kissing bugs" (family Reduviidae) tend to occur at night and are painless. Reactions to such bites depend on prior sensitization and include tender and pruritic papules, vesicular or bullous lesions, extensive urticaria, fever, lymphadenopathy, and (rarely) anaphylaxis. Bug bites are treated with topical antipruritic agents or oral antihistamines. Persons with anaphylactic reactions to reduviid bites should keep an epinephrine kit available. Some reduviids transmit *Trypanosoma cruzi*, the agent of New World trypanosomiasis (Chagas disease) **(Chap. 227)**.

The cosmopolitan and tropical bed bugs (*Cimex lectularius* and *C. hemipterus*) hide in crevices of mattresses, bed frames and other furniture, walls, and picture frames and under loose wallpaper, actively seeking blood meals at night. These bugs are now a common pest in homes, dormitories, and hotels; on cruise ships; and even in medical facilities. Their bite is painless. Bites on persons without prior exposure to bedbugs may not be noticeable. Persons sensitized to bed bug saliva develop erythema, itching, and wheals around a central hemorrhagic punctum. Reactions may manifest within minutes of the bites, or they may be delayed for days or even a week or more. Bed bugs are not known to transmit pathogens.

CENTIPEDE BITES AND MILLIPEDE DERMATITIS

Two groups of myriapods ("many-footed" arthropods) can harm humans. Centipedes, with one pair of legs per body segment, are fast-moving, aggressive, and carnivorous. They stun and kill their prey—usually other arthropods, earthworms, and rarely small vertebrates—with a venomous bite. The fangs of centipedes of the genus *Scolopendra* can penetrate human skin and deliver a venom that produces intense burning pain, swelling, erythema, and sterile lymphangitis. Dizziness, nausea, and anxiety are described occasionally, and rhabdomyolysis and renal failure have been reported. Treatment includes washing of the site, application of cold dressings, oral analgesic administration or local lidocaine infiltration, and tetanus prophylaxis.

Millipedes, with two pairs of legs per segment, are slow-moving, docile, and feed mostly on decaying plant materials. They do not bite, but some secrete defensive fluids that may burn and discolor human skin. Affected skin turns brown overnight and may blister and exfoliate. Secretions in the eye cause intense pain and inflammation that can result in corneal ulcers and even blindness. Management includes irrigation with copious amounts of water or saline, use of analgesics, and local care of denuded skin.

CATERPILLAR STINGS AND DERMATITIS

Caterpillars of several moth species are covered with hairs or spines that produce mechanical irritation and may contain or be coated with venom. Contact with these caterpillars or their hairs may lead to erucism (a pruritic urticarial or papular rash) or caterpillar envenomation. The response typically consists of an immediate burning sensation followed by local swelling and erythema and occasionally by regional lymphadenopathy, nausea, vomiting, and headache. A rare reaction to a South American caterpillar, *Lonomia obliqua*, can cause disseminated coagulopathy and fatal hemorrhagic shock.

Dermatitis is most often associated with caterpillars of io, puss, saddleback, and browntail moths in North America and with the oak processionary moth in Europe. Even contact with detached hairs of other caterpillars, such as gypsy moth larvae, can later produce erucism. Spines may be deposited on tree trunks or drying laundry or may be airborne and cause irritation of the eyes and upper airways. Treatment of caterpillar stings consists of repeated application of adhesive or cellophane tape to remove the hairs, which can then be identified microscopically. Local ice packs, topical glucocorticoids, and oral antihistamines relieve symptoms.

Few adult moths cause human health problems. Adult yellowtail moths (*Hylesia* species), found mainly in coastal mangrove zones along the eastern coast of Central and South America, have bodies that are covered by fine hairs or setae. The hairs on the ventral surface can detach and, when in contact with human skin, cause an extremely pruritic reaction called "Carapito itch." This issue is especially problematic when the moths have population booms, creating swarms around coastal communities.

BEETLE VESICATION AND DERMATITIS

Several families of beetles have independently developed the ability to produce chemically unrelated vesicating toxins. When disturbed, blister beetles (family Meloidae) exude cantharidin, a low-molecular-weight toxin that produces thin-walled blisters (≤5 cm in diameter) 2–5 h after contact. The blisters are not painful or pruritic unless broken. They resolve without treatment in ≤10 days. Nephritis may follow unusually heavy cantharidin exposure.

The hemolymph of certain rove beetles (*Paederus* species, Staphylinidae family) contains pederin, a potent vesicant. When these beetles are crushed or brushed against the skin, the released fluid causes painful, red, flaccid bullae. These beetles occur worldwide but are most numerous and problematic in parts of Africa (where they are called "Nairobi fly") and southwestern Asia. Ocular lesions may develop after impact with flying beetles at night or unintentional transfer of the vesicant on the fingers. Treatment is rarely necessary, although ruptured blisters should be kept clean and bandaged.

Larvae of common carpet beetles are adorned with dense arrays of ornate hairs called *hastisetae*. Contact with these larvae or their setae results in delayed dermal reactions in sensitized individuals. The lesions are commonly mistaken for bites of bed bugs.

DELUSIONAL INFESTATIONS

The groundless conviction that one is infested with arthropods or other parasites (Ekbom syndrome, delusory parasitosis, delusions of parasitosis, and perhaps Morgellons syndrome) is extremely difficult to treat and, unfortunately, is not uncommon **(Fig. 461-2)**. Patients describe uncomfortable sensations of something moving in or on their skin. Excoriations and self-induced ulcerations typically accompany the pruritus, dysesthesias, and imaginary insect bites. Patients often believe that some invisible or as yet undescribed creatures are infesting their skin, clothing, homes, or environment in general. Frequently, patients submit as evidence of infestation specimens that consist of plant-feeding and nonbiting peridomestic arthropods, pieces of skin, vegetable matter, lint, and other inanimate detritus. In the evaluation of a patient with possible delusional parasitosis, it is imperative to rule out true infestations and bites by arthropods, endocrinopathies, sensory disorders due to neuropathies, opiate and other drug use, environmental irritants (e.g., fiberglass threads), and other causes of tingling or prickling sensations. Frequently, such patients repeatedly seek medical consultations, resist alternative explanations for their symptoms, and exacerbate their discomfort by self-treatment. Long-term pharmacotherapy with pimozide or other psychotropic agents has been more helpful than psychotherapy in treating this disorder. Patients with delusory parasitosis often develop the unshakeable conviction that they are infested by a previously unknown pathogen, while their personal lives, family support, and employment collapse around them.

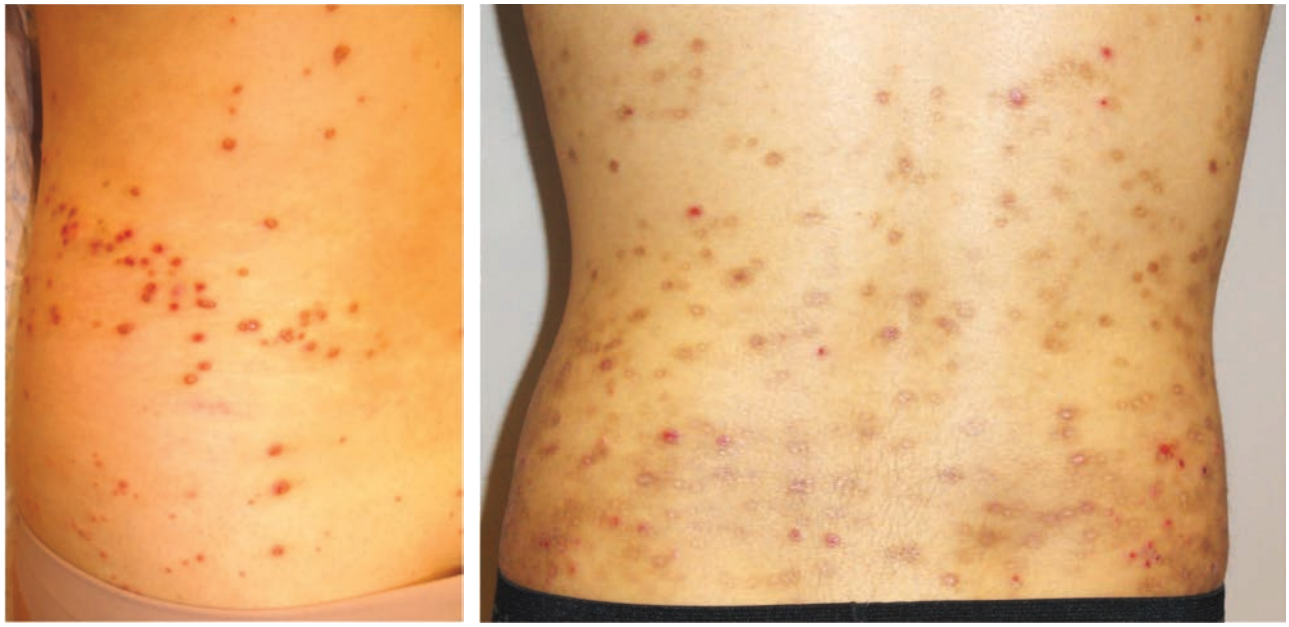

FIGURE 461-2 Real (*left*) versus delusional (*right*) infestation: comparable images of the lower backs of two young adults with multiple lesions. ***Left:*** A young woman developed innumerable widespread lesions during a camping ecotour near Manaus, Brazil. Note scattered clusters of irregularly spaced lesions, accompanied by dozens of single or isolated lesions, consistent with the semi-random feeding pattern of biting flies. Lesions appear to be in roughly the same stage of development, a feature indicating that they were acquired at roughly the same time. No lesions were present before her ecotour; none have arisen since. This patient scratches the intensely pruritic lesions and causes superficial erosions. Unexcoriated lesions are also present on her midback, where she cannot scratch. ***Right:*** A young man has innumerable widespread lesions that have accumulated for several years, with a few new lesions appearing several times a week. His lesions are in various stages of development (fresh, crusted, re-epithelialized, pigmented, and scarred), a feature indicating a long-standing process. The lesions are distributed in a regular pattern consistent with periodic "excavations" to remove alleged parasites that he believes are crawling through his skin. Scarring is due to manipulations that create dermal ulcers rather than superficial excoriations and erosions. Parts of his upper midback, where he cannot scratch, are free of lesions.

462 Altitude Illness

Buddha Basnyat, Geoffrey Tabin

EPIDEMIOLOGY

Mountains cover one-fifth of the earth's surface; 140 million people live permanently at altitudes ≥2500 m, and 100 million people travel to high-altitude locations each year. Skiers in the Alps or Aspen; tourists to La Paz, Ladakh, or Lahsa; religious pilgrims to Kailash-Manasarovar or Gosainkunda; trekkers and climbers to Kilimanjaro, Aconcagua, or Everest; miners working in high-altitude sites in South America; and military personnel deployed to high-altitude locations are all at risk of developing acute mountain sickness (AMS), high-altitude cerebral edema (HACE), high-altitude pulmonary edema (HAPE), and other altitude-related problems. AMS is the benign form of altitude illness, whereas HACE and HAPE are life-threatening. Altitude illness is likely to occur above 2500 m but has been documented even at 1500–2500 m. In the Mount Everest region of Nepal, ~50% of trekkers who walk to altitudes >4000 m over ≥5 days develop AMS, as do 84% of people who fly directly to 3860 m. The incidences of HACE and HAPE are much lower than that of AMS, with estimates in the range of 0.1–4%. Finally, reentry HAPE, which in the past was generally limited to highlanders (long-term residents of altitudes >2500 m) in the Americas, is now being seen in Himalayan and Tibetan highlanders—and often misdiagnosed as a viral illness—as a result of recent rapid air, train, and motorable-road access to high-altitude settlements.

PHYSIOLOGY

Ascent to a high altitude subjects the body to a decrease in barometric pressure that results in a decreased partial pressure of oxygen in the inspired gas in the lungs. This change leads in turn to less pressure, driving oxygen diffusion from the alveoli and throughout the oxygen cascade. A normal initial "struggle response" to such an ascent includes increased ventilation—the cornerstone of acclimatization—mediated by the carotid bodies. Hyperventilation may cause respiratory alkalosis and dehydration. Respiratory alkalosis may be extreme, with an arterial blood pH of >7.7 (e.g., at the summit of Everest). Alkalosis may depress the ventilatory drive during sleep, with consequent periodic breathing and hypoxemia. During early acclimatization, renal suppression of carbonic anhydrase and excretion of dilute alkaline urine combat alkalosis and tend to bring the pH of the blood to normal. Other physiologic changes during normal acclimatization include increased sympathetic tone; increased erythropoietin levels, leading to increased hemoglobin levels and red blood cell mass; increased tissue capillary density and mitochondrial numbers; and higher levels of 2,3-bisphosphoglycerate, enhancing oxygen utilization. Even with normal acclimatization, however, ascent to a high altitude decreases maximal exercise capacity (by ~1% for every 100 m gained above 1500 m) and increases susceptibility to cold injury due to peripheral vasoconstriction. If the ascent is made faster than the body can adapt to the stress of hypobaric hypoxemia, altitude-related disease states can result.

GENETICS

Hypoxia-inducible factor, which acts as a master switch in high-altitude adaptation, controls transcriptional responses to hypoxia throughout the body and is involved in the release of vascular endothelial growth factor (VEGF) in the brain, erythropoiesis, and other pulmonary and cardiac functions at high altitudes. In particular, the gene *EPAS1*, which codes for transcriptional regulator hypoxia-inducible factor 2α, appears to play an important role in the adaptation of Tibetans living at high altitude, resulting in lower hemoglobin concentrations than are found in Han Chinese or South American highlanders. Other genes implicated include *EGLN1* and *PPARA*, which are also associated with hemoglobin concentration. Some evidence indicates that these genetic changes occurred within the past 3000 years, which is very fast in evolutionary terms. An intriguing question is whether the Sherpas' well-known mountain-climbing ability is partially attributable to their Tibetan ancestry, with overrepresentation of variants of *EPAS*. A striking recent finding is that some of these genetic characteristics may stem from those of Denisovan hominids who were contemporaries of the Neanderthals.

For acute altitude illness, a single gene variant is unlikely to be found, but differences in the susceptibility of individuals and populations, familial clustering of cases, and a positive association of some genetic variants all clearly support a role for genetics.

ACUTE MOUNTAIN SICKNESS AND HIGH-ALTITUDE CEREBRAL EDEMA

AMS is a neurologic syndrome characterized by nonspecific symptoms (headache, nausea, fatigue, and dizziness), with a paucity of physical findings, developing 6–12 h after ascent to a high altitude. AMS is a clinical diagnosis. For uniformity in research studies, the Lake Louise Scoring System, created at the 1991 International Hypoxia Symposium, is generally used without the sleep disturbance score. AMS must be distinguished from exhaustion, dehydration, hypothermia, alcoholic hangover, and hyponatremia. AMS and HACE are thought to represent opposite ends of a continuum of altitude-related neurologic disorders. HACE (but not AMS) is an encephalopathy whose hallmarks are ataxia and altered consciousness with diffuse cerebral involvement but generally without focal neurologic deficits. Progression to these signal manifestations can be rapid. Papilledema and, more commonly, retinal hemorrhages may develop. In fact, retinal hemorrhages occur frequently at ≥5000 m, even in individuals without clinical symptoms of AMS or HACE.

Risk Factors The most important risk factors for the development of altitude illness are the rate of ascent and a prior history of high-altitude illness. Exertion is a risk factor, but lack of physical fitness is not. An attractive but still speculative hypothesis proposes that AMS develops in people who have inadequate cerebrospinal capacity to buffer the brain swelling that occurs at high altitude. Children and adults seem to be equally affected, but people >50 years of age may be less likely to develop AMS than younger people. In general, there is no gender difference in AMS incidence. Sleep desaturation—a common phenomenon at high altitude—is associated with AMS. Debilitating fatigue consistent with severe AMS on descent from a summit is an important risk factor for death in mountaineers. A prospective study involving trekkers and climbers who ascended to altitudes between 4000 and 8848 m showed that high oxygen desaturation and low ventilatory response to hypoxia during exercise are independent predictors of severe altitude illness. However, because there may be a large overlap between groups of susceptible and nonsusceptible individuals, accurate cutoff values are hard to define. Prediction is made more difficult because the pretest probabilities of HAPE and HACE are low. Neck irradiation or surgery damaging the carotid bodies, respiratory tract infections, and dehydration appear to be other potential risk factors for altitude illness. Unless guided by clinical signs and symptoms, pulse oximeter readings alone on a trek should not be used to predict AMS.

Pathophysiology Hypobaric hypoxia is the main trigger for altitude illness. In established AMS, raised intracranial pressure, increased sympathetic activity, relative hypoventilation, fluid retention and redistribution, and impaired gas exchange have all been well noted; these factors may play an important role in the pathophysiology of AMS. Severe hypoxemia can lead to a greater than normal increase in cerebral blood flow. However, the exact mechanisms underlying AMS and HACE are unknown. Evidence points to a central nervous system process. MRI studies have suggested that vasogenic (interstitial) cerebral edema is a component of the pathophysiology of HACE. In the

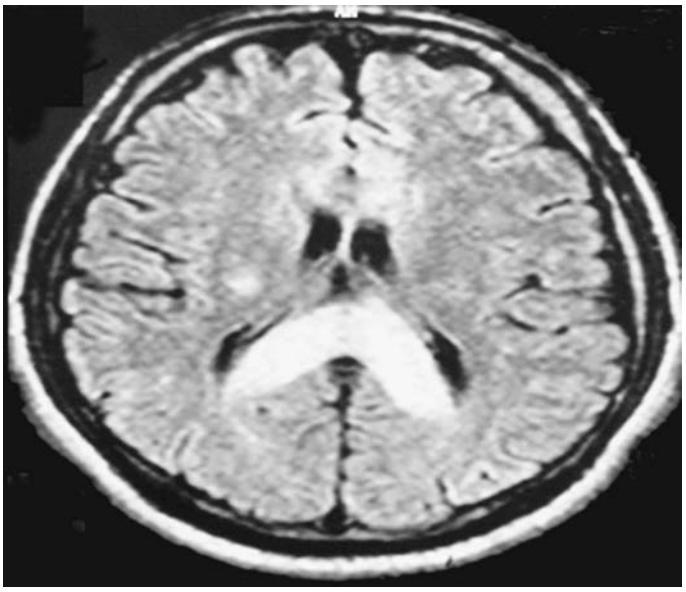

FIGURE 462-1 T2 magnetic resonance image of the brain of a patient with high-altitude cerebral edema (HACE) shows marked swelling and a hyperintense posterior body and splenium of the corpus callosum (area with dense opacity). The patient, a climber, went on to climb Mount Everest about 9 months after this episode of HACE. *(Source: FJ Trayers 3rd: Wilderness preventive medicine. Wilderness Environ Med 15:53, 2004.)*

TABLE 462-1 Management of Altitude Illness

CONDITION	MANAGEMENT
Acute mountain sickness (AMS), mild[a]	Discontinuation of ascent Treatment with acetazolamide (250 mg q12h) Descent[b]
AMS, moderate[a]	Immediate descent for worsening symptoms Use of low-flow oxygen if available Treatment with acetazolamide (250 mg q12h) and/or dexamethasone (4 mg q6h)[c] Hyperbaric therapy[d]
High-altitude cerebral edema (HACE)	Immediate descent or evacuation Administration of oxygen (2–4 L/min) Treatment with dexamethasone (8 mg PO/IM/IV; then 4 mg q6h) Hyperbaric therapy if descent is not possible
High-altitude pulmonary edema (HAPE)	Immediate descent or evacuation Minimization of exertion while patient is kept warm Administration of oxygen (4–6 L/min) to bring O_2 saturation to >90% Adjunctive therapy with nifedipine[e] (30 mg, extended-release, q12h) Hyperbaric therapy if descent is not possible

[a]Categorization of cases as mild or moderate is a subjective judgment based on the severity of headache and the presence and severity of other manifestations (nausea, fatigue, dizziness). [b]No fixed altitude is specified; the patient should descend to a point below that at which symptoms developed. [c]Acetazolamide treats and dexamethasone masks symptoms. For prevention (as opposed to treatment) of AMS, 125 mg of acetazolamide q12h or (when acetazolamide is contraindicated—e.g., in people with a history of sulfa anaphylaxis) 4 mg of dexamethasone q12h may be used. [d]In hyperbaric therapy (Fig. 462-2), the patient is placed in a portable altitude chamber or bag to simulate descent. [e]Nifedipine at this dose is also effective for the prevention of HAPE, as are tadalafil (10 mg twice daily), sildenafil (50 mg three times per day), and dexamethasone (8 mg twice daily). Preventative therapy should be continued for about 3 days after arriving at the target altitude. If prompt descent follows arrival at target altitude, continuation of preventative therapy is unnecessary.

setting of high-altitude illness, the MRI findings shown in Fig. 462-1 are confirmatory of HACE, with increased signal in the white matter and particularly in the splenium of the corpus callosum. In addition, hemosiderin deposits in the corpus callosum have been characterized as long-lasting footprints of HACE. Quantitative analysis in an MRI study revealed that hypoxia is associated with mild vasogenic cerebral edema irrespective of AMS. This finding is in keeping with case reports of suddenly symptomatic brain tumors and of cranial nerve palsies without AMS at high altitudes. Vasogenic edema may become cytotoxic (intracellular) in severe HACE.

Impaired cerebral autoregulation in the presence of hypoxic cerebral vasodilation and altered permeability of the blood-brain barrier due to hypoxia-induced chemical mediators like histamine, arachidonic acid, and VEGF may all contribute to brain edema. In 1995, VEGF was first proposed as a potent promoter of capillary leakage in the brain at high altitude, and studies in mice have borne out this role. Although studies of VEGF in climbers have yielded inconsistent results regarding its association with altitude illness, indirect evidence of a role for this growth factor in AMS and HACE comes from the observation that dexamethasone, when used in the prevention and treatment of these conditions, blocks hypoxic upregulation of VEGF. Other factors in the development of cerebral edema may be the release of calcium-mediated nitric oxide and neuronally mediated adenosine, which may promote cerebral vasodilation. Venous outflow obstruction resulting in increased brain capillary pressure is also thought to play an important role in the development of HACE. Lesions in the globus pallidum (which is sensitive to hypoxia) leading to Parkinson's disease have been reported to be complications of HACE.

The pathophysiology of the most common and prominent symptom of AMS—headache—remains unclear because the brain itself is an insensate organ; only the meninges contain trigeminal sensory nerve fibers. The cause of high-altitude headache is multifactorial. Various chemicals and mechanical factors activate a final common pathway, the trigeminovascular system. In the genesis of high-altitude headache, the response to nonsteroidal anti-inflammatory drugs and glucocorticoids provides indirect evidence for involvement of the arachidonic acid pathway and inflammation.

Prevention and Treatment (Table 462-1) Gradual ascent, with adequate time for acclimatization, is the best method for the prevention of altitude illness. Even though there may be individual variation in the rate of acclimatization, a conservative approach would be a graded ascent of ≤300 m from the previous day's sleeping altitude above 3000 m, and taking every third day of gain in sleeping altitude as an extra day for acclimatization is helpful. Spending one night at an intermediate altitude before proceeding to a higher altitude may enhance acclimatization and attenuate the risk of AMS. Another protective factor in AMS is high-altitude exposure during the preceding 2 months; for example, the incidence and severity of AMS at 4300 m are reduced by 50% with an ascent after 1 week at an altitude ≥2000 m rather than with an ascent from sea level. However, regarding the benefits of acclimatization, clear-cut randomized studies are lacking. Repeated exposure at low altitudes to hypobaric or normobaric hypoxia is termed *preacclimatization*. Preacclimatization is gaining popularity. For example, many Everest climbers in the spring of 2019 claimed to use commercially available "tents" at home with a hypoxic environment for weeks to months in preparation for the climb. However, the optimal method based on robust studies for preacclimatization is yet to be determined.

Clearly, a flexible itinerary that permits additional rest days will be helpful. Sojourners to high-altitude locations must be aware of the symptoms of altitude illness and should be encouraged not to ascend further if these symptoms develop. Any hint of HAPE (see below) or HACE mandates descent. Proper hydration (but not overhydration) in high-altitude trekking and climbing, aimed at countering fluid loss due to hyperventilation and sweating, may play a role in avoiding AMS. Pharmacologic prophylaxis at the time of travel to high altitudes is warranted for people with a history of AMS or when a graded ascent and acclimatization are not possible—e.g., when rapid ascent is necessary for rescue purposes or when flight to a high-altitude location is required. Acetazolamide is the drug of choice for AMS prevention. It inhibits renal carbonic anhydrase, causing prompt bicarbonate diuresis that leads to metabolic acidosis and hyperventilation. Acetazolamide (125 mg twice daily), administered for 1 day before ascent and continued for about 3 days at the same altitude, is effective. Treatment can be restarted if symptoms return after discontinuation of the drug.

Higher doses are not required. A meta-analysis limited to randomized controlled trials revealed that 125 mg of acetazolamide twice daily was effective in the prevention of AMS, with a relative-risk reduction of ~48% from values obtained with placebo. Even lower doses (62.5 mg twice daily) have been reported to be effective. Paresthesia and a tingling sensation are common side effects of acetazolamide. Some other uncommon side effects are myopia and drowsiness. This drug is a nonantibiotic sulfonamide that has low-level cross-reactivity with sulfa antibiotics; as a result, severe reactions are rare. Dexamethasone (8 mg/d in divided doses) is also effective. A large-scale, randomized, double-blind, placebo-controlled trial in partially acclimatized trekkers clearly showed that *Ginkgo biloba* is ineffective in the prevention of AMS. In randomized studies, ibuprofen (600 mg three times daily) has been shown to be beneficial in the prevention of AMS. Recently, acetaminophen (1 g three times daily) was as effective as ibuprofen at the above dosage in a randomized, double-blind study, which did not have a placebo arm. However, more definitive studies and (for ibuprofen) a proper gastrointestinal bleeding risk assessment need to be conducted before these drugs can be routinely recommended for AMS prevention. Many drugs, including spironolactone, medroxyprogesterone, magnesium, calcium channel blockers, and antacids, confer no benefit in the prevention of AMS. Starkly conflicting results from a number of trials of inhaled budesonide for the prevention of AMS have recently been published, but, in all likelihood, the drug is ineffective. Similarly, no efficacy studies are available for coca leaves (a weak form of cocaine), which are offered to high-altitude travelers in the Andes, or for *soroche* pills, which contain aspirin, caffeine, and acetaminophen and are sold over the counter in Bolivia and Peru. Finally, a word of caution applies in the pharmacologic prevention of altitude illness. A fast-growing population of climbers in pursuit of a summit are injudiciously using prophylactic drugs such as glucocorticoids in an attempt to improve their performance; the outcome can be tragic because of potentially severe side effects of these drugs, especially if taken for a long duration.

For the treatment of mild AMS, rest alone with analgesic use may be adequate. Descent and the use of acetazolamide and (if available) oxygen are sufficient to treat most cases of moderate AMS. Even a minor descent (400–500 m) may be adequate for symptom relief. For moderate AMS or early HACE, dexamethasone (4 mg orally or parenterally) is highly effective. For HACE, immediate descent is mandatory. When descent is not possible because of poor weather conditions or darkness, a simulation of descent in a portable hyperbaric chamber **(Fig. 462-2)** can be very effective. Pressurization in the bag for 1–2 h often leads to spectacular improvement and, like dexamethasone administration, "buys time." Thus, in certain high-altitude locations (e.g., remote pilgrimage sites), the decision to bring along the lightweight hyperbaric chamber may prove lifesaving. Like nifedipine, phosphodiesterase-5 inhibitors have no role in the treatment of AMS or HACE. Finally, short-term oxygen inhalation using small cannisters of oxygen or by visiting oxygen bars is unhelpful in the prevention of AMS.

FIGURE 462-2 A hyperbaric bag. The cylindrical, portable (<7 kg) nylon bag has a one-way valve to prevent carbon dioxide buildup. A patient with severe acute mountain sickness (AMS), high-altitude cerebral edema (HACE), or high-altitude pulmonary edema (HAPE) is zipped inside the bag, which is continuously inflated with a foot pedal. The increased barometric pressure (2 psi) inside the bag simulates descent; for example, at 4250 m, the equivalent "elevation" inside the bag is ~2100 m. No supplemental oxygen is required.

HIGH-ALTITUDE PULMONARY EDEMA

Risk Factors and Manifestations Unlike HACE (a neurologic disorder), HAPE is primarily a pulmonary problem and therefore is not necessarily preceded by AMS. HAPE develops within 2–4 days after arrival at high altitude; it rarely occurs after >4 or 5 days at the same altitude, probably because of remodeling and adaptation that render the pulmonary vasculature less susceptible to the effects of hypoxia. A rapid rate of ascent, a history of HAPE, respiratory tract infections, and cold environmental temperatures are risk factors. Men are more susceptible than women. People with abnormalities of the cardiopulmonary circulation leading to pulmonary hypertension—e.g., mitral stenosis, primary pulmonary hypertension, and unilateral absence of the pulmonary artery—may be at increased risk of HAPE, even at moderate altitudes. Although patent foramen ovale, a common condition, is four times more common among HAPE-susceptible individuals than in the general population, there is no compelling evidence to suggest causal effect. Echocardiography is recommended when HAPE develops at relatively low altitudes (<3000 m) and whenever cardiopulmonary abnormalities predisposing to HAPE are suspected. The differential diagnosis of HAPE includes anxiety attack, pneumonia, pneumothorax, and pulmonary embolism.

The initial manifestation of HAPE may be a reduction in exercise tolerance greater than that expected at the given altitude. Although a dry, persistent cough may presage HAPE and may be followed by the production of blood-tinged sputum, cough in the mountains is almost universal and the mechanism is poorly understood. Tachypnea and tachycardia, even at rest, are important markers as illness progresses. Crackles may be heard on auscultation but are not diagnostic. HAPE may be accompanied by signs of HACE. Patchy or localized opacities **(Fig. 462-3)** or streaky interstitial edema may be noted on chest radiography. In the past, HAPE was mistaken for pneumonia due to the cold or for heart failure due to hypoxia and exertion. Kerley B lines or a bat-wing appearance are not seen on radiography. Electrocardiography may reveal right ventricular strain or even hypertrophy. Hypoxemia and respiratory alkalosis are consistently present unless the patient is taking acetazolamide, in which case metabolic acidosis may supervene. Assessment of arterial blood gases is not necessary in the evaluation of HAPE; an oxygen saturation reading with a pulse oximeter is generally adequate. The existence of a subclinical form of HAPE has been suggested by an increased alveolar-arterial oxygen gradient in Everest climbers near the summit, but hard evidence correlating this abnormality with the development of clinically relevant HAPE is

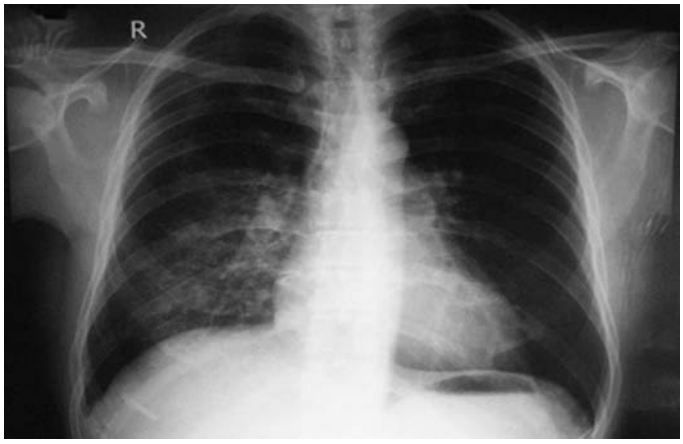

FIGURE 462-3 Chest radiograph of a patient with high-altitude pulmonary edema shows opacity in the right middle and lower zones simulating pneumonic consolidation. The opacity cleared almost completely in 2 days with descent and supplemental oxygen.

lacking. Comet-tail scoring—an ultrasound technique initially validated in cardiogenic pulmonary edema—has been used for evaluation of extravascular lung water at high altitude and has proven to be useful in detecting HAPE (clinical or subclinical) and even in ascertaining whether the presence of extravascular lung water is a harbinger of HAPE in patients with AMS.

Pathophysiology HAPE is a noncardiogenic pulmonary edema with normal pulmonary artery wedge pressure. It is characterized by patchy pulmonary hypoxic vasoconstriction that leads to overperfusion in some areas. This abnormality leads in turn to increased pulmonary capillary pressure (>18 mmHg) and capillary "stress" failure. The exact mechanism for this hypoxic vasoconstriction is unknown. Endothelial dysfunction due to hypoxia may play a role by impairing the release of nitric oxide, an endothelium-derived vasodilator. At high altitude, HAPE-prone persons have reduced levels of exhaled nitric oxide. The effectiveness of phosphodiesterase-5 inhibitors in alleviating altitude-induced pulmonary hypertension, decreased exercise tolerance, and hypoxemia supports the role of nitric oxide in the pathogenesis of HAPE. One study demonstrated that prophylactic use of tadalafil, a phosphodiesterase-5 inhibitor, decreases the risk of HAPE by 65%. In contrast, the endothelium also synthesizes endothelin-1, a potent vasoconstrictor whose concentrations are higher than average in HAPE-prone mountaineers.

Exercise and cold lead to increased pulmonary intravascular pressure and may predispose to HAPE. In addition, hypoxia-triggered increases in sympathetic drive may lead to pulmonary venoconstriction and extravasation into the alveoli from the pulmonary capillaries. Consistent with this concept, phentolamine, which elicits α-adrenergic blockade, improves hemodynamics and oxygenation in HAPE more than do other vasodilators. The study of tadalafil cited above also investigated dexamethasone in the prevention of HAPE. Surprisingly, dexamethasone reduced the incidence of HAPE by 78%—a greater decrease than with tadalafil. Besides possibly increasing the availability of endothelial nitric oxide, dexamethasone may have altered the excessive sympathetic activity associated with HAPE: the heart rate of participants in the dexamethasone arm of the study was significantly lowered. Finally, people susceptible to HAPE also display enhanced sympathetic activity during short-term hypoxic breathing at low altitudes.

Because many patients with HAPE have fever, peripheral leukocytosis, and an increased erythrocyte sedimentation rate, inflammation has been considered an etiologic factor in HAPE. However, strong evidence suggests that inflammation in HAPE is an epiphenomenon rather than the primary cause. Nevertheless, inflammatory processes (e.g., those elicited by viral respiratory tract infections) do predispose persons to HAPE—even those who are constitutionally resistant to its development.

Another proposed mechanism for HAPE is impaired transepithelial clearance of sodium and water from the alveoli. β-Adrenergic agonists upregulate the clearance of alveolar fluid in animal models. In a single double-blind, randomized, placebo-controlled study of HAPE-susceptible mountaineers, prophylactic inhalation of the β-adrenergic agonist salmeterol reduced the incidence of HAPE by 50%. However, the dosage of salmeterol (125 μg twice daily) used was very high, which could result in excessive tachycardia and tremors. Other effects of β agonists may also contribute to the prevention of HAPE, and these findings are in keeping with the concept that alveolar fluid clearance may play a pathogenic role in this illness.

Prevention and Treatment (Table 462-1) Allowing sufficient time for acclimatization by ascending gradually (as discussed above for AMS and HACE) is the best way to prevent HAPE. Sustained-release nifedipine (30 mg), given twice daily, prevents HAPE in people who must ascend rapidly or who have a history of HAPE. Other drugs for the prevention of HAPE are listed in Table 462-1 (footnote e). Although dexamethasone is listed for prevention, its adverse effect profile requires close monitoring. Acetazolamide has been shown to blunt hypoxic pulmonary vasoconstriction in animal models, and this observation warrants further study in HAPE prevention. However, one large study failed to show a decrease in pulmonary vasoconstriction in partially acclimatized individuals given acetazolamide. Inhaled salmeterol is not recommended as clinical experience with this drug is limited at high altitude. Finally, potent diuretics like furosemide should be avoided in the treatment of HAPE. Early recognition is paramount in the treatment of HAPE, especially when it is not preceded by the AMS symptoms of headache and nausea. Fatigue and dyspnea at rest may be the only initial manifestations. Descent and the use of supplementary oxygen (aimed at bringing oxygen saturation to >90%) are the most effective therapeutic interventions. Exertion should be kept to a minimum, and the patient should be kept warm. Hyperbaric therapy (Fig. 462-2) in a portable altitude chamber may be lifesaving, especially if descent is not possible and oxygen is not available. Oral sustained-release nifedipine (30 mg twice daily) can be used as adjunctive therapy. No studies have investigated phosphodiesterase-5 inhibitors in the treatment of HAPE, but reports have described their use in clinical practice. The mainstays of treatment remain descent and (if available) oxygen.

In AMS, if symptoms abate (with or without acetazolamide), the patient may reascend gradually to a higher altitude. Unlike that in acute respiratory distress syndrome (another noncardiogenic pulmonary edema), the architecture of the lung in HAPE is usually well preserved, with rapid reversibility of abnormalities (Fig. 462-3). This fact has allowed some people with HAPE to reascend slowly after a few days of descent and rest. In HACE, reascent after a few days may not be advisable during the same trip.

OTHER HIGH-ALTITUDE PROBLEMS

Sleep Impairment The mechanisms underlying sleep problems, which are among the most common adverse reactions to high altitude, include increased periodic breathing; changes in sleep architecture, with increased time in lighter sleep stages; and changes in rapid eye movement sleep. Sojourners should be reassured that sleep quality improves with acclimatization. In cases where drugs do need to be used, acetazolamide (125 mg before bedtime) is especially useful because this agent decreases hypoxemic episodes and alleviates sleeping disruptions caused by excessive periodic breathing. Whether combining acetazolamide with temazepam or zolpidem is more effective than administering acetazolamide alone is unknown. In combinations, the doses of temazepam and zolpidem should not be increased by >10 mg at high altitudes. Limited evidence suggests that diazepam causes hypoventilation at high altitudes and therefore is contraindicated. For trekkers with obstructive sleep apnea who are using a continuous positive airway pressure (CPAP) machine, the addition of acetazolamide, which will decrease centrally mediated sleep apnea, may be helpful. There is evidence to show that obstructive sleep apnea at high altitude may decrease and "convert" to central sleep apnea.

Gastrointestinal Issues High-altitude exposure may be associated with increased gastric and duodenal bleeding, but further studies are required to determine whether there is a causal effect. Because of decreased atmospheric pressure and consequent intestinal gas expansion at high altitudes, many sojourners experience abdominal bloating and distension as well as excessive flatus expulsion. In the absence of diarrhea, these phenomena are normal, if sometimes uncomfortable. Accompanying diarrhea, however, may indicate the involvement of bacteria or *Giardia* parasites, which are common at many high-altitude locations in the developing world. Prompt treatment with fluids and empirical antibiotics may be required to combat dehydration in the mountains. Hemorrhoids are common on high-altitude treks; treatment includes hot soaks, application of hydrocortisone ointment, and measures to avoid constipation.

High-Altitude Cough High-altitude cough can be debilitating and is sometimes severe enough to cause rib fracture, especially at >5000 m. The etiology of this common problem is probably multifactorial. Although high-altitude cough has been attributed to inspiration of cold dry air, this explanation appears not to be sufficient by itself; in long-duration studies in hypobaric chambers, cough has occurred

despite controlled temperature and humidity. The implication is that hypoxia also plays a role. Exercise can precipitate cough at high altitudes, possibly because of water loss from the respiratory tract. In general, infection does not seem to be a common etiology. Many trekkers find it useful to wear a balaclava to trap some moisture and heat. In most situations, cough resolves upon descent.

High-Altitude Neurologic Events Unrelated to "Altitude Illness" Transient ischemic attacks (TIAs) and strokes have been well described in high-altitude sojourners outside the setting of altitude sickness. However, these descriptions are not based on cause (hypoxia) and effect. In general, symptoms of AMS present gradually, whereas many of these neurologic events happen suddenly. The population that suffers strokes and TIAs at sea level is generally an older age group with other risk factors, whereas those so afflicted at high altitudes are generally younger and probably have fewer risk factors for atherosclerotic vascular disease. Other mechanisms (e.g., migraine, vasospasm, focal edema, hypocapneic vasoconstriction, hypoxia in the watershed zones of minimal cerebral blood flow, or cardiac right-to-left shunt) may be operative in TIAs and strokes at high altitude.

Subarachnoid hemorrhage, transient global amnesia, delirium, and cranial nerve palsies (e.g., lateral rectus palsy) occurring at high altitudes but outside the setting of altitude sickness have been well described. Syncope is common at moderately high altitudes, generally occurs shortly after ascent, usually resolves without descent, and appears to be a vasovagal event related to hypoxemia. Seizures occur rarely with HACE, but hypoxemia and hypocapnia, which are prevalent at high altitudes, are well-known triggers that may contribute to new or breakthrough seizures in predisposed individuals. Nevertheless, the consensus among experts is that sojourners with well-controlled seizure disorders can ascend to high altitudes.

Finally, persons with hypercoagulable conditions (e.g., antiphospholipid syndrome, protein C deficiency) who are asymptomatic at sea level may experience cerebral venous thrombosis (possibly due to enhanced blood viscosity triggered by polycythemia and dehydration) at high altitudes. Proper history taking, examination, and prompt investigations where possible will help define these conditions as entities separate from altitude sickness. Administration of oxygen (where available) and prompt descent are the cornerstones of treatment of most of these neurologic conditions.

Ocular Problems Ocular issues are common in sojourners to high altitudes. Hypoxemia induced by altitude leads to increased retinal blood flow, which can be visible as engorged retinal veins on ophthalmoscopic examination. Both high flow and hypoxemic vascular damage causing permeability have been implicated in a breakdown of the blood-retina barrier and the formation of retinal hemorrhages. Blot, dot, flame, and white-centered hemorrhages can be observed. These hemorrhages usually resolve spontaneously with descent, with only mild symptoms and no lasting visual damage in most healthy eyes. The exception is hemorrhage in the macular area. Macular hemorrhages can cause devastating initial visual loss, particularly if bilateral, and have been reported to cause permanently decreased vision in a few cases.

Stroke syndromes such as retinal vein occlusion, retinal artery occlusion, ischemic optic neuropathy, and cortical visual loss have all been reported. With unilateral vision loss, it is always important to check for a relative afferent pupillary defect. Increased hematocrit combined with dehydration may contribute to these maladies. Glaucomatous optic nerve damage may progress with hypoxemia of altitude. Acetazolamide is helpful both in combating the respiratory alkalosis that comes with increased ventilation at high altitude and in lowering the interocular pressure; its use should be considered in patients with stable controlled glaucoma. Macular degeneration and diabetic eye disease are not directly exacerbated by ascent to high altitude. Dry eye and solar damage to the cornea, known as "snow blindness," are common. Wearing of high-quality UV-blocking sunglasses, even on cloudy days, and attention to protecting and supplementing the tear film with artificial tear drops can greatly improve comfort and vision. Although modern refractive surgeries, such as photorefractive keratectomy (PRK) and laser in situ keratomileusis (LASIK), are stable at high altitude, patients who have undergone radial keratotomy should be cautioned that hypoxemia to the cornea can lead to swelling that shifts the refraction during ascent.

Psychological/Psychiatric Problems Delirium characterized by a sudden change in mental status, a short attention span, disorganized thinking, and an agitated state during the period of confusion has been well described in mountain climbers and trekkers without a prior history. In addition, anxiety attacks, often triggered at night by excessive periodic breathing, are well documented. The contribution of hypoxia to these conditions is unknown. Expedition medical kits need to include antipsychotic injectable drugs to control psychosis in patients in remote high-altitude locations.

PREEXISTING MEDICAL ISSUES

Because travel to high altitudes is increasingly popular, common conditions such as hypertension, coronary artery disease, and diabetes are more frequently encountered among high-altitude sojourners. This situation is of particular concern for the millions of elderly pilgrims with medical problems who visit high-altitude sacred areas (e.g., in the Himalayas) each year. In recent years, high-altitude travel has attracted intrepid trekkers who are taking immunosuppressive medications (e.g., kidney transplant recipients or patients undergoing chemotherapy). Recommended vaccinations and other precautions (e.g., hand washing) may be especially important for this group. Although most of these medical conditions do not appear to influence susceptibility to altitude illness, they may be exacerbated by ascent to altitude, exertion in cold conditions, and hypoxemia. Advice regarding the advisability of high-altitude travel and the impact of high-altitude hypoxia on these preexisting conditions is becoming increasingly relevant, but there are no evidence-based guidelines. In addition, recommendations made for relatively low altitudes (~3000 m) may not hold true for higher altitudes (>4000 m), where hypoxic stress is greater. Personal risks and benefits must be clearly thought through before ascent.

Hypertension At high altitudes, enhanced sympathetic activity may lead to a transient rise in blood pressure. Occasionally, nonhypertensive, healthy, asymptomatic trekkers have pathologically high blood pressure at high altitude that rapidly normalizes without medicines on descent. Sojourners should continue to take their antihypertensive medications at high altitudes. Importantly, hypertensive patients are not more likely than others to develop altitude illness. Because the probable mechanism of high-altitude hypertension is α-adrenergic activity, anti-α-adrenergic drugs such as prazosin have been suggested for symptomatic patients and those with labile hypertension. It is best to start taking the drug several weeks before the trip and to carry a sphygmomanometer if a trekker has labile hypertension. Sustained-release nifedipine may also be useful. A recent observational cohort study of 672 hypertensive and nonhypertensive trekkers in the Himalayas showed that most travelers, including those with well-controlled hypertension, can be reassured that their blood pressure will remain relatively stable at high altitude. Although blood pressure may be extremely elevated at high altitude in normotensive and hypertensive people, it is unlikely to cause symptoms.

Coronary Artery Disease Myocardial oxygen demand and maximal heart rate are reduced at high altitudes because the VO_2 max (maximal oxygen consumption) decreases with increasing altitude. This effect may explain why signs of cardiac ischemia or dysfunction usually are not seen in healthy persons at high altitudes. Asymptomatic, fit individuals with no risk factors need not undergo any tests for coronary artery disease before ascent. For persons with ischemic heart disease, previous myocardial infarction, angioplasty, and/or bypass surgery, an exercise treadmill test is indicated. A strongly positive treadmill test is a contraindication for high-altitude trips. Patients with poorly controlled arrhythmias should avoid high-altitude travel, but patients with arrhythmias that are well controlled with antiarrhythmic medications do not seem to be at increased risk. Sudden cardiac deaths

are not noted with a greater frequency in the Alps than at lower altitudes; although sudden cardiac deaths are encountered every trekking season in the higher Himalayan range, accurate documentation is lacking.

Cerebrovascular Disease Patients with TIAs should avoid travel to high altitude for at least 3 months. Patients with known cerebral aneurysm should also avoid high-altitude travel because of possible rupture of the aneurysm due to increased cerebral blood flow at high altitude.

Migraine Trekkers with a history of migraine may have an increased likelihood of suffering from AMS and may also be predisposed to headaches including altered character of their migraine presenting with focal neurologic deficits. Oxygen inhalation may reduce AMS-triggered headache, whereas a migraine headache usually persists even after 10–15 min of oxygen inhalation.

Asthma Although cold air and exercise may provoke acute bronchoconstriction, asthmatic patients usually have fewer problems at high than at low altitudes, possibly because of decreased allergen levels and increased circulating catecholamine levels. Nevertheless, asthmatic individuals should carry all their medications, including oral glucocorticoids, with proper instructions for use in case of an exacerbation. Severely asthmatic persons should be cautioned against ascending to high altitudes.

Pregnancy In general, low-risk pregnant women ascending to 3000 m are not at special risk except for the relative unavailability of medical care in many high-altitude locations, especially in developing countries. Despite the lack of firm data on this point, venturing higher than 3000 m to altitudes at which oxygen saturation drops steeply seems unadvisable for pregnant women.

Obesity Although living at a high altitude has been suggested as a means of controlling obesity, obesity has also been reported to be a risk factor for AMS, probably because nocturnal hypoxemia is more pronounced in obese individuals. Hypoxemia may also lead to greater pulmonary hypertension, thus possibly predisposing the trekker to HAPE.

Sickle Cell Disease High altitude is one of the rare environmental exposures that occasionally provokes a crisis in persons with sickle cell anemia. Even when traversing mountain passes as low as 2500 m, people with sickle cell anemia have been known to have a vaso-occlusive crisis. Patients with known sickle cell anemia who need to travel to high altitudes should use supplemental oxygen and travel with caution. Thalassemia has not been known to cause problems at high altitude.

Diabetes Mellitus Well-controlled diabetes is not a contraindication for travel to high altitude. Most of the high-altitude diabetes advice is based on patients with type 1 diabetes and not type 2 diabetic patients with comorbidities. An eye examination before travel may be useful. Insulin pumps are increasingly used, but bubble formation in the system may need to be closely monitored. Diabetic patients need to carry a reliable glucometer. Ready access to sweets is also essential. It is important for companions of diabetic trekkers to be fully aware of potential problems like hypoglycemia. Dexamethasone, as far as possible, should be avoided in the prevention or treatment of altitude illness in a diabetic patient.

Chronic Lung Disease Depending on disease severity and access to medical care, preexisting lung disease may not always preclude high-altitude travel. A proper pretravel evaluation must be conducted. Supplemental oxygen may be required if the predicted PaO_2 for the altitude is <50–55 mmHg. Preexisting pulmonary hypertension may also need to be assessed in these patients. If the result is positive, patients should be discouraged from ascending to high altitudes; if such travel is necessary, treatment with sustained-release nifedipine (20 mg twice a day) should be considered. Small-scale studies have revealed that when patients with bullous disease reach ~5000 m, bullous expansion and pneumothorax are not noted. Compared with information on chronic obstructive pulmonary disease, fewer data exist about the safety of travel to high altitude for people with pulmonary fibrosis, but acute exacerbation of pulmonary fibrosis has been seen at high altitude. A handheld pulse oximeter can be useful to check for oxygen saturation.

Chronic Kidney Disease Patients with chronic kidney disease can tolerate short-term stays at high altitudes, but theoretical concern persists about progression to end-stage renal disease. Acetazolamide, the drug most commonly used for altitude sickness, should be avoided by anyone with preexisting metabolic acidosis, which can be exacerbated by this drug. In addition, the acetazolamide dosage should be adjusted when the glomerular filtration rate falls to <50 mL/min, and the drug should not be used at all if this value falls to <10 mL/min.

Cirrhosis Of patients with cirrhosis, 16% may have portopulmonary arterial hypertension, and 32% may have hepatopulmonary syndrome; these conditions may be detrimental at high altitude as they may cause exaggerated hypoxemia. Thus, screening for these problems is important in cirrhotic patients planning a high-altitude trip. In addition, acetazolamide may be inadvisable in these patients as the drug may increase the risk of hepatic encephalopathy.

Dental Problems Air resulting from decay in the root system could expand on ascent and lead to increasing pain. A good dental checkup before a trekking or climbing trip may be prudent.

CHRONIC MOUNTAIN SICKNESS AND HIGH-ALTITUDE PULMONARY HYPERTENSION IN HIGHLANDERS

The largest populations of highlanders live in the South American Andes, the Tibetan Plateau, and parts of Ethiopia. Chronic mountain sickness (*Monge's disease*) is a disease in highlanders that is characterized by excessive erythrocytosis with moderate to severe pulmonary hypertension leading to cor pulmonale. This condition was originally described in South America and has also been documented in Colorado and in the Han Chinese population in Tibet; it is much less common in Tibetans or in Ethiopian highlanders. Migration to a low altitude results in the resolution of chronic mountain illness. Venesection and acetazolamide are helpful.

High-altitude pulmonary hypertension is also a subacute disease of long-term high-altitude residents. Unlike Monge's disease, this syndrome is characterized primarily by pulmonary hypertension (not erythrocytosis) leading to heart failure. Indian soldiers living at extreme altitudes for prolonged periods and Han Chinese infants born in Tibet have presented with the adult and infantile forms, respectively. High-altitude pulmonary hypertension bears a striking pathophysiologic resemblance to brisket disease in cattle. Descent to a lower altitude is curative.

463 Hyperbaric and Diving Medicine

Michael H. Bennett, Simon J. Mitchell

WHAT IS HYPERBARIC AND DIVING MEDICINE?

Hyperbaric medicine is the treatment of health disorders using whole-body exposure to pressures >101.3 kPa (1 atmosphere or 760 mmHg). In practice, this almost always means the administration of *hyperbaric oxygen therapy* (HBO_2T). The Undersea and Hyperbaric Medical Society (UHMS) defines HBO_2T as: "an intervention in which an individual breathes near 100% oxygen intermittently while inside a hyperbaric chamber that is pressurized to greater than sea level pressure (1 atmosphere absolute, or ATA). For clinical purposes, the pressure must equal or exceed 1.4 ATA." The chamber is an airtight vessel variously called a hyperbaric chamber, recompression chamber, or decompression chamber, depending on the clinical and historical context. Such chambers may be capable of compressing a single patient (a monoplace chamber) or multiple patients and attendants as required (a multiplace chamber) **(Figs. 463-1 and 463-2)**. Historically, these compression chambers were first used for the treatment of divers and compressed air workers suffering decompression sickness (DCS; "the bends"). Although the prevention and treatment of disorders arising after decompression in diving, aviation, and space flight have developed into a specialized field of their own, they remain closely linked to the broader practice of hyperbaric medicine.

Despite an increased understanding of mechanisms and an improving evidence basis, hyperbaric medicine has struggled to achieve widespread recognition as a "legitimate" therapeutic measure. There are several contributing factors, but high among them are a poor grounding in general oxygen physiology and oxygen therapy at medical schools and a continuing tradition of charlatans advocating hyperbaric therapy (often using air) as a panacea. Funding for both basic and clinical research has been difficult in an environment where the pharmacologic agent under study is abundant, cheap, and unpatentable. There are signs of an improved appreciation of the potential importance of HBO_2T with significant National Institutes of Health (NIH) funding for mechanisms research, from the U.S. military for clinical investigation, and as evidenced by the recent appreciation of HBO_2T as a potentially useful tool for improving oxygenation in severe COVID-19 (see "Further Readings").

MECHANISMS OF HYPERBARIC OXYGEN

Increased hydrostatic pressure will reduce the volume of any bubbles present within the body (see "Diving Medicine"), and this is partly responsible for the success of prompt recompression in DCS and arterial gas embolism. Supplemental oxygen breathing has a dose-dependent effect on oxygen transport, ranging from improvement in hemoglobin oxygen saturation when a few liters per minute are delivered by simple mask at 101.3 kPa (1 ATA) to raising the dissolved plasma oxygen sufficiently to sustain life without the need for hemoglobin at all when 100% oxygen is breathed at 303.9 kPa (3 ATA). Most HBO_2T regimens involve oxygen breathing at between 202.6 and 283.6 kPa (2 and 2.8 ATA), and the resultant increase in arterial oxygen tensions to >133.3 kPa (1000 mmHg) has widespread physiologic and pharmacologic consequences **(Fig. 463-3)**.

FIGURE 463-1 A monoplace chamber. *(Prince of Wales Hospital, Sydney.)*

FIGURE 463-2 A chamber designed to treat multiple patients. *(Karolinska University Hospital.)*

One direct consequence of such high intravascular tension is to increase greatly the effective capillary-tissue diffusion distance for oxygen such that oxygen-dependent cellular processes can resume in hypoxic tissues. Important as this may be, the mechanism of action is not limited to this restoration of oxygenation in hypoxic tissue. Indeed, there are pharmacologic effects that are profound and long-lasting. Although removal from the hyperbaric chamber results in a rapid return of poorly vascularized tissues to their hypoxic state, even a single dose of HBO_2T produces changes in fibroblast, leukocyte and angiogenic functions, and antioxidant defenses that persist many hours after oxygen tensions are returned to pretreatment levels.

It is widely accepted that oxygen in high doses produces adverse effects due to the production of reactive oxygen species (ROS) such as superoxide (O_2^-) and hydrogen peroxide (H_2O_2). It has become increasingly clear over the past decade that both ROS and reactive nitrogen species (RNS) such as nitric oxide (NO) participate in diverse intracellular signaling pathways involved in the production of a range of cytokines, growth factors, and other inflammatory and repair modulators. Such mechanisms are complex and at times apparently paradoxical. For example, when used to treat chronic hypoxic wounds, HBO_2T has been shown to enhance the clearance of cellular debris and bacteria by providing the substrate for macrophage phagocytosis; stimulate growth factor synthesis by increased production and stabilization of hypoxia-inducible factor 1 (HIF-1); inhibit leukocyte activation and adherence to damaged endothelium; and mobilize CD34+ pluripotent vasculogenic progenitor cells from the bone marrow. The interactions between these mechanisms remain a very active field of investigation. One exciting development is the concept of *hyperoxic preconditioning* in which a short exposure to HBO_2 can induce tissue protection against future hypoxic/ischemic insult, most likely through an inhibition of mitochondrial permeability transition pore (MPTP) opening and the release of cytochrome c. By targeting these mechanisms of cell death during reperfusion events, HBO_2 has potential applications in a variety of settings including organ transplantation. One randomized clinical trial suggested that HBO_2T prior to coronary artery bypass grafting reduces biochemical markers of ischemic stress and improves neurocognitive outcomes.

ADVERSE EFFECTS OF THERAPY

HBO_2T is generally well tolerated and safe in clinical practice. About 17% of patients experience an adverse event at some time during their treatment course, and most are mild and self-limiting. Adverse effects

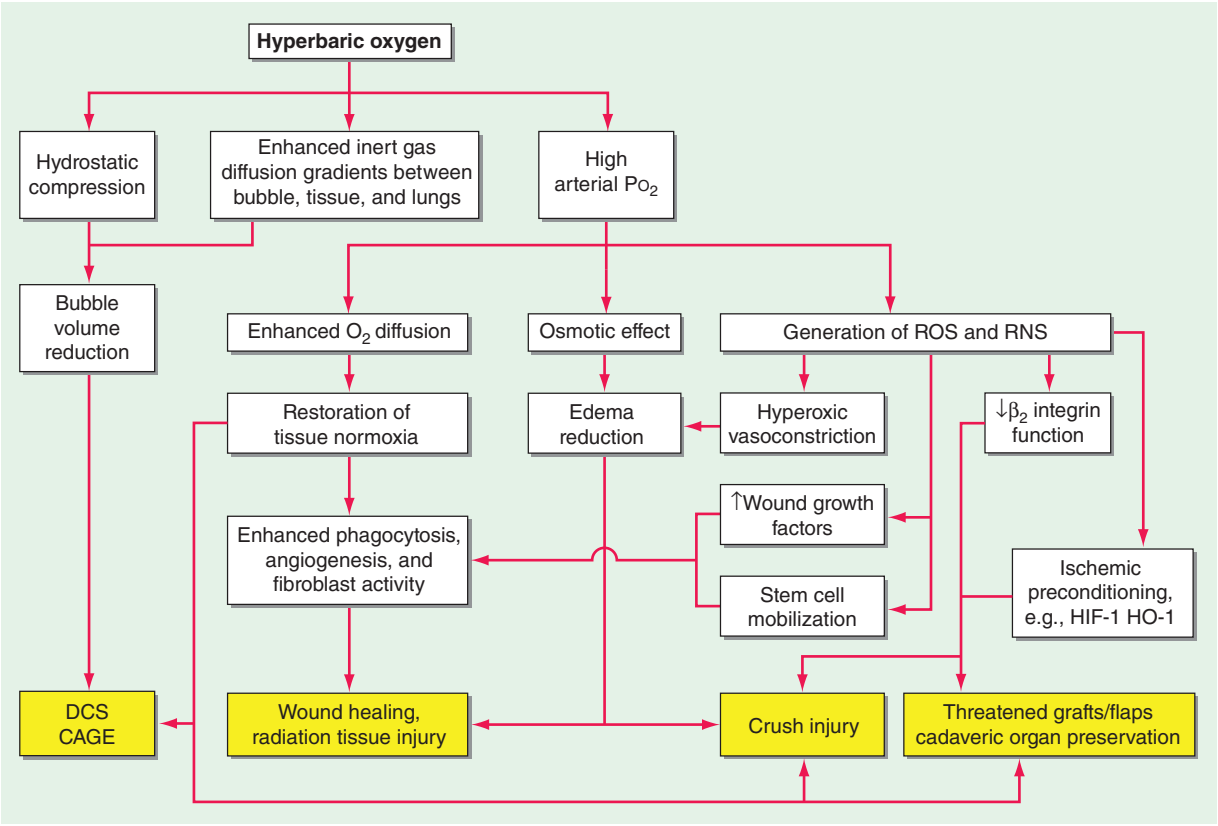

FIGURE 463-3 Mechanisms of action of hyperbaric oxygen. There are many consequences of compression and oxygen breathing. The cell-signaling effects of hyperbaric oxygen therapy (HBO_2T) are the least understood but potentially most important. Examples of indications for use are shown in the shaded boxes. CAGE, cerebral arterial gas embolism; DCS, decompression sickness; HIF-1, hypoxia-inducible factor-1; HO-1, hemoxygenase 1; RNS, reactive nitrogen species; ROS, reactive oxygen species.

are associated with both alterations in pressure (barotrauma) and the administration of oxygen.

BAROTRAUMA

Barotrauma occurs when any noncompliant gas-filled space within the body does not equalize with environmental pressure during compression or decompression. About 10% of patients complain of some difficulty equalizing middle-ear pressure early in compression, and although most of these problems are minor and can be overcome with training, 2–5% of conscious patients require middle-ear ventilation tubes or formal grommets across the tympanic membrane. Unconscious patients cannot equalize and should have middle-ear ventilation tubes placed prior to compression if possible. Other less common sites for barotrauma of compression include the respiratory sinuses and dental caries. The lungs are potentially vulnerable to barotrauma of decompression as described below in the section on diving medicine, but the decompression following HBO_2T is so slow that pulmonary gas trapping is extremely rare in the absence of an undrained pneumothorax or lesions such as bullae.

OXYGEN TOXICITY

The practical limit to the dose of oxygen, either in a single treatment session or in a series of daily sessions, is oxygen toxicity. The most common acute manifestation is a seizure, often preceded by anxiety and agitation, during which time a switch from oxygen to air breathing may avoid the convulsion. Hyperoxic seizures are typically generalized tonic-clonic seizures followed by a variable postictal period. The cause is an overwhelming of the antioxidant defense systems within the brain. Although clearly dose-dependent, onset is very variable both between individuals and within the same individual on different days. In routine clinical hyperbaric practice, the incidence is ~1:1500 to 1:3000 compressions.

Chronic oxygen poisoning most commonly manifests as myopic shift. This is due to alterations in the refractive index of the lens following oxidative damage that reduces the solubility of lenticular proteins in a process similar to that associated with senescent cataract formation. Up to 75% of patients show deterioration in visual acuity after a course of 30 treatments at 202.6 kPa (2 ATA). Although most return to pretreatment values 6–12 weeks after cessation of treatment, a small proportion do not recover. A more rapid maturation of preexisting cataracts has occasionally been associated with HBO_2T. Although a theoretical problem, the development of pulmonary oxygen toxicity over time does not seem to be problematic in practice—probably due to the intermittent nature of the exposure.

CONTRAINDICATIONS TO HYPERBARIC OXYGEN

There are few absolute contraindications to HBO_2T. The most commonly encountered is an untreated pneumothorax. A pneumothorax may expand rapidly on decompression and come under tension. Prior to any compression, patients with a pneumothorax should have a patent chest drain in place. The presence of other obvious risk factors for pulmonary gas trapping such as bullae should trigger a very cautious analysis of the risks of treatment versus benefit. Prior bleomycin treatment deserves special mention because of its association with a partially dose-dependent pneumonitis in ~20% of people. These individuals appear to be at particular risk for rapid deterioration of ventilatory function following exposure to high oxygen tensions. The relationship between distant bleomycin exposure and subsequent risk of pulmonary oxygen toxicity is uncertain; however, late pulmonary fibrosis is a potential complication of bleomycin, and any patient with a history of receiving this drug should be carefully counseled prior to exposure to HBO_2T. For those recently exposed to doses >300,000 IU (200 mg) and whose course was complicated by a respiratory reaction to bleomycin, compression should be avoided except in a life-threatening situation.

INDICATIONS FOR HYPERBARIC OXYGEN

The appropriate indications for HBO_2T are controversial and evolving. Practitioners in this area are in an unusual position. Unlike most branches of medicine, hyperbaric physicians do not deal with a range of disorders within a defined organ system, nor are they masters of a therapy specifically designed for a single category of disorders.

TABLE 463-1 Current List of Indications for Hyperbaric Oxygen Therapy

1. Air or gas embolism (includes diving-related, iatrogenic, and accidental causes)
2. Carbon monoxide poisoning (including poisoning complicated by cyanide poisoning)
3. Clostridial myositis and myonecrosis (gas gangrene)
4. Crush injury, compartment syndrome, and acute traumatic ischemias
5. Decompression sickness
6. Arterial insufficiency including central retinal arterial occlusion and problem wounds
7. Severe anemia
8. Intracranial abscess
9. Necrotizing soft tissue infections (e.g., Fournier's gangrene)
10. Osteomyelitis (refractory to other therapy)
11. Delayed radiation injury (soft-tissue injury and bony necrosis)
12. Skin grafts and flaps (compromised)
13. Acute thermal burn injury
14. Sudden sensorineural hearing loss

Source: The Undersea and Hyperbaric Medical Society (2021).

Inevitably, the encroachment of hyperbaric physicians into other medical fields generates suspicion from specialist practitioners in those fields. At the same time, this relatively benign therapy, the prescription and delivery of which requires no medical license in most jurisdictions (including the United States), attracts both charlatans and well-motivated proselytizers who tout the benefits of oxygen for a plethora of chronic incurable diseases. This battle on two fronts has meant that mainstream hyperbaric physicians have been particularly careful to claim effectiveness only for those conditions where there is a reasonable body of supporting evidence.

In 1977, the UHMS systematically examined claims for the use of HBO_2T in >100 disorders and found sufficient evidence to support routine use in only 12. The Hyperbaric Oxygen Therapy Committee of that organization has continued to update this list periodically with an increasingly formalized system of appraisal for new indications and emerging evidence **(Table 463-1)**. Around the world, other relevant medical organizations have generally taken a similar approach. Indications vary considerably across the globe—particularly those recommended by hyperbaric medical societies in Russia and China where HBO_2T has gained much wider support than in the United States, Europe, and Australasia. Nevertheless, there are now 31 Cochrane reviews summarizing the randomized trial evidence for 27 putative indications, including attempts to examine the cost-effectiveness of HBO_2T. **Table 463-2** is a synthesis of these two approaches and lists the estimated cost of attaining health outcomes with the use of HBO_2T. Any savings associated with alternative treatment strategies avoided as a result of HBO_2T are not accounted for in these estimates (e.g., the avoidance of lower leg amputation in diabetic foot ulcers). Following are short reviews of three important indications currently accepted by the UHMS.

LATE RADIATION TISSUE INJURY

Radiotherapy is a well-established treatment for suitable malignancies. In the United States alone, ~300,000 individuals annually will become long-term survivors of cancer treated by irradiation. Serious radiation-related complications developing months or years after treatment (late radiation tissue injury [LRTI]) will significantly affect between 5 and 15% of those long-term survivors, although incidence varies widely with dose, age, and site. LRTI is most common in the head and neck, chest wall, breast, and pelvis.

Pathology and Clinical Course With time, tissues undergo a progressive deterioration characterized by a reduction in the density of small blood vessels (reduced vascularity) and the replacement of normal tissue with dense fibrous tissue (fibrosis). An alternative model of pathogenesis suggests that rather than a primary hypoxia, the principal trigger is an overexpression of inflammatory cytokines that promote fibrosis, probably through oxidative stress and mitochondrial dysfunction, and a secondary tissue hypoxia. Ultimately, and often triggered by a further physical insult such as surgery or infection, there may be insufficient oxygen to sustain normal function, and the tissue becomes necrotic (radiation necrosis). LRTI may be life-threatening and significantly reduce quality of life. Historically, the management of these injuries has been unsatisfactory. Conservative treatment is usually restricted to symptom management, whereas definitive treatment traditionally entails surgery to remove the affected part and extensive repair. Surgical intervention in an irradiated field is often disfiguring and associated with an increased incidence of delayed healing, breakdown of a surgical wound, or infection. HBO_2T may act by several mechanisms to improve this situation, including edema reduction, vasculogenesis, and enhancement of macrophage activity (Fig. 463-3). The intermittent application of HBO_2 is the only intervention shown to increase the microvascular density in irradiated tissue.

Clinical Evidence The typical course of HBO_2T consists of 30 once-daily compressions to 202.6–243.1 kPa (2–2.4 ATA) for 1.5–2 h each session, often bracketed around surgical intervention if required. Although HBO_2T has been used for LRTI since at least 1975, most clinical studies have been limited to small case series or individual case reports. In a review, Feldmeier and Hampson located 71 such reports involving a total of 1193 patients across eight different tissues. There were clinically significant improvements in the majority of patients, and only 7 of 71 reports indicated a generally poor response to HBO_2T. A Cochrane systematic review with meta-analysis included 14 randomized trials published since 1985 and drew the following conclusions (see Table 463-2 for numbers needed to treat): HBO_2T improves healing in radiation proctitis (relative risk [RR] of healing with HBO_2T, 1.72; 95% confidence interval [CI], 1.0–2.9) and achievement of mucosal cover of bone after hemimandibulectomy and reconstruction of the mandible (RR, 1. 3; 95% CI, 1.1–1.6); HBO_2T prevents the development of osteoradionecrosis following tooth extraction from a radiation field (RR, 1.4; 95% CI, 1.08–1.7) and reduces the risk of wound dehiscence following grafts and flaps in the head and neck (RR, 4.2; 95% CI, 1.1–16.8). Conversely, there was no evidence of benefit in established radiation brachial plexus lesions or brain injury.

SELECTED PROBLEM WOUNDS

A problem wound is any cutaneous ulceration that requires a prolonged time to heal, does not heal, or recurs. In general, wounds referred to hyperbaric facilities are those where sustained attempts to heal by other means have failed. Problem wounds are common and constitute a significant health problem. It has been estimated that 1% of the population of industrialized countries will experience a leg ulcer at some time. The global cost of chronic wound care may be as high as U.S. $25 billion per year.

Pathology and Clinical Course By definition, chronic wounds are indolent or progressive and resistant to the wide array of treatments applied. Although there are many contributing factors, most commonly, these wounds arise in association with one or more comorbidities such as diabetes, peripheral venous or arterial disease, or prolonged pressure (decubitus ulcers). First-line treatments are aimed at correction of the underlying pathology (e.g., vascular reconstruction, compression bandaging, or normalization of blood glucose level), and HBO_2T is an adjunctive therapy to good general wound care practice to maximize the chance of healing.

For most indolent wounds, hypoxia is a major contributor to failure to heal. Many guidelines to patient selection for HBO_2T include the interpretation of transcutaneous oxygen tensions around the wound while breathing air and oxygen at pressure **(Fig. 463-4)**. Wound healing is a complex and incompletely understood process. While it appears that in acute wounds healing is stimulated by the initial hypoxia, low pH, and high lactate concentrations found in freshly injured tissue, some elements of tissue repair are extremely oxygen dependent, for example, collagen elaboration and deposition by fibroblasts and bacterial killing by macrophages. In this complicated interaction between

TABLE 463-2 Selected Indications for Which There Is Promising Efficacy for the Application of Hyperbaric Oxygen Therapy

DIAGNOSIS	OUTCOME (NUMBER OF SESSIONS)	NNT AND 95% CI	ESTIMATED COST TO PRODUCE ONE EXTRA FAVORABLE OUTCOME AND 95% CI (USD)	COMMENTS AND RECOMMENDATIONS
Radiation tissue injury	**More information is required on the subset of disease severity, the affected tissue type that is most likely to benefit, and the time over which benefit may persist.**			
	Resolved proctitis (30)	3	22,392	Large ongoing multicenter trial
		2–11	14,928–82,104	
	Healed mandible (30)	4	29,184	Based on one poorly reported study
		2–8	14,592–58,368	
	Mucosal cover in ORN (30)	3	29,888	Based on one poorly reported study
		2–4	14,592–29,184	
	Bony continuity in ORN (30)	4	29,184	Based on one poorly reported study
		2–8	14,592–58,368	
	Prevention of ORN after dental extraction (30)	4	29,184	Based on a single study
		2–13	14,592–94,848	
	Prevention of dehiscence (30)	5	36,480	Based on one poorly reported study
		3–8	21,888–58,368	
Chronic wounds	**More information is required on the subset of disease severity or classification most likely to benefit, the time over which benefit may persist, and the most appropriate oxygen dose. Economic analysis is required.**			
	Diabetic ulcer healed at 1 year (30)	2	14,928	Based on one small study, more research required
		1–5	7464–37,320	
	Diabetic ulcer, major amputation avoided (30)	4	29,856	Three small studies; outcome over a longer time period required
		3–11	22,392–82,104	
ISSNHL	**No evidence of benefit >2 weeks after onset. More research is required to define the role (if any) of HBO_2T in routine therapy.**			
	Improvement of 25% in hearing loss within 2 weeks of onset (15)	5	18,240	Some improvement in hearing, but functional significance unknown
		3–20	10,944–72,960	
Acute coronary syndrome	**More information is required on the subset of disease severity and timing of therapy most likely to result in benefit. Given the potential of HBO_2T in modifying ischemia-reperfusion injury, attention should be given to the combination of HBO_2T and thrombolysis in early management and in the prevention of restenosis after stent placement.**			
	Episode of MACE (5)	4	4864	Based on a single small study; more research required
		3–10	3648–12,160	
	Incidence of significant dysrhythmia (5)	6	7296	Based on a single moderately powered study in the 1970s
		3–24	3648–29,184	
Traumatic brain injury	**Limited evidence that for acute injury HBO_2T reduces mortality but not functional morbidity. Routine use not yet justified.**			
	Mortality (15)	7	34,104	Based on four heterogeneous studies
		4–22	19,488–58,464	
Enhancement of radiotherapy	**There is some evidence that HBO_2T improves local tumor control, reduces mortality for cancers of the head and neck, and reduces the chance of local tumor recurrence in cancers of the head, neck, and uterine cervix.**			
	Head and neck cancer: 5-year mortality (12)	5	14,592	Based on trials performed in the 1970s and 1980s. There may be some confounding by radiation fractionation schedule.
		3–14	8755–40,858	
	Local recurrence 1 year (12)	5	14,592	May no longer be relevant to therapy
		4–8	11,674–23,347	
	Cancer of uterine cervix: Local recurrence at 2 years (20)	5	24,320	As above
		4–8	19,456–38,912	
Decompression illness[a]	**Reasonable evidence for reduced number of HBO_2T sessions but similar outcomes when NSAID added.**			
	Reduction of HBO_2T treatment requirement by 1	5 3–18	N/R	Single appropriately powered randomized trial

[a]Tenoxicam used as an adjunct to recompression on oxygen.

Abbreviations: CI, confidence interval; HBO_2T, hyperbaric oxygen therapy; ISSNHL, idiopathic sudden sensorineural hearing loss; MACE, major adverse cardiac events; NNT, number needed to treat; N/R, not remarkable; NSAID, nonsteroidal anti-inflammatory drug; ORN, osteoradionecrosis; USD, U.S. dollars.

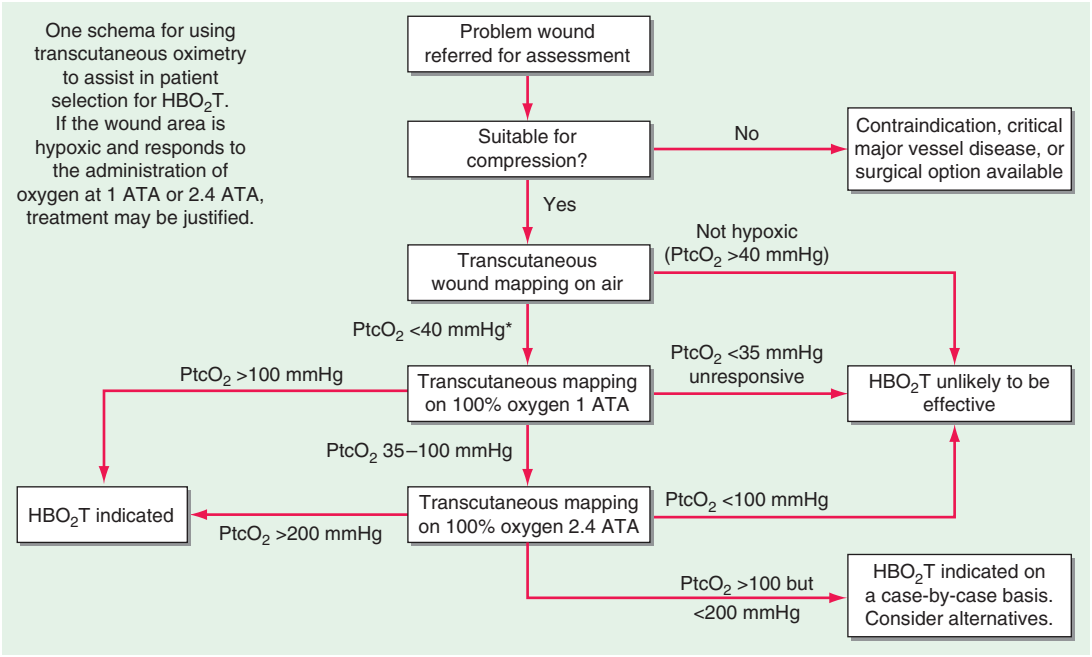

FIGURE 463-4 Determining suitability for hyperbaric oxygen therapy (HBO_2T) guided by transcutaneous oximetry around the wound bed. *In diabetic patients, <50 mmHg may be more appropriate. $PtcO_2$, transcutaneous oxygen pressure.

wound hypoxia and periwound oxygenation, successful healing relies on adequate tissue oxygenation in the area surrounding the fresh wound. Certainly, wounds that lie in hypoxic tissue beds are those that most often display poor or absent healing. Some causes of tissue hypoxia will be reversible with HBO_2T, whereas some will not (e.g., in the presence of severe large vessel disease). When tissue hypoxia can be overcome by a high driving pressure of oxygen in the arterial blood, this can be demonstrated by measuring the tissue partial pressure of oxygen using an implantable oxygen electrode or, more commonly, a modified transcutaneous Clarke electrode.

The intermittent presentation of oxygen to those hypoxic tissues facilitates a resumption of healing. These short exposures to high oxygen tensions have long-lasting effects (at least 24 h) on a wide range of healing processes (Fig. 463-3). The result is a gradual improvement in oxygen tension around the wound that reaches a plateau in experimental studies at ~20 treatments over 4 weeks. Improvements in oxygenation are associated with an eight- to ninefold increase in vascular density over both normobaric oxygen and air-breathing controls.

Clinical Evidence The typical course of HBO_2T consists of 20–30 once-daily compressions to 2–2.4 ATA for 1.5–2 h each session but is highly dependent on the clinical response. There are many case series in the literature supporting the use of HBO_2T for a wide range of problem wounds. Both retrospective and prospective cohort studies suggest that 6 months after a course of therapy, ~70% of indolent ulcers will be substantially improved or healed. Often these ulcers have been present for many months or years, suggesting the application of HBO_2T has a profound effect, either primarily or as a facilitator of other strategies. A recent Cochrane review included 12 randomized controlled trials (RCTs) and concluded that the chance of a diabetic ulcer healing improved with HBO_2T (10 trials; RR, 2.35; 95% CI, 1.19–4.62; $p = .01$). Although there was a trend to benefit with HBO_2T, there was no statistically significant difference in the rate of major amputations (RR, 0.36; 95% CI, 0.11–1.18).

CARBON MONOXIDE POISONING

Carbon monoxide (CO) is a colorless, odorless gas formed during incomplete hydrocarbon combustion. Although CO is an essential endogenous neurotransmitter linked to NO metabolism and activity, it is also a leading cause of poisoning death and, in the United States alone, results in >50,000 emergency department visits per year and ~2000 deaths. Although there are large variations from country to country, about half of nonlethal exposures are due to self-harm. Accidental poisoning is commonly associated with defective or improperly installed heaters, house fires, and industrial exposures. The motor vehicle is by far the most common source of intentional poisoning.

Pathology and Clinical Course The pathophysiology of CO exposure is incompletely understood. CO binds to hemoglobin with an affinity >200 times that of oxygen, directly reducing the oxygen-carrying capacity of blood and further promoting tissue hypoxia by shifting the oxyhemoglobin dissociation curve to the left. CO is also an anesthetic agent that inhibits evoked responses and narcotizes experimental animals in a dose-dependent manner. The associated loss of airway patency together with reduced oxygen carriage in blood may cause death from acute arterial hypoxia in severe poisoning. CO may also cause harm by other mechanisms including direct disruption of cellular oxidative processes, binding to myoglobin and hepatic cytochromes, and peroxidation of brain lipids.

The brain and heart are the most sensitive target organs due to their high blood flow, poor tolerance of hypoxia, and high oxygen requirements. Minor exposure may be asymptomatic or present with vague constitutional symptoms such as headache, lethargy, and nausea, whereas higher doses may present with poor concentration and cognition, short-term memory loss, confusion, seizures, and loss of consciousness. While carboxyhemoglobin (COHb) levels on admission do not necessarily reflect the severity or the prognosis of CO poisoning, cardiorespiratory arrest carries a very poor prognosis. Over the longer term, surviving patients commonly have neuropsychological sequelae. Motor disturbances, peripheral neuropathy, hearing loss, vestibular abnormalities, dementia, and psychosis have all been reported. Risk factors for poor outcome are age >35 years, exposure for >24 h, acidosis, and loss of consciousness.

Clinical Evidence The typical course of HBO_2T consists of two to three compressions to 2–2.8 ATA for 1.5–2 h each session. It is common for the first two compressions to be delivered within 24 h of the exposure. CO poisoning is one of the longest-standing indications for HBO_2T—based largely on the obvious connection between exposure, tissue hypoxia, and the ability of HBO_2T to rapidly overcome this hypoxia. CO is eliminated rapidly via the lungs on application of HBO_2T, with a half-life of ~21 min at 2.0 ATA versus 5.5 h breathing air and 71 min breathing oxygen at sea level. In practice, however, it seems unlikely that HBO_2T can be delivered in time to prevent either

acute hypoxic death or irreversible global cerebral hypoxic injury. If HBO_2T is beneficial in CO poisoning, it must reduce the likelihood of persisting and/or delayed neurocognitive deficit through a mechanism other than the simple reversal of arterial hypoxia due to high levels of COHb. The difficulty in accurately assessing neurocognitive deficit has been one of the primary sources of controversy surrounding the clinical evidence in this area. To date, there have been six RCTs of HBO_2T for CO poisoning, although only four have been reported in full. While a Cochrane review suggested there is insufficient evidence to confirm a beneficial effect of HBO_2T on the chance of persisting neurocognitive deficit following poisoning (34% of patients treated with oxygen at 1 atmosphere vs 29%, of those treated with HBO_2T; odds ratio [OR], 0.78; 95% CI, 0.54–1.1), this may have more to do with poor reporting and inadequate follow-up than with evidence that HBO_2T is not effective. The interpretation of the literature has much to do with how one defines neurocognitive deficit. In the most methodologically rigorous of these studies (Weaver et al.), a professionally administered battery of validated neuropsychological tests and a definition based on the deviation of individual subtest scores from the age-adjusted normal values was used; if the patient complained of memory, attention, or concentration difficulties, the required decrement was decreased. Using this approach, 6 weeks after poisoning, 46% of patients treated with normobaric oxygen alone had cognitive sequelae compared to 25% of those who received HBO_2T ($p = .007$; number needed to treat [NNT] = 5; 95% CI, 3–16). At 12 months, the difference remained significant (32 vs 18%; $p = .04$; NNT = 7; 95% CI, 4–124) despite considerable loss to follow-up.

On this basis, HBO_2T remains widely advocated for the routine treatment of patients with moderate to severe poisoning—in particular in those older than 35 years, presenting with a metabolic acidosis on arterial blood-gas analysis, exposed for lengthy periods, or with a history of unconsciousness. Conversely, many toxicologists remain unconvinced about the place of HBO_2T in this situation and call for further well-designed studies.

CURRENT CONTROVERSIES IN HYPERBARIC MEDICINE

The use of hyperbaric oxygen has been associated with controversy since it was first instituted in the 1950s. A vigorous debate has recently developed around the concept of performing sham controlled RCTs, particularly when assessing outcomes where a placebo effect could significantly influence interpretation. The most popular method employed to achieve blinding of both staff and patients is the exposure of patients in the control arm to a modest pressure while breathing air in the chamber (between 1.1 and 1.3 ATA). While this strategy is effective in blinding the exposure, critics claim this exposure to air at pressure (equivalent to breathing ~27% oxygen at 1.0 ATA) is therapeutic in a way yet to be identified. These critics use this putative therapeutic effect to explain the modest measured benefits in patients with a range of chronic neurologic conditions including cerebral palsy, autism spectrum disorders, and mild traumatic brain injury when exposed to either air at 1.1–1.3 ATA or 100% oxygen at 2.0–2.4 ATA (HBO_2T) in a number of trials. These benefits have traditionally been interpreted as the result of a participation or placebo effect, with the various authors concluding there was no evidence of a specific effect for HBO_2T in any of these conditions. The search continues for a convincing sham exposure that is universally regarded as inactive. Some workers claim this is not possible and that patient-blinded trials are therefore similarly unachievable. This impasse needs resolution, and there is some hope that the restriction of pressure exposure to short periods of modest compression at the start and end of each sham session may be convincing for both sides of the argument.

DIVING MEDICINE

INTRODUCTION

Underwater diving is both a popular recreational activity and a means of employment in a range of tasks from underwater construction to military operations. It is a complex activity with unique hazards and medical complications arising mainly as a consequence of the dramatic changes in pressure associated with both descent and ascent through the water column. For every 10.1-m increase in depth of seawater, the ambient pressure (P_{amb}) increases by 101.3 kPa (1 atmosphere) so that, for example, a diver at 20 m depth is exposed to a P_{amb} of 303.9 kPa (3 ATA), made up of 1 ATA due to atmospheric pressure and 2 ATA generated by the water column.

BREATHING EQUIPMENT

Most diving is undertaken using self-contained underwater breathing apparatus (scuba) consisting of one or more cylinders of compressed gas connected to a pressure-reducing regulator and a demand valve activated by inspiratory effort. Some divers use "rebreathers," which comprise a closed or semi-closed breathing circuit with a carbon dioxide scrubber and an oxygen addition system designed to maintain a safe inspired Po_2. Exhaled gas is recycled, and gas consumption is limited to little more than the oxygen metabolized by the diver. Rebreathers are therefore popular for deep dives where expensive helium is included in the respired mix (see below). Occupational divers frequently use "surface supply" equipment where gas, along with other utilities such as communications and power, is supplied via an "umbilical" cable from the surface.

All these systems must supply gas to the diver at the P_{amb} of the surrounding water or inspiration would be impossible against the water pressure. For most recreational diving, the respired gas is air. Pure oxygen is rarely used because there is a dose-dependent risk (where "dose" is a function of exposure time and inspired Po_2) that oxygen may provoke seizures above an inspired Po_2 of 130 kPa (1.3 ATA). The maximum acceptable inspired Po_2 in diving is often considered to be 161 kPa (1.6 ATA), which would be achieved when breathing pure oxygen at 6 m or air at 66 m. This is a conspicuously lower Po_2 than routinely used for hyperbaric therapy (see earlier), reflecting a higher risk of oxygen toxic seizures during immersion and exercise. In order to avoid dangerous oxygen exposures, very deep diving requires the use of inspired oxygen fractions lower than in air (Fo_2 0.21), and divers tailor the oxygen content of their gases to remain within recommended exposure guidelines. Deep-diving gases include helium as a substitute for some or all of the nitrogen to reduce both the narcotic effect and high gas density that result from breathing nitrogen at high pressures.

SUITABILITY FOR DIVING

The most common reason for physician consultation in relation to diving is for the evaluation of suitability for diver training or continuation of diving after a health event. Occupational diver candidates are usually compelled to see doctors with specialist training in the field, both at entry to the industry and periodically thereafter, and their medical evaluations are usually conducted according to legally mandated standards. In contrast, in most jurisdictions, prospective recreational diver candidates simply complete a self-assessment medical questionnaire prior to diver training. If there are no positive responses, the candidate proceeds directly to training, but positive responses mandate the candidate see a doctor for evaluation of the identified medical issue. Prospective divers will often present to their family medicine practitioner for this purpose. In the modern era, such consultations have evolved from a simple proscriptive exercise of excluding those with potential contraindications to an approach in which each case is considered on its own merits and an individualized evaluation of risk is made. Such evaluations require integration of diving physiology, the impact of associated medical problems, and knowledge of the specific medical condition(s) of the candidate. A detailed discussion is beyond the scope of this chapter, but several important principles are outlined below.

There are three primary questions that should be answered in relation to any medical condition reported by a prospective diver: (1) Could the condition be exacerbated by diving? (2) Could the condition make a diving medical problem more likely? (3) Could the condition prevent the diver from meeting the functional requirements of diving? As examples of positive answers to these questions (respectively): epilepsy is usually considered to imply high risk because there are epileptogenic stimuli such as high inspired oxygen pressures encountered in diving that could make a seizure (and drowning) more likely; active

asthma is considered to increase risk because it could predispose to air trapping and pulmonary barotrauma (see below); and ischemic heart disease increases risk because it could prevent a diver from exercising sufficiently to get out of a difficult situation such as being caught in a current. It can be a complex matter to recognize the relevant interactions between diving and medical conditions and to determine their impact on suitability for diving. There may follow an equally complex discussion about whether such interactions impart a disqualifying risk, and this may be influenced by the individual candidate's level of risk acceptance and the extent to which others involved (such as dive partners) might be affected. Guidelines are occasionally published on assessment of diving candidates with risk factors for important comorbidities like cardiovascular disease or who have suffered topical problems such as COVID-19 infection (see "Further Reading" list). Physicians interested in regularly conducting such evaluations should obtain relevant training. Short courses providing relevant training are offered by specialist groups in most countries.

BAROTRAUMA

Barotrauma is essentially tissue injury arising as a result of ambient pressure changes. Middle-ear barotrauma (MEBT) in diving is similar to the problem that may occur during descent from altitude in an airplane, but difficulties with equalizing pressure in the middle ear are exaggerated underwater by both the rapidity and magnitude of pressure change as a diver descends or ascends. Failure to periodically insufflate the middle-ear spaces via the eustachian tubes during descent results in increasing pain. As the P_{amb} increases, the tympanic membrane (TM) may be bruised or even ruptured as it is pushed inward. Negative pressure in the middle ear results in engorgement of blood vessels in the surrounding mucous membranes and leads to effusion or bleeding, which can be associated with a *conductive* hearing loss. MEBT is much less common during ascent because expanding gas in the middle-ear space tends to open the eustachian tube automatically. Barotrauma may also affect the respiratory sinuses, although the sinus ostia are usually widely patent and allow automatic pressure equalization without the need for specific maneuvers. If equalization fails, pain usually results in termination of the dive. Difficulty with equalizing ears or sinuses may respond to oral or nasal decongestants.

Much less commonly, divers may suffer inner ear barotrauma (IEBT). Several explanations have been proposed, of which the most favored holds that forceful attempts to insufflate the middle-ear space by Valsalva maneuvers during descent result in transmission of pressure to the perilymph via the cochlear aqueduct and outward rupture of the round window, which is already under tension because of negative middle-ear pressure. The clinician should be alerted to possible IEBT after diving by a *sensorineural* hearing loss or true vertigo (which is often accompanied by nausea, vomiting, nystagmus, and ataxia). These manifestations can also occur in vestibulocochlear DCS (see below) but should never be attributed to MEBT. Immediate review by an expert diving physician is recommended, and urgent referral to an otologist will often follow.

The lungs are also vulnerable to barotrauma but are at most risk during ascent. If expanding gas becomes trapped in the lungs as P_{amb} falls, this may rupture alveoli and associated vascular tissue. Gas trapping may occur if divers intentionally or involuntarily hold their breath during ascent or if there are bullae. The extent to which asthma predisposes to pulmonary barotrauma is debated, but the presence of active bronchoconstriction must increase risk. For this reason, asthmatics who regularly require bronchodilator medications or whose airways are sensitive to exercise or cold air are usually discouraged from diving. While possible consequences of pulmonary barotrauma include pneumothorax and mediastinal emphysema, the most feared is the introduction of gas into the pulmonary veins leading to cerebral arterial gas embolism (CAGE). Manifestations of CAGE include loss of consciousness, confusion, hemiplegia, visual disturbances, and speech difficulties appearing immediately or within minutes after surfacing. The management is the same as for DCS described below. The natural history of CAGE often includes substantial or complete resolution of symptoms early after the event. This is probably the clinical correlate of bubble involution and redistribution with consequent restoration of flow. Patients exhibiting such remissions should still be reviewed at specialist diving medical centers because secondary deterioration or re-embolization can occur. Unsurprisingly, these events can be misdiagnosed as typical strokes or transient ischemic attacks (TIAs) **(Chap. 427)** when patients are seen by clinicians unfamiliar with diving medicine. *All patients presenting with neurologic symptoms after diving should have their symptoms discussed with a specialist in diving medicine and be considered for recompression therapy*.

DECOMPRESSION SICKNESS

DCS is caused by the formation of bubbles from dissolved inert gas (usually nitrogen) during or after ascent (decompression) from a compressed gas dive. Bubble formation is also possible following decompression for extravehicular activity during space flight and with ascent to altitude in unpressurized aircraft. DCS in the latter scenarios is probably rare in comparison with diving, where the incidence is ~1:10,000 recreational dives.

Breathing at elevated P_{amb} results in increased uptake of inert gas into blood and then into tissues. The rate at which tissue inert gas equilibrates with the inspired inert gas pressure is proportional to tissue blood flow and the blood-tissue partition coefficient for the gas. Similar factors dictate the kinetics of inert gas washout during ascent. If the rate of gas washout from tissues does not match the rate of decline in P_{amb}, then the sum of dissolved gas pressures in the tissue will exceed P_{amb}, a condition referred to as "supersaturation." This is the prerequisite for bubbles to form during decompression, although other less well-understood factors are also involved. Deeper and longer dives result in greater inert gas absorption and greater likelihood of tissue supersaturation during ascent. Divers control their ascent for a given depth and time exposure using algorithms that often include periods where ascent is halted for a prescribed period at different depths to allow time for gas washout ("decompression stops"). Although a breach of these protocols increases the risk of DCS, adherence does not guarantee that it will be prevented. DCS should be considered in any diver manifesting postdive symptoms not readily explained by an alternative mechanism.

Bubbles may form within tissues themselves, where they cause symptoms by mechanical distraction of pain-sensitive or functionally important structures. They also appear in the venous circulation, almost certainly forming in capillary beds as blood passes through supersaturated tissues. Some venous bubbles are tolerated without symptoms and are filtered from the circulation in the pulmonary capillaries. However, in sufficiently large numbers, these bubbles are capable of inciting inflammatory and coagulation cascades, damaging endothelium, activating formed elements of blood such as platelets, and causing symptomatic pulmonary vascular obstruction. Moreover, if there is a right-to-left shunt through a patent foramen ovale (PFO) or an intrapulmonary shunt, then venous bubbles may enter the arterial circulation (25% of adults have a probe-patent PFO). The risk of cerebral, spinal cord, inner ear, and skin manifestations appears higher in the presence of significant shunts, suggesting that these "arterialized" venous bubbles can cause harm, perhaps by disrupting flow in the microcirculation of target organs. Circulating microparticles, which are elevated in number and size after diving, are currently under investigation as indicators of decompression stress and as injurious agents in their own right. How they arise and their exact role in DCS remain unclear.

Table 463-3 lists manifestations of DCS grouped according to organ system. The majority of cases present with mild symptoms, including musculoskeletal pain, fatigue, and minor neurologic manifestations such as patchy paresthesias. Serious presentations are much less common. Pulmonary and cardiovascular manifestations can be life-threatening, and spinal cord involvement frequently results in permanent disability. Latency is variable. Serious DCS usually manifests within minutes of surfacing, but mild symptoms may not appear for several hours. Symptoms arising >24 h after diving are very unlikely to be DCS. The presentation may be confusing and nonspecific, and there are no useful diagnostic investigations. Diagnosis is based on integration of findings from examination of the dive profile, the nature and

TABLE 463-3 Manifestations of Decompression Sickness

ORGAN SYSTEM	MANIFESTATIONS
Musculoskeletal	Limb pain
Neurologic	
Cerebral	Confusion
	Visual disturbances
	Speech disturbances
Spinal	Muscular weakness
	Paralysis
	Upper motor neuron signs
	Bladder and sphincter dysfunction
	Dermatomal sensory disturbances
	Abdominal pain
	Girdle pain
Vestibulocochlear	Hearing loss
	Vertigo and ataxia
	Nausea and vomiting
Peripheral	Patchy nondermatomal sensory disturbance

	Dyspnea
Cardiovascular	Hemoconcentration
	Coagulopathy
	Hypotension
Cutaneous	Rash, itch
Lymphatic	Soft tissue edema, often relatively localized
Constitutional	Fatigue and malaise

temporal relationship of symptoms, and the clinical examination. Some DCS presentations may be difficult to separate from CAGE following pulmonary barotrauma, but from a clinical perspective, the distinction is unimportant because the first aid and definitive management of both conditions are the same.

TREATMENT

Diving Medicine

First aid for either DCS or CAGE includes horizontal positioning (especially if there are cerebral manifestations), intravenous fluids if available, and sustained 100% oxygen administration. The latter accelerates inert gas washout from tissues and promotes resolution of bubbles. Definitive treatment of DCS or CAGE with recompression and hyperbaric oxygen is justified in most instances, although some mild or marginal DCS cases may be managed with first aid measures alone—an option that may be invoked by experienced diving physicians under various circumstances, but especially if evacuation for recompression is hazardous or extremely difficult. Long-distance evacuations are usually undertaken using a helicopter flying at low altitude or a fixed-wing air ambulance pressurized to 1 ATA.

Recompression reduces bubble volume in accordance with Boyle's law and increases the inert gas partial pressure difference between a bubble and surrounding tissue. At the same time, oxygen administration markedly increases the inert gas partial pressure difference between alveoli and tissue. The net effect is to significantly increase the rate of inert gas diffusion from bubble to tissue and tissue to blood, thus accelerating bubble resolution. Hyperbaric oxygen also helps oxygenate compromised tissues and may ameliorate some of the proinflammatory effects of bubbles. Various recompression protocols have been advocated, but there are no data that define the optimum approach. Recompression typically begins with oxygen administered at 2.8 ATA, the maximum pressure at which the risk of oxygen toxicity remains acceptable in a hyperbaric chamber. There follows a stepwise decompression over variable periods adjusted to symptom response. The most widely used algorithm is the U.S. Navy Table 6, whose shortest format lasts 4 h and 45 min. Typically, shorter "follow-up" recompressions are repeated daily while symptoms persist and appear responsive to treatment. Adjuncts to recompression include intravenous fluids and other supportive care as necessary. Occasionally, very sick divers require intubation, ventilation, and high-level intensive care.

The presentation of sick divers to physicians or hospitals without diving medicine expertise creates a risk of misinterpretation of nonspecific manifestations and of consequent mistakes in diagnosis and management. Physicians finding themselves in this situation are strongly advised to expeditiously contact the 24-h diving emergency advisory service provided by the Divers Alert Network (DAN). This can be accessed at +1-919-684-9111, and there are subsidiary or related services in virtually all jurisdictions globally.

464 Hypothermia and Peripheral Cold Injuries

Daniel F. Danzl

HYPOTHERMIA

Accidental hypothermia occurs when there is an unintentional drop in the body's core temperature below 35°C (95°F). At this temperature, many of the compensatory physiologic mechanisms that conserve heat begin to fail. *Primary accidental hypothermia* is a result of the direct exposure of a previously healthy individual to the cold. The mortality rate is much higher for patients who develop *secondary hypothermia* as a complication of a serious systemic disorder or injury.

TABLE 464-1 Risk Factors for Hypothermia

Age extremes	Endocrine-related
Elderly	Diabetes mellitus
Neonates	Hypoglycemia
Environmental exposure	Hypothyroidism
Occupational	Adrenal insufficiency
Sports-related	Hypopituitarism
Inadequate clothing	Neurologic
Immersion	Cerebrovascular accident
Toxicologic and pharmacologic	Hypothalamic disorders
Ethanol	Parkinson's disease
Anesthetics	Spinal cord injury
Antipsychotics	Multisystemic
Antidepressants	Trauma
Anxiolytics	Sepsis
Benzodiazepines	Shock
Neuromuscular blockers	Hepatic or renal failure
Insufficient fuel	Carcinomatosis
Malnutrition	Burns and exfoliative dermatologic disorders
Marasmus	Immobility or debilitation
Kwashiorkor	

CAUSES

Primary accidental hypothermia is geographically and seasonally pervasive. Although most cases occur in the winter months and in colder climates, this condition is surprisingly common in warmer regions as well. Multiple variables render individuals at the extremes of age—both the elderly and neonates—particularly vulnerable to hypothermia **(Table 464-1)**. The elderly have diminished thermal perception and are more susceptible to immobility, malnutrition, and systemic illnesses that interfere with heat generation or conservation. Dementia, psychiatric illness, and socioeconomic factors often compound these problems. Neonates have high rates of heat loss because of their increased surface-to-mass ratio and their lack of effective shivering and adaptive behavioral responses. At all ages, malnutrition can contribute to heat loss because of diminished subcutaneous fat and as a result of depleted energy stores used for thermogenesis.

Individuals whose occupations or hobbies entail extensive exposure to cold weather are at increased risk for hypothermia. Military history is replete with hypothermic tragedies. Hunters, sailors, skiers, and climbers also are at great risk of exposure, whether it involves injury, changes in weather, or lack of preparedness.

Ethanol causes vasodilation (which increases heat loss), reduces thermogenesis and gluconeogenesis, and may impair judgment or lead to obtundation. Some antipsychotics, antidepressants, anxiolytics, benzodiazepines, and other medications reduce centrally mediated vasoconstriction. Many hypothermic patients are admitted to intensive care because of drug overdose. Anesthetics can block shivering responses; these effects are compounded when patients are not insulated adequately in the operating or recovery units.

Several types of endocrine dysfunction cause hypothermia. Hypothyroidism—particularly when extreme, as in myxedema coma—reduces the metabolic rate and impairs thermogenesis and behavioral responses. Adrenal insufficiency and hypopituitarism also increase susceptibility to hypothermia. Hypoglycemia, most commonly caused by insulin or oral hypoglycemic agents, is associated with hypothermia, in part because of neuroglycopenic effects on hypothalamic function. Increased osmolality and metabolic derangements associated with uremia, diabetic ketoacidosis, and lactic acidosis can lead to altered hypothalamic thermoregulation.

Neurologic injury from trauma, cerebrovascular accident, subarachnoid hemorrhage, and a hypothalamic lesion increases susceptibility to hypothermia. Agenesis of the corpus callosum (*Shapiro's syndrome*) is one cause of episodic hypothermia. In this syndrome, profuse perspiration is followed by a rapid fall in temperature. Acute spinal cord injury disrupts the autonomic pathways that lead to shivering and will prevent cold-induced reflex vasoconstrictive responses.

Hypothermia associated with sepsis is a poor prognostic sign. Hepatic failure causes decreased glycogen storage and gluconeogenesis as well as a diminished shivering response. In acute myocardial infarction associated with low cardiac output, hypothermia may be reversed after adequate resuscitation. With extensive burns, psoriasis, erythrodermas, and other skin diseases, increased peripheral-blood flow leads to excessive heat loss.

THERMOREGULATION

Heat loss occurs through five mechanisms: radiation (55–65% of heat loss), conduction (10–15% of heat loss, increased in cold water), convection (increased in the wind), respiration, and evaporation; both of the latter two mechanisms are affected by the ambient temperature and the relative humidity.

The preoptic anterior hypothalamus normally orchestrates thermoregulation **(Chap. 18)**. The immediate defense of thermoneutrality is via the autonomic nervous system, whereas delayed control is mediated by the endocrine system. Autonomic nervous system responses include the release of norepinephrine, increased muscle tone, and shivering, leading to thermogenesis and an increase in the basal metabolic rate. Cutaneous cold thermoreception causes direct reflex vasoconstriction to conserve heat. Prolonged exposure to cold also stimulates the thyroid axis, leading to an increased metabolic rate.

CLINICAL PRESENTATION

In most cases of hypothermia, the history of exposure to environmental factors (e.g., prolonged exposure to the outdoors without adequate clothing) makes the diagnosis straightforward. In urban settings, however, the presentation is often more subtle, and other disease processes, toxin exposures, or psychiatric diagnoses should be considered. Predicting the core temperature based on the clinical presentation is very difficult.

After initial stimulation by hypothermia, there is progressive depression of all organ systems. The timing of the appearance of these clinical manifestations varies widely **(Table 464-2)**. Without knowing the core temperature, it can be difficult to interpret other vital signs. For example, tachycardia disproportionate to the core temperature suggests secondary hypothermia resulting from hypoglycemia, hypovolemia, or a toxin overdose. Because carbon dioxide production declines progressively, the respiratory rate should be low; persistent hyperventilation suggests a central nervous system (CNS) lesion or an organic acidosis. A markedly depressed level of consciousness in a patient with mild hypothermia suggests an overdose or CNS dysfunction due to infection or trauma.

Physical examination findings will also be altered by hypothermia. For instance, the assumption that areflexia is solely attributable to hypothermia can obscure the diagnosis of a spinal cord lesion. Patients with hypothermia may be confused or combative; these symptoms abate more rapidly with rewarming than with chemical or physical restraint. A classic example of maladaptive behavior in patients with hypothermia is paradoxical undressing, which involves the inappropriate removal of clothing in response to a cold stress. The cold-induced ileus and abdominal rectus spasm can mimic or mask the presentation of an acute abdomen **(Chap. 15)**.

When a patient in hypothermic cardiac arrest is first discovered, cardiopulmonary resuscitation (CPR) is indicated unless (1) a do-not-resuscitate status is verified, (2) obviously lethal injuries are identified, or (3) the depression of a frozen chest wall is not possible. Continuous CPR is normally recommended, and interruptions should be avoided if possible. In the field, when the core temperature is <28°C, intermittent CPR may also be effective.

As the resuscitation proceeds, the prognosis is grave if there is evidence of widespread cell lysis, as reflected by potassium levels >10–12 mmol/L (10–12 meq/L). Other findings that may preclude continuing resuscitation include a core temperature <10–12°C (<50–54°F), a pH <6.5, and evidence of intravascular thrombosis with a fibrinogen value <0.5 g/L (<50 mg/dL). The decision to terminate resuscitation

TABLE 464-2 Physiologic Changes Associated with Accidental Hypothermia

SEVERITY	BODY TEMPERATURE	CENTRAL NERVOUS SYSTEM	CARDIOVASCULAR	RESPIRATORY	RENAL AND ENDOCRINE	NEUROMUSCULAR
Mild	35°C (95°F)–32.2°C (90°F)	Linear depression of cerebral metabolism; amnesia; apathy; dysarthria; impaired judgment; maladaptive behavior	Tachycardia, then progressive bradycardia; cardiac cycle prolongation; vasoconstriction; increase in cardiac output and blood pressure	Tachypnea, then progressive decrease in respiratory minute volume; declining oxygen consumption; bronchorrhea; bronchospasm	Diuresis; increase in catecholamines, adrenal steroids, triiodothyronine, and thyroxine; increase in metabolism with shivering	Increased preshivering muscle tone, then fatiguing
Moderate	<32.2°C (90°F)–28°C (82.4°F)	EEG abnormalities; progressive depression of level of consciousness; pupillary dilation; paradoxical undressing; hallucinations	Progressive decrease in pulse and cardiac output; increased atrial and ventricular arrhythmias; suggestive (J-wave) ECG changes	Hypoventilation: 50% decrease in carbon dioxide production per 8°C (17.6°F) drop in temperature; absence of protective airway reflexes	50% increase in renal blood flow; renal autoregulation intact; impaired insulin action	Hyporeflexia; diminishing shivering-induced thermogenesis; rigidity
Severe	<28°C (<82.4°F)	Loss of cerebrovascular autoregulation; decline in cerebral blood flow; coma; loss of ocular reflexes; progressive decrease in EEG abnormalities	Progressive decrease in blood pressure, heart rate, and cardiac output; reentrant dysrhythmias; maximal risk of ventricular fibrillation; asystole	Pulmonic congestion and edema; 75% decrease in oxygen consumption; apnea	Decrease in renal blood flow that parallels decrease in cardiac output; extreme oliguria; poikilothermia; 80% decrease in basal metabolism	No motion; decreased nerve-conduction velocity; peripheral areflexia; no corneal or oculocephalic reflexes

Abbreviations: ECG, electrocardiogram; EEG, electroencephalogram.

before rewarming the patient past 33°C (91°F) should be predicated on the type and severity of the precipitants of hypothermia. Survival has occurred with a cardiac arrest time over 7 h. There is an ongoing search for validated prognostic indicators for recovery from hypothermia. The Swiss grading system considers core body temperature and the clinical findings. Other scoring systems also consider age, albumin, and lactate levels. A history of asphyxia, as in an avalanche, with secondary cooling is the most important negative predictor of survival.

DIAGNOSIS AND STABILIZATION

Hypothermia is confirmed by measurement of the core temperature, preferably at two sites. Rectal probes should be placed to a depth of 15 cm and not adjacent to cold feces. A simultaneous esophageal probe can be placed 24 cm below the larynx; it may read falsely high during heated inhalation therapy. Relying solely on infrared tympanic thermography is not advisable.

After a diagnosis of hypothermia is established, cardiac monitoring should be instituted, along with attempts to limit further heat loss. If the patient is in ventricular fibrillation, it is unclear at what core temperature ventricular defibrillation (2 J/kg) should first be attempted. One biphasic attempt below 30°C is warranted. Further defibrillation attempts should usually be deferred until some rewarming (1°–2°C) is achieved and ventricular fibrillation is coarser. Although cardiac pacing for hypothermic bradydysrhythmias is rarely indicated, the transthoracic technique is preferable. The J or Osborn wave at the junction of the QRS complex and ST segment suggests the diagnosis. Obvious J waves are routinely misdiagnosed by automated readings as injury current.

Supplemental oxygenation is always warranted, since tissue oxygenation is affected adversely by the leftward shift of the oxyhemoglobin dissociation curve. Pulse oximetry is often unreliable in patients with vasoconstriction. If protective airway reflexes are absent, gentle endotracheal intubation should be performed. Adequate preoxygenation will prevent ventricular arrhythmias.

Insertion of a gastric tube prevents dilation secondary to decreased bowel motility. Indwelling bladder catheters facilitate monitoring of cold-induced diuresis and can provide an ancillary approach for temperature monitoring. Dehydration is encountered commonly with chronic hypothermia, and most patients benefit from an intravenous or intraosseous crystalloid bolus. Normal saline is preferable to lactated Ringer's solution, as the liver in hypothermic patients inefficiently metabolizes lactate. The placement of a pulmonary artery catheter can cause perforation of the less compliant pulmonary artery. Insertion of a central venous catheter deeply into the cold right atrium should be avoided since this procedure, similar to transvenous pacing, can precipitate refractory arrhythmias.

Arterial blood gases should *not* be corrected for temperature **(Chap. 55)**. An uncorrected pH of 7.42 and a P_{CO_2} of 40 mmHg reflect appropriate alveolar ventilation and acid-base balance at any core temperature. Acid-base imbalances should be corrected gradually, since the bicarbonate buffering system is inefficient. A common error is overzealous hyperventilation in the setting of depressed CO_2 production. When the P_{CO_2} decreases by 10 mmHg at 28°C (82°F), it doubles the pH increase of 0.08 that occurs at 37°C (99°F).

The severity of anemia may be underestimated because the hematocrit increases 2% for each 1°C drop in temperature. White blood cell sequestration and bone marrow suppression are common, potentially masking an infection. Although hypokalemia is more common in chronic hypothermia, hyperkalemia also occurs; the expected electrocardiographic changes are often obscured by hypothermia. Patients with renal insufficiency, metabolic acidosis, or rhabdomyolysis are at greatest risk for electrolyte disturbances.

Coagulopathies are common because cold inhibits the enzymatic reactions required for activation of the intrinsic cascade. In addition, thromboxane B_2 production by platelets is temperature dependent, and platelet function is impaired. The administration of platelets and fresh-frozen plasma is therefore not effective. Coagulation studies can be deceptively normal and contrast with the observed in vivo coagulopathy. This contradiction occurs because all coagulation tests are routinely performed at 37°C (99°F), and the enzymes are thus rewarmed.

REWARMING STRATEGIES

The key initial decision is whether to rewarm the patient passively or actively. *Passive external rewarming* simply involves covering and insulating the patient in a warm environment. With the head also covered, the rate of rewarming is usually 0.5°–2°C (1.10°–4.4°F) per hour. This technique is ideal for previously healthy patients who develop acute, mild primary accidental hypothermia. The patient must have sufficient glycogen to support endogenous thermogenesis.

The application of heat directly to the extremities of patients with chronic severe hypothermia should be avoided because it can induce peripheral vasodilation and precipitate core temperature "afterdrop," a response characterized by a continual decline in the core temperature

after removal of the patient from the cold. Truncal heat application reduces the risk of afterdrop.

Active rewarming is necessary under the following circumstances: core temperature <32°C (<90°F) (*poikilothermia*), cardiovascular instability, age extremes, CNS dysfunction, hormone insufficiency, and suspicion of secondary hypothermia. *Active external rewarming* is best accomplished with forced-air heating blankets. Other options include devices that circulate water through external heat exchange pads, radiant heat sources, and hot packs. Monitoring a patient with hypothermia in a heated tub is extremely difficult. Electric blankets should be avoided because vasoconstricted skin is easily burned.

There are numerous widely available options for *active core rewarming*. Airway rewarming with heated humidified oxygen (40°–45°C [104°–113°F]) via mask or endotracheal tube is a convenient option. Although airway rewarming provides less heat than do some other forms of active core rewarming, it eliminates respiratory heat loss and adds 1°–2°C (2.2°–4.4°F) to the overall rewarming rate. Crystalloids should be heated to 40°–42°C (104°–108°F), but the quantity of heat provided is significant only during massive volume resuscitation. The most efficient method for heating and delivering fluid or blood is with a countercurrent in-line heat exchanger. Heated irrigation of the gastrointestinal tract or bladder transfers minimal heat because of the limited available surface area. These methods should be reserved for patients in cardiac arrest and then used in combination with all available active rewarming techniques.

Closed thoracic lavage is far more efficient in severely hypothermic patients with cardiac arrest. The hemithoraxes are irrigated through two inserted large-bore thoracostomy tubes. Thoracostomy tubes should not be placed in the left chest of a spontaneously perfusing patient for purposes of rewarming. Peritoneal lavage with the dialysate at 40°–45°C (104°–113°F) efficiently transfers heat when delivered through two catheters with outflow suction. Like peritoneal dialysis, standard hemodialysis is especially useful for patients with electrolyte abnormalities, rhabdomyolysis, or toxin ingestion. Another option involves the use of endovascular temperature control catheters.

Extracorporeal blood rewarming options **(Table 464-3)** should be considered in severely hypothermic patients, especially those with *primary accidental hypothermia*. Extracorporeal life support, including bypass, should be considered in nonperfusing patients without documented contraindications to resuscitation. Circulatory support may be the only effective option in patients with completely frozen extremities or those with significant tissue destruction coupled with rhabdomyolysis. There is no evidence that extremely rapid rewarming improves survival in perfusing patients.

TABLE 464-3 Options for Extracorporeal Blood Rewarming

EXTRACORPOREAL REWARMING TECHNIQUE	CONSIDERATIONS
Continuous venovenous (CVV) rewarming	Circuit: CV catheter to CV, dual-lumen CV, or peripheral catheter No oxygenator/circulatory support Flow rates 150–400 mL/min ROR 2°–3°C (4.4°–6.6°F)/h
Hemodialysis	Circuit: single- or dual-vessel cannulation Stabilizes electrolyte or toxicologic abnormalities Exchange cycle volumes 200–500 mL/min ROR 2°–3°C (4.4°–6.6°F)/h
Continuous arteriovenous rewarming (CAVR)	Circuit: percutaneous 8.5-Fr femoral catheters Requires systolic blood pressure of 60 mmHg No perfusionist/pump/anticoagulation Flow rates 225–375 mL/min ROR 3°–4°C (6.6°–8.8°F)/h
Cardiopulmonary bypass (CPB)	Circuit: full circulatory support with pump and oxygenator Perfusate-temperature gradient 5°–10°C (11°–22° F) Flow rates 2–7 L/min (average 3–4 L/min) ROR up to 9.5°C (20.9°F)/h
Venoarterial extracorporeal membrane oxygenation (VA-ECMO)	Decreased risk of post-rewarming cardiorespiratory failure Improved neurologic outcome

Abbreviations: CV, central venous; ROR, rate of rewarming.

TREATMENT

Hypothermia

When a patient is hypothermic, target organs and the cardiovascular system respond minimally to most medications. Generally, medications are withheld below 30°C (86°F). In contrast to antiarrhythmics, low-dose vasopressor medications may improve the intra-arrest rates of return of spontaneous circulation. Because of increased binding of drugs to proteins as well as impaired metabolism and excretion, either a lower dose or a longer interval between doses should be used to avoid toxicity. As an example, the administration of repeated doses of digoxin or insulin would be ineffective while the patient is hypothermic, but the residual drugs would be potentially toxic during rewarming.

Achieving a mean arterial pressure of at least 60 mmHg should be an early objective. If the hypotension is disproportionate for temperature and does not respond to crystalloid/colloid infusion and rewarming, low-dose dopamine support (2–5 μg/kg per min) should be considered. Perfusion of the vasoconstricted cardiovascular system also may improve with low-dose IV nitroglycerin.

Atrial arrhythmias should be monitored initially without intervention, as the ventricular response should be slow and, unless preexistent, most will convert spontaneously during rewarming. The role of prophylaxis and treatment of ventricular arrhythmias is complex. Preexisting ventricular ectopy may be suppressed by hypothermia and reappear during rewarming. None of the class I agents is proven to be safe and efficacious.

Initiating empirical therapy for adrenal insufficiency usually is not warranted unless the history suggests steroid dependence or hypoadrenalism or efforts to rewarm with standard therapy fail. The administration of parenteral levothyroxine to euthyroid patients with hypothermia, however, is potentially hazardous. Because laboratory results can be delayed and confounded by the presence of the sick euthyroid syndrome **(Chap. 382)**, historic clues or physical findings suggestive of hypothyroidism should be sought. When myxedema is the cause of hypothermia, the relaxation phase of the Achilles reflex is prolonged more than is the contraction phase.

Hypothermia obscures most of the symptoms and signs of infection, notably fever and leukocytosis. Shaking rigors from infection may be mistaken for shivering. Except in mild cases, extensive cultures and repeated physical examinations are essential. Unless an infectious source is identified, empirical antibiotic prophylaxis is most warranted in the elderly, neonates, and immunocompromised patients.

FROSTBITE

Peripheral cold injuries include both freezing and nonfreezing injuries to tissue. Tissue freezes quickly when in contact with thermal conductors such as metal and volatile solutions. Other predisposing factors include constrictive clothing or boots, immobility, and vasoconstrictive medications. Frostbite occurs when the tissue temperature drops below 0°C (32°F). Ice-crystal formation subsequently distorts and destroys the cellular architecture. Once the vascular endothelium is damaged, stasis progresses rapidly to microvascular thrombosis. After the tissue thaws, there is progressive dermal ischemia. The microvasculature begins to collapse, arteriovenous shunting increases tissue pressures, and edema forms. Finally, thrombosis, ischemia, and superficial necrosis appear. The development of mummification and demarcation may take weeks to months.

CLINICAL PRESENTATION

The initial presentation of frostbite can be deceptively benign. The symptoms always include a sensory deficiency affecting light touch, pain, or temperature perception. The acral areas and distal extremities are the most common insensate areas. Some patients describe a clumsy or "chunk of wood" sensation in the extremity.

Deep frostbitten tissue can appear waxy, mottled, yellow, or violaceous-white. Favorable presenting signs include some warmth or sensation with normal color. The injury is often superficial if the subcutaneous tissue is pliable or if the dermis can be rolled over bony prominences.

Clinically, frostbite is superficial or deep. Superficial frostbite does not entail tissue loss but rather causes only anesthesia and erythema. The appearance of vesiculation surrounded by edema and erythema implies deeper involvement **(Fig. 464-1)**. Hemorrhagic vesicles reflect a serious injury to the microvasculature and indicate severe frostbite. Damages in subcuticular, muscular, or osseous tissues may result in amputation. An alternative classification establishes grades based on the location of presenting cyanosis; that is grade 1, absence of cyanosis; grade 2, cyanosis on the distal phalanx; grade 3, cyanosis up to the metacarpophalangeal (MP) joint; and grade 4 cyanosis proximal to the MP joint.

The two most common nonfreezing peripheral cold injuries are *chilblain* (*pernio*) and *immersion* (*trench*) *foot*. Chilblain results from neuronal and endothelial damage induced by repetitive exposure to damp cold above the freezing point. Young females, particularly those with a history of Raynaud's phenomenon, are at greatest risk. Persistent vasospasticity and vasculitis can cause erythema, mild edema, and pruritus. Eventually plaques, blue nodules, and ulcerations develop. These lesions typically involve the dorsa of the hands and feet. In contrast, immersion foot results from repetitive exposure to wet cold above the freezing point. The feet initially appear cyanotic, cold, and edematous. The subsequent development of bullae is often indistinguishable from frostbite. This vesiculation rapidly progresses to ulceration and liquefaction gangrene. Patients with milder cases report hyperhidrosis, cold sensitivity, and painful ambulation for many years.

FIGURE 464-1 Frostbite with vesiculation, surrounded by edema and erythema.

TREATMENT

Peripheral Cold Injuries

When frostbite accompanies hypothermia, hydration may improve vascular stasis. Frozen tissue should be thawed rapidly and completely by immersion in circulating water at 37°–40°C (99°–104°F) for 30–60 min and not by using hot air. Rapid rewarming often produces an initial hyperemia. The early formation of large clear distal blebs is more favorable than that of smaller proximal dark hemorrhagic blebs. A common error is the premature termination of thawing, since the reestablishment of perfusion is intensely painful. Parenteral narcotics will be necessary with deep frostbite. If cyanosis persists after rewarming, the tissue compartment pressures should be monitored carefully.

Many antithrombotic and vasodilatory treatment regimens have been evaluated. The prostacyclin analogue iloprost given within 48 h after rewarming is an option. There is no conclusive evidence that sympathectomy, steroids, calcium channel blockers, or hyperbaric oxygen salvages tissue.

Patients who have deep frostbite injuries with the potential for significant morbidity should be considered for intravenous or intraarterial thrombolytic therapy. Angiography or pyrophosphate scanning may help evaluate the injury and monitor the progress of tissue plasminogen activator therapy (rt-PA). Heparin is recommended as adjunctive therapy. Intraarterial thrombolysis may reduce the need for digital and more proximal amputations when administered within 24 h of severe injuries. A treatment protocol for frostbite is summarized in **Table 464-4**.

Unless infection develops, any decision regarding debridement or amputation should generally be deferred. Angiography or

TABLE 464-4 Treatment for Frostbite

BEFORE THAWING	DURING THAWING	AFTER THAWING
Remove from environment.	Consider parenteral analgesia and ketorolac.	Gently dry and protect part; elevate; place pledgets between toes, if macerated.
Prevent partial thawing and refreezing.	Administer ibuprofen (400 mg PO).	If clear vesicles are intact, aspirate sterilely; if broken, debride and dress with antibiotic or sterile aloe vera ointment.
Stabilize core temperature and treat hypothermia.	Immerse part in 37°–40°C (99°–104°F) (thermometer-monitored) circulating water containing an antiseptic soap until distal flush (10–45 min).	Leave hemorrhagic vesicles intact to prevent desiccation and infection.
Protect frozen part—no friction or massage.	Encourage patient to gently move part.	Continue ibuprofen (400–600 mg PO [12 mg/kg per day] q8 to 12h).
Address medical or surgical conditions.	If pain is refractory, reduce water temperature to 35°–37°C (95°–99°F) and administer parenteral narcotics.	Consider tetanus and streptococcal prophylaxis; elevate part. Administer hydrotherapy at 37°C (99°F). Consider dextran or phenoxybenzamine or, in severe cases, thrombolysis rt-PA (IV or intraarterial).

Abbreviation: rt-PA, recombinant tissue plasminogen activator.

technetium-99 bone scan may assist in the determination of surgical margins. Magnetic resonance angiography may also demonstrate the line of demarcation earlier than does clinical demarcation.

The most common symptomatic sequelae reflect neuronal injury and persistently abnormal sympathetic tone, including paresthesia, thermal misperception, and hyperhidrosis. Delayed findings include nail deformities, cutaneous carcinomas, and epiphyseal damage in children.

Management of the chilblain syndrome is usually supportive. With refractory perniosis, alternatives include nifedipine, steroids, and limaprost, a prostaglandin E_1 analogue.

465 Heat-Related Illnesses

Daniel F. Danzl

Heat-related illnesses include a spectrum of disorders ranging from heat syncope, muscle cramps, and heat exhaustion to medical emergencies such as heatstroke. The core body temperature is normally maintained within a very narrow range. Although significant levels of hypothermia are tolerated **(Chap. 464)**, multiorgan dysfunction occurs rapidly at temperatures >41°–43°C. In contrast to heatstroke, the far more common sign of fever reflects intact thermoregulation.

THERMOREGULATION

Humans are capable of significant heat generation. Strenuous exercise can increase heat generation twentyfold. The heat load from metabolic heat production and environmental heat absorption is balanced by a variety of heat dissipation mechanisms. These central integrative dissipation pathways are orchestrated by the central thermostat, which is located in the preoptic nucleus of the anterior hypothalamus. Efferent signals sent via the autonomic nervous system trigger cutaneous vasodilation and diaphoresis to facilitate heat loss.

Normally, the body dissipates heat into the environment via four mechanisms. The *evaporation* of skin moisture is the single most efficient mechanism of heat loss but becomes progressively ineffective as the relative humidity rises to >70%. The *radiation* of infrared electromagnetic energy directly into the surrounding environment occurs continuously. (Conversely, radiation is a major source of heat gain in hot climates.) *Conduction*—the direct transfer of heat to a cooler object—and *convection*—the loss of heat to air currents—become ineffective when the environmental temperature exceeds the skin temperature.

Factors that interfere with the evaporation of diaphoresis significantly increase the risk of heat illness. Examples include dripping of sweat off the skin, constrictive or occlusive clothing, dehydration, and excessive humidity. While air is an effective insulator, the thermal conductivity of water is 25 times greater than that of air at the same temperature. The *wet-bulb globe temperature* is a commonly used index to assess the environmental heat load. This calculation considers the ambient air temperature, the relative humidity, and the degree of radiant heat.

The regulation of this heat load is complex and involves the central nervous system (CNS), thermosensors, and thermoregulatory effectors. The central thermostat activates the effectors that produce peripheral vasodilation and sweating. The skin surface is in effect the radiator and the principal location of heat loss, since skin blood flow can increase 25–30 times over the basal rate. This dramatic increase in skin blood flow, coupled with the maintenance of peripheral vasodilation, efficiently radiates heat. At the same time, there is a compensatory vasoconstriction of the splanchnic and renal beds.

Acclimatization to heat reflects a constellation of physiologic adaptations that permit the body to lose heat more efficiently. This process often requires one to several weeks of exposure and work in a hot environment. During acclimatization, the thermoregulatory set point is altered, and this alteration affects the onset, volume, and content of diaphoresis. The threshold for the initiation of sweating is lowered, and the amount of sweat increases, with a lowered salt concentration. Sweating rates can be 1–2 L/h in acclimated individuals during heat stress. Plasma volume expansion also occurs and improves cutaneous vascular flow. The heart rate lowers, with a higher stroke volume. After the individual leaves the hot environment, improved tolerance to heat stress dissipates rapidly, the plasma volume decreases, and deacclimatization occurs within weeks.

PREDISPOSING FACTORS AND DIFFERENTIAL DIAGNOSIS

When there is an excessive heat load, unacclimated individuals can develop a variety of heat-related illnesses. Heat waves exacerbate the mortality rate, particularly among the elderly and among persons lacking adequate nutrition and access to air-conditioned environments. Secondary vascular events, including cerebrovascular accidents and myocardial infarctions, occur at least 10 times more often in conditions of extreme heat.

Exertional heat illness continues to occur when laborers, military personnel, or athletes exercise strenuously in the heat. In addition to the very young and very old, preadolescents and teenagers are at risk since they may use poor judgment when vigorously exercising in high humidity and heat. Other risk factors include obesity, poor conditioning with lack of acclimatization, and mild dehydration.

Cardiovascular inefficiency is a common feature of heat illness. Any physiologic or pharmacologic impediment to cutaneous perfusion impairs heat loss. Many patients are unaware of the heat risk associated with their medications. Anticholinergic agents impair sweating and blunt the normal cardiovascular response to heat. Phenothiazines and heterocyclic antidepressants also have anticholinergic properties that interfere with the function of the preoptic nucleus of the anterior hypothalamus due to central depletion of dopamine.

Calcium channel blockers, beta blockers, and various stimulants also inhibit sweating by reducing peripheral blood flow. To maintain the mean arterial blood pressure, increased cardiac output must be capable of compensating for progressive dehydration. A variety of stimulants and substances of abuse also increase muscle activity and heat production.

Careful consideration of the differential diagnosis is important in the evaluation of a patient for a potential heat-related illness. The clinical setting may suggest other etiologies, such as malignant hyperthermia after general anesthesia. Neuroleptic malignant syndrome can be triggered by certain antipsychotic medications, including selective serotonin reuptake inhibitors. A variety of infectious and endocrine disorders as well as toxicologic or CNS etiologies may mimic heatstroke **(Table 465-1)**.

MINOR HEAT-EMERGENCY SYNDROMES

Heat edema is characterized by mild swelling of the hands, feet, and ankles during the first few days of significant heat exposure. The principal mechanism involves cutaneous vasodilation and pooling of interstitial fluid in response to heat stress. Heat also increases the secretion

TABLE 465-1 Heat-Related Illness: Predisposing Factors and Differential Diagnosis

ILLNESS	PREDISPOSING FACTORS
Cardiovascular inefficiency	Age extremes Beta/calcium channel blockade Congestive heart failure Dehydration Diuresis Obesity Poor physical fitness
Central nervous system illness	Cerebellar injury Cerebral hemorrhage Hypothalamic cerebrovascular accident Psychiatric disorders Status epilepticus
Impaired heat loss	Antihistamines Heterocyclic antidepressants Occlusive clothing Skin abnormalities
Endocrine and immune-related illness	Diabetic ketoacidosis Multiple-organ dysfunction syndrome Pheochromocytoma Systemic inflammatory response syndrome Thyroid storm
Excessive heat load	Environmental conditions Exertion Fever Hypermetabolic state Lack of acclimatization
Infectious illness	Cerebral abscess Encephalitis Malaria Meningitis Sepsis syndrome Tetanus Typhoid
Toxicologic illness	Amphetamines Anticholinergic toxidrome Cocaine Dietary supplements Hallucinogens Malignant hyperthermia Neuroleptic malignant syndrome Salicylates Serotonin syndrome Strychnine Sympathomimetics Withdrawal syndromes (ethanol, hypnotics)

of antidiuretic hormone and aldosterone. Systemic causes of edema, including cirrhosis, nephrotic syndrome, and congestive heart failure, can usually be excluded by the history and physical examination. Heat edema generally resolves without treatment in several days. Simple leg elevation or compression stockings will usually suffice. Diuretics are *not* effective and, in fact, predispose to volume depletion and the development of more serious heat-related illnesses.

Prickly heat (*miliaria rubra*, *lichen tropicus*) is a maculopapular, pruritic, erythematous rash that commonly occurs in clothed areas. Blockage of the sweat pores by debris from macerated stratum corneum causes inflammation in the sweat ducts. As the ducts dilate, they rupture and produce superficial vesicles. The predominant symptom is pruritus. In addition to antihistamines, chlorhexidine in a light cream or lotion provides some relief. In adults, localized areas may benefit from 1% salicylic acid TID, with caution taken to avoid salicylate intoxication. Clothing with breathable fabric should be clean and loose fitting, and activities or environments that induce diaphoresis should be avoided.

Heat syncope (exercise-associated collapse) can follow endurance exercise or occur in the elderly. Other common clinical scenarios include prolonged standing while stationary in the heat and sudden standing after prolonged exposure to heat. Heat stress routinely causes relative volume depletion, decreased vasomotor tone, and peripheral vasodilation. The cumulative effect of this decrease in venous return is postural hypotension, especially in nonacclimated elderly individuals. Many of those affected also have comorbidities. Therefore, other cardiovascular, neurologic, and metabolic causes of syncope should be considered. After removal from the heat source, most patients will recover promptly with cooling and rehydration.

Hyperventilation tetany occurs in some individuals when exposure to heat stimulates hyperventilation, producing respiratory alkalosis, paresthesia, and carpopedal spasm. Unlike heat cramps, heat tetany causes very little muscle-compartment pain. Treatment includes providing reassurance, moving the patient out of the heat, and addressing the hyperventilation.

HEAT CRAMPS

Heat cramps (exercise-associated muscle cramps) are intermittent, painful, and involuntary spasmodic contractions of skeletal muscles. They typically occur in an unacclimated individual who is at rest after vigorous exertion in a humid, hot environment. In contrast, cramps that occur in athletes during exercise last longer, are relieved by stretching and massage, and resolve spontaneously.

Of note, not all muscle cramps are related to exercise, and the differential diagnosis includes many other disorders. A variety of medications, myopathies, endocrine disorders, and sickle cell trait are other possible causes.

The typical patient with heat cramps is usually profusely diaphoretic and has been replacing fluid losses with copious water or other hypotonic fluids. Roofers, firefighters, military personnel, athletes, steel workers, and field workers are commonly affected. Other predisposing factors include insufficient sodium intake before intense activity in the heat and lack of heat acclimatization, resulting in sweat with a high salt concentration.

The precise pathogenesis of heat cramps appears to involve a relative deficiency of sodium, potassium, and fluid at the intracellular level. Coupled with copious hypotonic fluid ingestion, large amounts of sodium in the diaphoresis cause hyponatremia and hypochloremia, resulting in muscle cramps due to calcium-dependent muscle relaxation. Total-body depletion of potassium may be observed during the period of heat acclimatization. Rhabdomyolysis is very rare with routine exercise-associated muscle cramps.

Heat cramps that are not accompanied by significant dehydration can be treated with commercially available electrolyte solutions. Although the flavored electrolyte solutions are far more palatable, two 650-mg salt tablets dissolved in 1 quart of water produce a 0.1% saline solution. Individuals should avoid the ingestion of undissolved salt tablets, which are a gastric irritant and may induce vomiting.

HEAT EXHAUSTION

The physiologic hallmarks of heat exhaustion—in contrast to heatstroke—are the maintenance of thermoregulatory control and CNS function. The core temperature is usually elevated but is generally <40.5°C (<105°F). The two physiologic precipitants are water depletion and sodium depletion, which often occur in combination. Laborers, athletes, and elderly individuals exerting themselves in hot environments, without adequate fluid intake, tend to develop *water-depletion heat exhaustion*. Persons working in the heat frequently consume only two-thirds of their net water loss and are voluntarily dehydrated. In contrast, *salt-depletion heat exhaustion* occurs more slowly in unacclimated persons who have been consuming large quantities of hypotonic solutions.

Heat exhaustion is usually a diagnosis of exclusion because of the multitude of nonspecific symptoms. If any signs of heatstroke are present, rapid cooling and crystalloid resuscitation should be initiated immediately during stabilization and evaluation. Mild neurologic and gastrointestinal influenza-like symptoms are common. These symptoms may include headache, vertigo, ataxia, impaired judgment, malaise, dizziness, nausea, and muscle cramps. Orthostatic hypotension and sinus tachycardia develop frequently. More significant CNS impairment suggests heatstroke or other infectious, neurologic, or toxicologic diagnoses.

Hemoconcentration does not always develop, and rapid infusion of isotonic IV fluids should be guided by frequent electrolyte determinations and perfusion requirements. Most cases of heat exhaustion reflect mixed sodium and water depletion. Sodium-depletion heat exhaustion is characterized by hyponatremia and hypochloremia. Hepatic aminotransferases are mildly elevated in both types of heat exhaustion. Urinary sodium and chloride concentrations are usually low.

Some patients with heat exhaustion develop heatstroke after removal from the heat-stress environment. Aggressive cooling of nonresponders is indicated until their core temperature is 39°C (102.2°F). Except in mild cases, free water deficits should be replaced slowly over 24–48 h to avoid a decrease of serum osmolality by >2 mOsm/h.

The disposition of younger, previously healthy heat-exhaustion patients who have no major laboratory abnormalities may include hospital observation and discharge after IV rehydration. Older patients with comorbidities (including cardiovascular disease) or predisposing factors often require inpatient fluid and electrolyte replacement, monitoring, and reassessment.

HEATSTROKE

The clinical manifestations of heatstroke reflect a total loss of thermoregulatory function. Typical vital-sign abnormalities include tachypnea, various tachycardias, hypotension, and a widened pulse pressure. Although there is no single specific diagnostic test, the historical and physical triad of exposure to a heat stress, CNS dysfunction, and a core temperature >40.5°C helps establish the preliminary diagnosis. Some patients with impending heatstroke will initially appear lucid. The definitive diagnosis should be reserved until the other potential causes of hyperthermia are excluded. Many of the usual laboratory abnormalities seen with heatstroke overlap with other conditions. If the patient's mental status does not improve with cooling, toxicologic screening may be indicated, and cranial CT and spinal fluid analysis can be considered.

The premonitory clinical characteristics may be nonspecific and include weakness, dizziness, disorientation, ataxia, and gastrointestinal or psychiatric symptoms. These prodromal symptoms often resemble heat exhaustion. The sudden onset of heatstroke occurs when the maintenance of adequate perfusion requires peripheral vasoconstriction to stabilize the mean arterial blood pressure. As a result, the cutaneous radiation of heat ceases. At this juncture, the core temperature rises dramatically. Since many patients with heatstroke also meet the criteria for systemic inflammatory response syndrome (SIRS) and have a broad differential diagnosis, rapid cooling is essential during the extensive diagnostic evaluation. Heat-induced SIRS reflects the responses of both the innate and the adaptive immune systems (Table 465-1).

There are two forms of heatstroke with significantly different manifestations (Table 465-2). Classic (epidemic) heatstroke (CHS) usually occurs during long periods of high ambient temperature and humidity, as during summer heat waves. Patients with CHS commonly have chronic diseases that predispose to heat-related illness, and they may have limited access to oral fluids. Heat dissipation mechanisms are overwhelmed by both endogenous heat production and exogenous heat stress. Patients with CHS are often compliant with prescribed medications that can impair tolerance to a heat stress. In many of these dehydrated CHS patients, sweating has ceased and the skin is hot and dry.

If cooling is delayed, severe hepatic dysfunction, renal failure, disseminated intravascular coagulation, and fulminant multisystem organ failure may occur. Hepatocytes are very heat sensitive. On presentation, the serum level of aspartate aminotransferase (AST) is routinely elevated. Eventually, levels of both AST and alanine aminotransferase (ALT) often increase to >100 times the normal values. Coagulation studies commonly demonstrate decreased platelets, fibrinogen, and prothrombin. Most patients with CHS require cautious crystalloid resuscitation, electrolyte monitoring, and—in certain refractory cases—consideration of central venous pressure (CVP) measurements. Hypernatremia is secondary to dehydration in CHS. Many patients exhibit significant stress leukocytosis, even in the absence of infection.

TABLE 465-2 Typical Manifestations of Heatstroke

CLASSIC	EXERTIONAL
Older patient	Younger patient
Predisposing health factors/ medications	Healthy condition
Epidemiology (heat waves)	Sporadic cases
Sedentary	Exercising
Anhidrosis (possible)	Diaphoresis (common)
Central nervous system dysfunction	Myocardial/hepatic injury
Oliguria	Acute renal failure
Coagulopathy (mild)	Disseminated intravascular coagulation
Mild lactic acidosis	Marked lactic acidosis
Mild creatine kinase elevation	Rhabdomyolysis
Normoglycemia/calcemia	Hypoglycemia/calcemia
Normokalemia	Hyperkalemia
Normonatremia	Hyponatremia

Patients with exertional heatstroke (EHS), in contrast to those with CHS, are often young and previously healthy, and their diagnosis is usually more obvious from the history. Athletes, laborers, and military recruits are common victims. Unlike those with CHS, many EHS patients present profusely diaphoretic despite significant dehydration. As a result of muscular exertion, rhabdomyolysis and acute renal failure are more common in EHS. Studies to detect rhabdomyolysis and its complications, including hypocalcemia and hyperphosphatemia, should be considered. Hyponatremia, hypoglycemia, and coagulopathies are frequent findings. Elevated creatine kinase and lactate dehydrogenase levels also suggest EHS. Oliguria is a common finding. Renal failure can result from direct thermal injury, untreated rhabdomyolysis, or volume depletion. Common urinalysis findings include microscopic hematuria, myoglobinuria, and granular or red cell casts.

With both CHS and EHS, heat-related increases in cardiac biomarker levels may be present and reversible. Heatstroke often causes thermal cardiomyopathy. As a result, the CVP may be elevated despite significant dehydration. In addition, the patient often presents with potentially deceptive noncardiogenic pulmonary edema and basilar rales despite being significantly hypovolemic. The electrocardiogram commonly displays a variety of tachyarrhythmias, nonspecific ST-T wave changes, and heat-related ischemia or infarction. Rapid cooling—not the *initial* administration of antiarrhythmic medications—is essential.

Above 42°C (107.6°F), heat can rapidly produce direct cellular injury. Thermosensitive enzymes become nonfunctional, and eventually, there is irreversible uncoupling of oxidative phosphorylation. The production of heat-shock proteins increases, and cytokines mediate a systemic inflammatory response. The vascular endothelium is also damaged, and this injury activates the coagulation cascade. Significant shunting away from the splanchnic circulation produces gastrointestinal ischemia. Endotoxins further impair normal thermoregulation. As a result, if cooling is delayed, severe hepatic dysfunction, permanent renal failure, disseminated intravascular coagulation, and fulminant multisystem organ failure may occur.

COOLING STRATEGIES

Before cooling is initiated, endotracheal intubation and continuous core-temperature monitoring should be considered. Peripheral methods to measure temperature are *not* reliable. Hypoglycemia is

a frequent finding and can be addressed by glucose infusion. Since peripheral vasoconstriction delays heat dissipation, repeated administration of discrete boluses of isotonic crystalloid for hypotension is preferable to the administration of α-adrenergic agonists.

Evaporative cooling is frequently the most practical and effective technique. Rapid cooling is essential in both CHS and EHS, and an immediate improvement in vital signs and mental status may prove valuable for diagnostic purposes. Cool water (15°C [60°F]) is sprayed on the exposed skin while fans direct continuous airflow over the moistened skin. Cold packs applied to the neck, axillae, and groin are useful cooling adjuncts. If cardiac electrodes will not adhere, they can be applied to the patient's back.

Immersion cooling in ice-cold water is an alternative option in EHS but can induce peripheral vasoconstriction and shivering. The initial increase in temperature from peripheral vasoconstriction will rapidly be overcome by the large conductive thermal transfer into cold water. This technique presents significant monitoring and resuscitation challenges in many clinical settings. The safety of immersion cooling is best established for young, previously healthy patients with EHS (but not for those with CHS). To avoid hypothermic afterdrop (continued cooling after immersion), active cooling should be terminated at ~38°–39°C (100.4°F–102.2°F).

Cooling with commercially available cooling blankets should not be the sole technique used, since the rate of cooling is far too slow. Other methods are less efficacious and rarely indicated, such as IV infusion of cold fluids and cold irrigation of the bladder or gastrointestinal tract. Cold thoracic and peritoneal lavage are efficient maneuvers but are invasive and rarely necessary. Endovascular cooling also provides effective cooling.

RESUSCITATION

Aspiration commonly occurs in heatstroke, and endotracheal intubation is usually necessary. Depolarizing agents should be avoided. The metabolic demands are high, and supplemental oxygenation is essential due to hypoxemia induced by thermal stress and pulmonary dysfunction. The oxyhemoglobin dissociation curve is shifted to the right. Pneumonitis, pulmonary infarction, hemorrhage, edema, and acute respiratory distress syndrome occur frequently in heatstroke patients. Seizures are common and can occur during therapeutic cooling. Cold induced tonic-clonic muscular rigidity mimics seizure activity.

The circulatory fluid requirements, particularly in CHS, may be deceptively modest. Aggressive cooling and modest volume repletion usually elevate the CVP to 12–14 mmHg. The reading, however, may be deceptive. Many patients present with a thermally induced hyperdynamic circulation accompanied by a high cardiac index, low peripheral vascular resistance, and an elevated CVP caused by right-sided heart failure. In contrast, most patients with EHS require far more zealous isotonic crystalloid resuscitation.

The hypotension that is initially common among patients with heatstroke results from both dehydration and high-output cardiac failure caused by peripheral vasodilation. Inotropes causing α-adrenergic stimulation (e.g., norepinephrine) can impede cooling by causing significant vasoconstriction. Vasoactive catecholamines such as dopamine or dobutamine may be necessary if the cardiac output remains depressed despite an elevated CVP, particularly in patients with a hyperdynamic circulation.

A wide variety of tachyarrhythmias are routinely observed on presentation and usually resolve spontaneously during cooling. The administration of atrial or ventricular antiarrhythmic medications is rarely indicated during cooling. Anticholinergic medications (including atropine) inhibit sweating and should be avoided. With a cardiac rhythm that sustains perfusion, electrical cardioversion of the hyperthermic myocardium should be deferred until the myocardium is cooled. Significant shivering, discomfort, or extreme agitation is preferably mitigated with short-acting benzodiazepines, which are ideal due to their renal clearance. On the other hand, chlorpromazine may lower the seizure threshold, has anticholinergic properties, and can exacerbate the hypotension or cause neuroleptic malignant syndrome. With hepatic dysfunction, barbiturates should be avoided and seizures treated with benzodiazepines.

Coagulopathies more commonly occur after the first day of illness. After cooling, the patient should be monitored for disseminated intravascular coagulation, and replacement therapy with fresh-frozen plasma and platelets should be considered.

There is no therapeutic role for antipyretics in the control of environmentally induced hyperthermia; these drugs block the actions of pyrogens at hypothalamic receptor sites. Salicylates can further uncouple oxidative phosphorylation in heatstroke and exacerbate coagulopathies. Acetaminophen may further stress hepatic function. The safety and efficacy of dantrolene are not established. Although aminocaproic acid impedes fibrinolysis, it may cause rhabdomyolysis and is not recommended in heatstroke.

DISPOSITION

Most patients with minor heat-emergency syndromes (including heat edema, heat syncope, and heat cramps) require only stabilization and treatment with outpatient follow-up. Although there are no decision rules to guide disposition choices in heat exhaustion, many of these patients have multiple predisposing factors and comorbidities that will require prolonged observation or hospital admission.

Essentially all patients with actual heatstroke require admission to a monitored setting, and most require intensive care. There are reports of very high survival rates of patients following prehospital immersion cooling without intensive care. Most or all of these patients appear to have had heat exhaustion. Many actual heatstroke patients also require prolonged tracheal intubation, invasive hemodynamic monitoring, and support for various degrees of multiorgan dysfunction syndrome. The prognosis worsens if the initial core temperature exceeds 42°C (107.6°F) or if there was a prolonged period during which the core temperature exceeded this level. Other features of a negative prognosis include acute renal failure, massively elevated liver enzymes, and significant hyperkalemia. As expected, the number of dysfunctional organ systems also correlates directly with mortality risk.

466 Principles of Human Genetics

J. Larry Jameson, Peter Kopp

IMPACT OF GENETICS AND GENOMICS ON MEDICAL PRACTICE

Human genetics refers to the study of individual genes, their role and function in disease, and their mode of inheritance. Genomics refers to an organism's entire genetic information, the *genome*, and the function and interaction of DNA within the genome, as well as with environmental or nongenetic factors, such as a person's lifestyle. With the characterization of the human genome, genomics not only complements traditional genetics in our efforts to elucidate the etiology and pathogenesis of disease, but it now plays a prominent and continuously expanding role in diagnostics, prevention, and therapy **(Chap. 467)**. These transformative developments, originally emerging from the Human Genome Project, have been variably designated *genomic medicine*, *personalized medicine*, or *precision medicine*. Precision medicine aims at customizing medical decisions to an individual patient. For example, a patient's genetic characteristics (genotype) can be used to optimize drug therapy and predict efficacy, adverse events, and drug dosing of selected medications (*pharmacogenomics*) **(Chap. 68)**. The characterization of the mutational profile of a malignancy allows the identification of driver mutations or overexpressed signaling molecules, which then facilitates the selection of targeted therapies. Genome-wide polygenic risk scores (PRS) for common complex diseases are also beginning to emerge and potentially impact disease prevention.

Genetics has traditionally been viewed through the window of relatively rare single-gene diseases. These disorders account for ~10% of pediatric admissions and childhood mortality. Historically, genetics has focused predominantly on chromosomal and metabolic disorders, reflecting the long-standing availability of techniques to diagnose these conditions. For example, conditions such as trisomy 21 (Down's syndrome) or monosomy X (Turner's syndrome) can be diagnosed using cytogenetics. Likewise, many metabolic disorders (e.g., phenylketonuria, familial hypercholesterolemia) are diagnosed using biochemical analyses. The advances in DNA and RNA diagnostics have extended the field of genetics to include virtually all medical specialties and have led to the elucidation of the pathogenesis of the majority of monogenic disorders. In addition, it is apparent that virtually every medical condition has a genetic component. As is often evident from a patient's family history, many common disorders such as hypertension, heart disease, asthma, diabetes mellitus, and mental illnesses are significantly influenced by the genetic background. These polygenic or multifactorial (complex) disorders involve the contributions of many different genes, as well as environmental factors that can modify disease risk. Genome-wide association studies (GWAS) have elucidated numerous disease-associated loci and are providing novel insights into the allelic architecture of complex traits. These studies have been facilitated by the availability of comprehensive catalogues of human single nucleotide polymorphism (SNP) haplotypes (HapMap, International Genome Sample Resource/1000 Genomes Project). Next-generation DNA sequencing (NGS) technologies have evolved rapidly, and the cost of sequencing whole exomes (the exons within the genome; whole exome sequencing [WES]) or genomes (whole genome sequencing [WGS]) has plummeted. Comprehensive unbiased sequence analyses are now frequently used to characterize individuals with complex undiagnosed conditions or to determine the mutational profile of advanced malignancies in order to select targeted therapies. The routine assembly of diploid genomes, which can reveal a comprehensive spectrum of human genetic variation, will be possible in the near future and should provide further insights into heritability and disease mechanisms.

Cancer has a genetic basis because it results from acquired somatic mutations in genes controlling growth, apoptosis, and cellular differentiation **(Chap. 71)**. In addition, the development of many cancers is associated with a hereditary predisposition. Characterization of the genome (and epigenome) in various malignancies has led to fundamental new insights into cancer biology and reveals that the genomic profile of mutations is in many cases more important in determining the appropriate therapy than the organ in which the tumor originates. The Cancer Genome Atlas (TCGA) initiative of the National Cancer Institute and the National Human Genome Research Institute has already characterized the genomic landscape of >30 malignancies. TCGA consists of comprehensive analyses of genomic and proteomic alterations and is providing fundamental new insights into the molecular pathogenesis of cancer. These data, together with comprehensive catalogues of somatic mutations identified in human cancer, have direct clinical ramifications that impact cancer taxonomy, as well as the development and choice of targeted therapies.

Genetic and genomic approaches have proven invaluable for the detection of infectious pathogens and are used clinically to identify agents that are difficult to culture such as mycobacteria, viruses, and parasites, or to track infectious agents locally or globally. In many cases, molecular genetics has improved the feasibility and accuracy of diagnostic testing and is beginning to open new avenues for therapy, including gene and cellular therapies **(Chap. 470)**. Molecular genetics has also provided the opportunity to characterize the *microbiome*, a new field that characterizes the population dynamics of bacteria, viruses, and parasites that coexist with humans and other animals **(Chap. 471)**. Emerging data indicate that the microbiome has significant effects on normal physiology as well as various disease states, and the field is now focusing on defining the mechanisms underlying these interactions.

Molecular biology has significantly changed the treatment of human disease. Peptide hormones, growth factors, cytokines, and vaccines can be produced in large amounts using recombinant DNA and RNA technology (e.g., mRNA vaccines against SARS-CoV-2). Targeted modifications of recombinant peptides provide improved therapeutic tools, as illustrated by genetically modified insulin analogues with more favorable kinetics.

The astounding rate at which new genetic and genomic information is being generated has led to major challenges for physicians, health care providers, and basic investigators. Although many functional aspects of the genome remain unknown, there are many clinical situations where sufficient evidence exists for the use of genetic and genomic information to optimize patient care and treatment. Much genetic information resides in databases that provide easy access to the expanding information about the human genome, genetic disease, and genetic testing **(Table 466-1)**. For example, several thousand monogenic disorders are summarized in a large, continuously evolving compendium, referred to as the *Online Mendelian Inheritance in Man* (OMIM) catalogue (Table 466-1). The constant refinement of bioinformatics and new developments in *big data analytics*, together with the widespread adoption of electronic health records (EHRs), are simplifying the access, analysis, and integration of this daunting amount of new information. Importantly, genomic data can be integrated readily into EHRs and thus impact clinical practice.

THE HUMAN GENOME

Structure of the Human Genome The Human Genome Project was initiated in the mid-1980s as an ambitious effort to characterize the entire human genome and culminated in the completion of the DNA

Mouse genome informatics	*http://www.informatics.jax.org*	Mouse genome informatics, potential mouse models of human disease, information on phenotypic similarity between mouse models and human patients

Note: Databases are evolving constantly. Pertinent information may be found by using links listed in the few selected databases.

sequence for the last of the human chromosomes in 2006. The scope of a whole genome sequence analysis can be illustrated by the following analogy. Human DNA consists of ~3 billion base pairs (bp) of DNA per haploid genome, which is nearly 1000-fold greater than that of the *Escherichia coli* genome. If the human DNA sequence were printed out, it would correspond to about 120 volumes of *Harrison's Principles of Internal Medicine*.

In addition to the human genome, the genomes of thousands of organisms have been sequenced completely or partially (Genomes Online Database [GOLD]; Table 466-1). They include, among others, eukaryotes such as the mouse (*Mus musculus*), *Saccharomyces cerevisiae*, *Caenorhabditis elegans*, and *Drosophila melanogaster*; bacteria (e.g., *E. coli*); and archaea, viruses, organelles (mitochondria, chloroplasts), and plants (e.g., *Arabidopsis thaliana*). Genomic information of infectious agents has significant impact for the characterization of infectious outbreaks and epidemics. Other ramifications arising from the availability of genomic data include, among others, (1) the comparison of entire genomes (*comparative genomics*); (2) the study of large-scale expression of RNAs (*functional genomics*), proteins (*proteomics*), or protein families (e.g., the *kinome*, the complete set of protein kinases) to detect differences between various tissues in health and disease; (3) the characterization of the variation among individuals by establishing catalogues of sequence variations and SNPs; and (4) the identification of genes that play critical roles in the development of polygenic and multifactorial disorders.

CHROMOSOMES The human genome is divided into 23 different chromosomes, including 22 autosomes (numbered 1–22) and the X and Y sex chromosomes **(Fig. 466-1)**. Adult cells are *diploid*, meaning they contain two homologous sets of 22 autosomes and a pair of sex chromosomes. Females have two X chromosomes (XX), whereas males have one X and one Y chromosome (XY). As a consequence of meiosis, germ cells (sperm or oocytes) are haploid and contain one set of 22 autosomes and one of the sex chromosomes. At the time of fertilization, the diploid genome is reconstituted by pairing of the homologous chromosomes from the mother and father. With each cell division (mitosis), chromosomes are replicated, paired, segregated, and divided into two daughter cells.

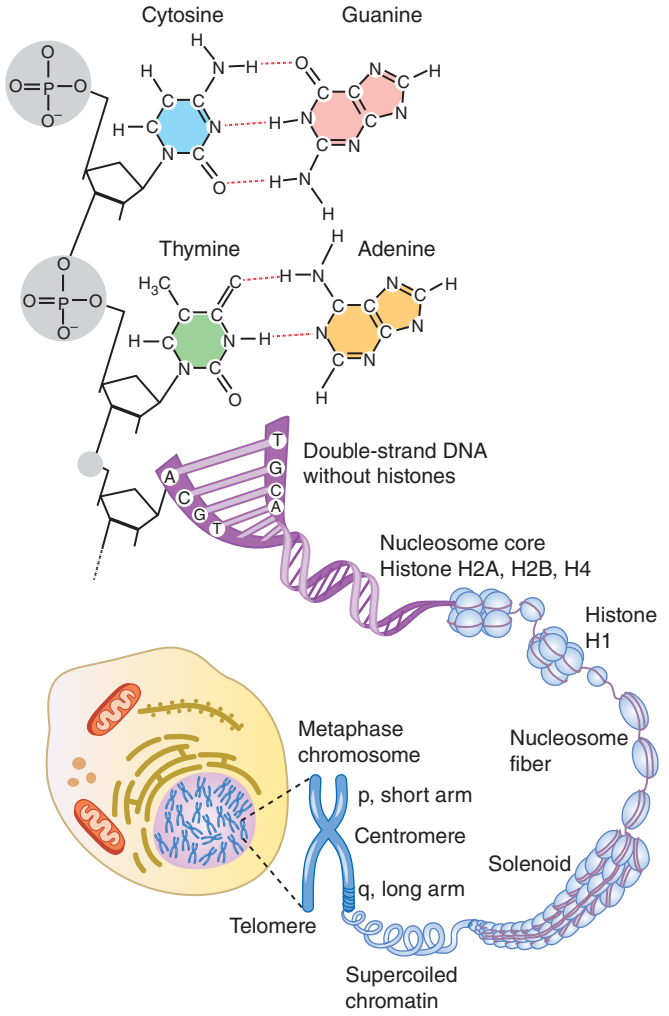

FIGURE 466-1 Structure of chromatin and chromosomes. Chromatin is composed of double-strand DNA that is wrapped around histone and nonhistone proteins forming nucleosomes. The nucleosomes are further organized into solenoid structures. Chromosomes assume their characteristic structure, with short (p) and long (q) arms at the metaphase stage of the cell cycle.

STRUCTURE OF DNA DNA is a double-stranded helix composed of four different bases: adenine (A), thymidine (T), guanine (G), and cytosine (C). Adenine is paired to thymidine, and guanine is paired to cytosine, by hydrogen bond interactions that span the double helix (Fig. 466-1). DNA has several remarkable features that make it ideal for the transmission of genetic information. It is relatively stable, and the double-stranded nature of DNA and its feature of strict base-pair complementarity permit faithful replication during cell division. Complementarity also allows the transmission of genetic information from DNA → RNA → protein **(Fig. 466-2)**. mRNA is encoded by the so-called sense or coding strand of the DNA double helix and is translated into proteins by ribosomes.

The presence of four different bases provides surprising genetic diversity. In the protein-coding regions of genes, the DNA bases are arranged into codons, a triplet of bases that specifies a particular amino acid. It is possible to arrange the four bases into 64 different triplet codons (4^3). Each codon specifies 1 of the 20 different amino acids, or a regulatory signal such as initiation and stop of translation. Because there are more codons than amino acids, the genetic code is degenerate; that is, most amino acids can be specified by several different codons. By arranging the codons in different combinations and in various lengths, it is possible to generate the tremendous diversity of primary protein structure.

DNA length is normally measured in units of 1000 bp (kilobases, kb) or 1,000,000 bp (megabases, Mb). In the human genome, only ~1% of DNA accounts for protein-coding sequences. The noncoding DNA has multiple functional and structural roles including (1) sequences that form introns; (2) regulatory elements (promoters, enhancers, silencers, insulators); (3) sequences that generate RNAs that do not code for proteins; (4) centromeres and telomeres; (5) regions defining chromatin structure and histone modifications; (6) various forms of repetitive sequences of variable length; and (7) pseudogenes and regions without currently discernible functional or structural roles (Fig. 466-1).

GENES A *gene* is a functional unit that is regulated by transcription (see below) and encodes an RNA product, which is most commonly, but not always, translated into a protein that exerts activity within or outside the cell **(Fig. 466-3)**. Historically, genes were identified because they conferred specific traits that are transmitted from one generation to the next. Now, they are frequently characterized based on expression in various tissues (*transcriptome*). The size of genes is quite broad; some genes are only a few hundred base pairs, whereas others are extraordinarily large (2 Mb). The number of genes greatly underestimates the complexity of genetic expression, because single genes can generate multiple spliced messenger RNA (mRNA) products (*isoforms*), which are translated into proteins that are subject to complex posttranslational modification such as phosphorylation. *Exons* refer to the portion of genes that are eventually spliced together to form mRNA. *Introns* refer to the spacing regions between the exons that are spliced out of precursor RNAs during RNA processing. The gene locus also includes regions that are necessary to control its expression (Fig. 466-2). Current estimates predict roughly 20,000 protein-coding genes in the human genome with an average of about four different coding transcripts per gene. Remarkably, the exome only constitutes 1.14% of the genome. Of note, the number of transcripts is close to 200,000 and includes thousands of noncoding transcripts (RNAs of various length such as microRNAs [miRNA] and long noncoding RNAs [lncRNA]). These noncoding RNAs are involved in numerous cellular processes such as transcriptional and posttranscriptional regulation of gene expression, chromatin remodeling, and protein trafficking, among others. Not surprisingly, aberrant expression and/or mutations in these RNAs play a pathogenic role in numerous diseases.

SINGLE-NUCLEOTIDE POLYMORPHISMS Each individual has roughly 5 million sequence variants that differentiate one person from another. Some of these variants have no impact on health, whereas others may increase or lower the risk for developing a specific disease. Remarkably, however, the primary DNA sequence of humans has ~99.9% similarity compared to that of any other human. An SNP is a variation of a single base pair in the DNA. The identification of the ~10 million SNPs estimated to occur in the human genome has generated a catalogue of common genetic variants that occur in human beings from distinct ethnic backgrounds (Fig. 466-3). SNPs are the most common type of sequence variation and account for ~90% of all sequence variation. They occur on average every 100–300 bases and are the major source of genetic heterogeneity. SNPs that are in close proximity are inherited together (e.g., they are linked) and are referred to as *haplotypes* **(Fig. 466-4)**. Haplotype maps describe the nature and location of these SNP haplotypes and how they are distributed among individuals within and among populations, information that has been facilitating GWAS designed to elucidate the complex interactions among multiple genes and lifestyle factors in multifactorial disorders (see below). Moreover, haplotype analyses are useful to assess variations in responses to medications (*pharmacogenomics*) and environmental factors, as well as the prediction of disease predisposition.

COPY NUMBER VARIATIONS Copy number variations (CNVs) are relatively large genomic regions (1 kb to several Mb) that have been duplicated or deleted on certain chromosomes and hence alter the diploid status of the DNA **(Fig. 466-5)**. It has been estimated that 5–10% of the genome can display CNVs. When comparing the genomes of two individuals, ~0.4–0.8% of their genomes differ in terms of CNVs scattered throughout the genome. Of note, de novo CNVs have been observed between monozygotic twins, who otherwise have identical genomes. Some CNVs have no functional consequences, whereas others have been associated with susceptibility or resistance to disease, and CNVs also occur in cancer cells.

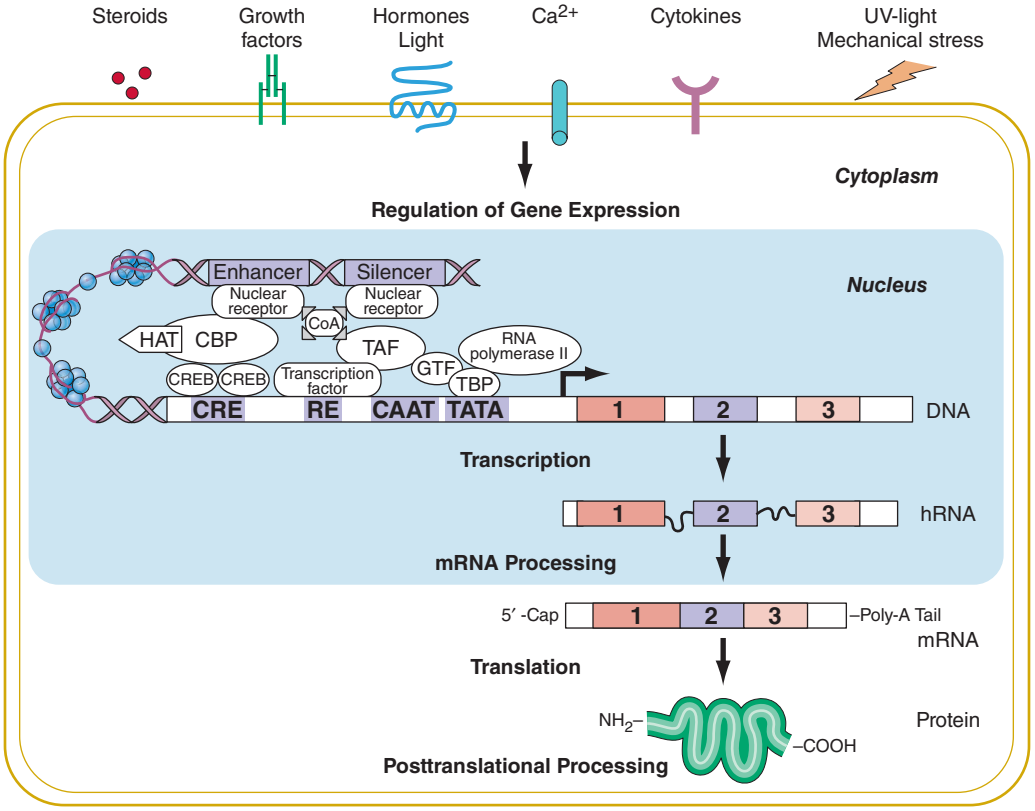

FIGURE 466-2 Flow of genetic information. Multiple extracellular signals activate intracellular signal cascades that result in altered regulation of gene expression through the interaction of transcription factors with regulatory regions of genes. RNA polymerase transcribes DNA into RNA that is processed to mRNA by excision of intronic sequences. The mRNA is translated into a polypeptide chain to form the mature protein after undergoing posttranslational processing. CBP, CREB-binding protein; CoA, co-activator; COOH, carboxyterminus; CRE, cyclic AMP responsive element; CREB, cyclic AMP response element–binding protein; GTF, general transcription factors; HAT, histone acetyl transferase; NH2, aminoterminus; RE, response element; TAF, TBP-associated factors; TATA, TATA box; TBP, TATA-binding protein.

Replication of DNA and Mitosis Genetic information in DNA is transmitted to daughter cells under two different circumstances: (1) somatic cells divide by *mitosis*, allowing the diploid ($2n$) genome to replicate itself completely in conjunction with cell division; and (2) germ cells (sperm and ova) undergo *meiosis*, a process that enables the reduction of the diploid ($2n$) set of chromosomes to the haploid state ($1n$).

Prior to mitosis, cells exit the resting, or G_0 state, and enter the cell cycle. After traversing a critical checkpoint in G_1, cells undergo DNA synthesis (S phase), during which the DNA in each chromosome is replicated, yielding two pairs of sister chromatids ($2n \rightarrow 4n$). The process of DNA synthesis requires stringent fidelity in order to avoid transmitting errors to subsequent generations of cells. Genetic abnormalities of DNA mismatch/repair include xeroderma pigmentosum, Bloom's syndrome, ataxia telangiectasia, and hereditary nonpolyposis colon cancer (HNPCC), among others. Many of these disorders strongly predispose to neoplasia because of the rapid acquisition of additional mutations **(Chap. 71)**. After completion of DNA synthesis, cells enter G_2 and progress through a second checkpoint before entering mitosis. At this stage, the chromosomes condense and are aligned along the equatorial plate at metaphase. The two identical sister chromatids, held together at the centromere, divide and migrate to opposite poles of the cell. After formation of a nuclear membrane around the two separated sets of chromatids, the cell divides and two daughter cells are formed, thus restoring the diploid ($2n$) state.

Assortment and Segregation of Genes During Meiosis Meiosis occurs only in germ cells of the gonads. It shares certain features with mitosis but involves two distinct steps of cell division that reduce the chromosome number to the haploid state. In addition, there is active recombination that generates genetic diversity. During the first cell division, two sister chromatids ($2n \rightarrow 4n$) are formed for each chromosome pair and there is an exchange of DNA between homologous paternal and maternal chromosomes. This process involves the formation of *chiasmata*, structures that correspond to the DNA segments that cross over between the maternal and paternal homologues **(Fig. 466-6)**. Usually there is at least one crossover on each chromosomal arm; recombination occurs more frequently in female meiosis than in male meiosis. Subsequently, the chromosomes segregate randomly. Because there are 23 chromosomes, there exist 2^{23} (>8 million) possible combinations of chromosomes. Together with the genetic exchanges that occur during recombination, chromosomal segregation generates tremendous diversity, and each gamete is genetically unique. The process of recombination and the independent segregation of chromosomes provide the foundation for performing linkage analyses, whereby one attempts to correlate the inheritance of certain chromosomal regions (or linked genes) with the presence of a disease or genetic trait (see below).

After the first meiotic division, which results in two daughter cells ($2n$), the two chromatids of each chromosome separate during a second meiotic division to yield four gametes with a haploid state ($1n$). When the egg is fertilized by sperm, the two haploid sets are combined, thereby restoring the diploid state ($2n$) in the zygote.

REGULATION OF GENE EXPRESSION

Regulation by Transcription Factors The expression of genes is regulated by DNA-binding proteins that activate or repress transcription. The number of DNA sequences and transcription factors that regulate transcription is much greater than originally anticipated. Most genes contain at least 15–20 discrete regulatory elements within 300 bp of the transcription start site. This densely packed promoter region often contains binding sites for ubiquitous transcription factors. However, factors involved in cell-specific expression may also bind to these sequences. Key regulatory elements may also reside at a large distance from the proximal promoter. The globin and the

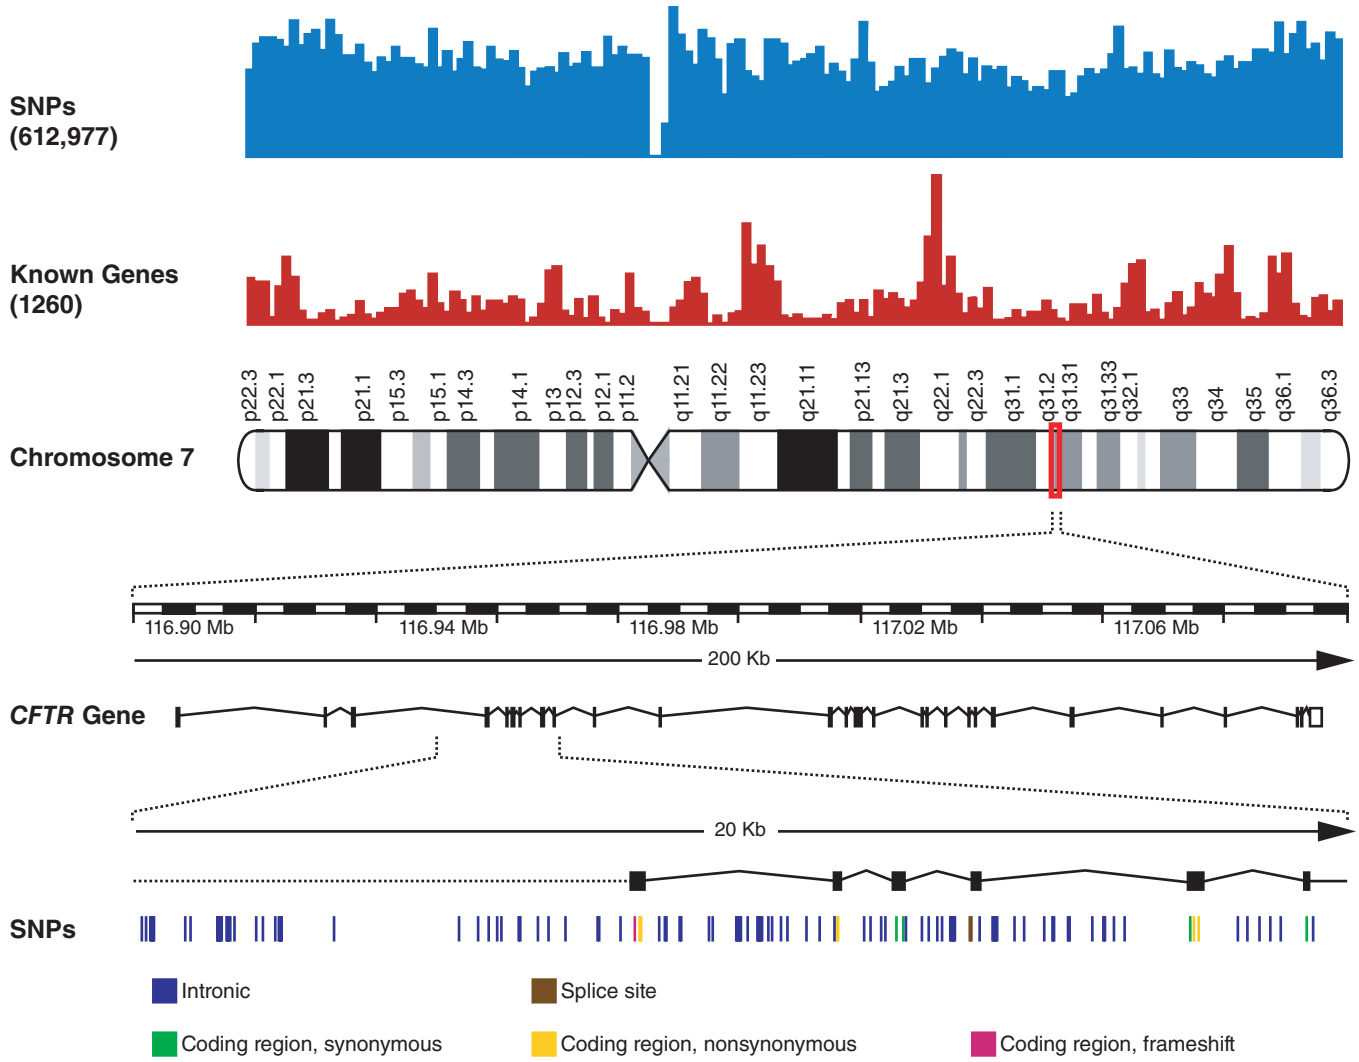

FIGURE 466-3 Chromosome 7 is shown with the density of single nucleotide polymorphisms (SNPs) and genes above. A 200-kb region in 7q31.2 containing the *CFTR* gene is shown below. The *CFTR* gene contains 27 exons. Close to 2000 mutations in this gene have been found in patients with cystic fibrosis. A 20-kb region encompassing exons 4–9 is shown further amplified to illustrate the SNPs in this region.

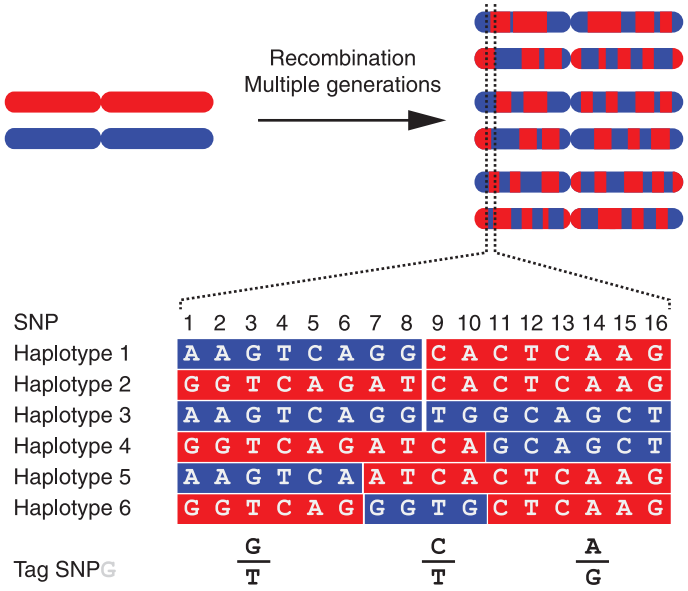

FIGURE 466-4 The origin of haplotypes is due to repeated recombination events occurring in multiple generations. Over time, this leads to distinct haplotypes. These haplotype blocks can often be characterized by genotyping selected Tag single nucleotide polymorphisms (SNPs), an approach that facilitates performing genome-wide association studies (GWAS).

immunoglobulin genes, for example, contain *locus control regions* that are several kilobases away from the structural sequences of the gene. Specific groups of transcription factors that bind to these promoter and enhancer sequences provide a combinatorial code for regulating transcription. In this manner, relatively ubiquitous factors interact with more restricted factors to allow each gene to be expressed and regulated in a unique manner that is dependent on developmental state, cell type, and numerous extracellular stimuli. Regulatory factors also bind within the gene itself, particularly in the intronic regions. The transcription factors that bind to DNA actually represent only the first level of regulatory control. Other proteins—*co-activators* and *co-repressors*—interact with the DNA-binding transcription factors to generate large regulatory complexes. These complexes are subject to control by numerous cell-signaling pathways and enzymes, leading to phosphorylation, acetylation, sumoylation, and ubiquitination. Ultimately, the recruited transcription factors interact with, and stabilize, components of the basal transcription complex that assembles at the site of the TATA box and initiator region. This basal transcription factor complex consists of >30 different proteins. Gene transcription occurs when RNA polymerase begins to synthesize RNA from the DNA template. A large number of identified genetic diseases involve transcription factors (Table 466-2).

The field of *functional genomics* is based on the concept that understanding alterations of gene expression under various physiologic and pathologic conditions provides insight into the underlying functional

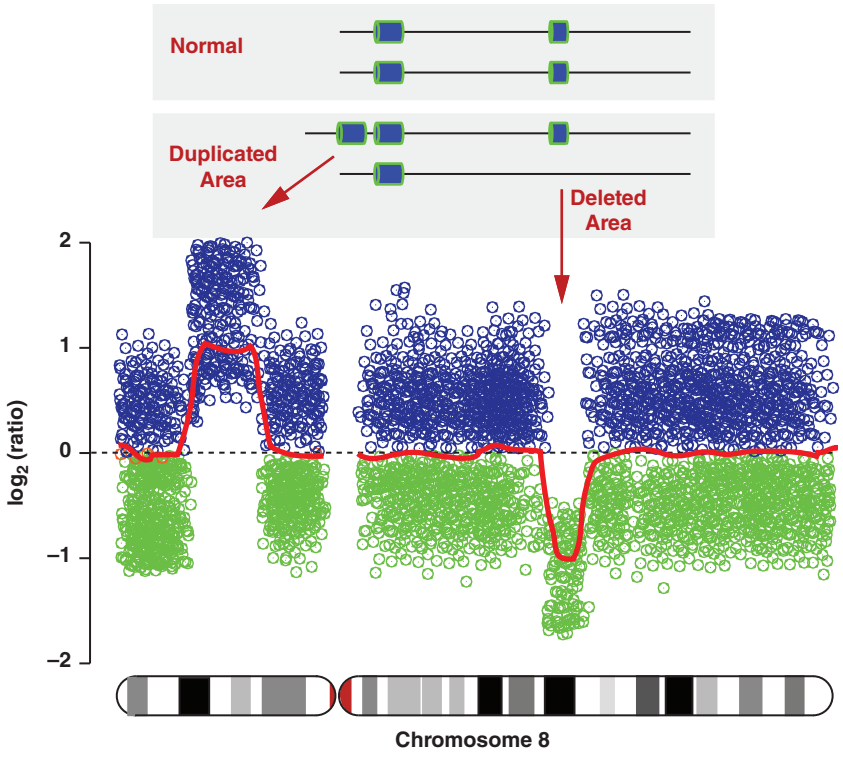

FIGURE 466-5 Copy number variations (CNV) encompass relatively large regions of the genome that have been duplicated or deleted. Chromosome 8 is shown with a CNV detected by genomic hybridization. An increase in the signal strength indicates a duplication, whereas a decrease reflects a deletion of the covered chromosomal regions.

role of the gene. The ENCODE (Encyclopedia of DNA Elements) project aims to compile and annotate all functional sequences in the human genome. By revealing specific gene expression profiles, this knowledge can be of diagnostic and therapeutic relevance. The large-scale study of expression profiles is referred to as *transcriptomics* because the complement of mRNAs transcribed by the cellular genome is called the *transcriptome*.

Most studies of gene expression have focused on the regulatory DNA elements of genes that control transcription. However, it should be emphasized that gene expression requires a series of steps, including mRNA processing, protein translation, and posttranslational modifications, all of which are actively regulated (Fig. 466-2).

Epigenetic Regulation of Gene Expression (see Chap. 483)

Epigenetics describes mechanisms and phenotypic changes that are not a result of variation in the primary DNA nucleotide sequence but are caused by secondary modifications of DNA or histones. These modifications include heritable changes such as X-inactivation and imprinting, but they can also result from dynamic posttranslational protein modifications in response to environmental influences such as diet, age, or drugs. The epigenetic modifications result in altered expression of individual genes or chromosomal loci encompassing multiple genes. The term *epigenome* describes the constellation of covalent modifications of DNA and histones that impact chromatin structure, as well as noncoding transcripts that modulate the transcriptional activity of DNA. Although the primary DNA sequence is usually identical in all cells of an organism, tissue-specific changes in the epigenome contribute to determining the transcriptional signature of a cell (transcriptome) and hence the protein expression profile (proteome).

Mechanistically, DNA and histone modifications can result in the activation or silencing of gene expression (Fig. 466-7). DNA methylation involves the addition of a methyl group to cytosine residues. This is usually restricted to cytosines of CpG dinucleotides, which are abundant throughout the genome. Methylation of these dinucleotides is thought to represent a defense mechanism that minimizes the expression of sequences that have been incorporated into the genome such as retroviral sequences. CpG dinucleotides also exist in so-called *CpG islands*, stretches of DNA characterized by a high CG content, which are found in the majority of human gene promoters. CpG islands in promoter regions are typically unmethylated, and the lack of methylation facilitates transcription.

Histone methylation involves the addition of a methyl group to lysine residues in histone proteins (Fig. 466-7). Depending on the specific lysine residue being methylated, this alters chromatin configuration, making it either more open or tightly packed. Acetylation of histone proteins is another well-characterized mechanism that results in an open chromatin configuration, which favors active transcription. Acetylation is generally more dynamic than methylation, and many transcriptional activation complexes have histone acetylase activity, whereas repressor complexes often contain deacetylases and remove acetyl groups from histones. Other histone modifications include, among others, phosphorylation and sumoylation.

Furthermore, noncoding RNAs and RNA regulatory networks that bind to DNA have a significant impact on transcriptional activity.

Physiologically, epigenetic mechanisms play an important role in several instances. For example, X-inactivation refers to the relative silencing of one of the two X chromosome copies present in females. The inactivation process is a form of dosage compensation such that females (XX) do not generally express twice as many X-chromosomal gene products as males (XY). In a given cell, the choice of which chromosome is inactivated occurs randomly in humans. But once the maternal or paternal X chromosome is inactivated,

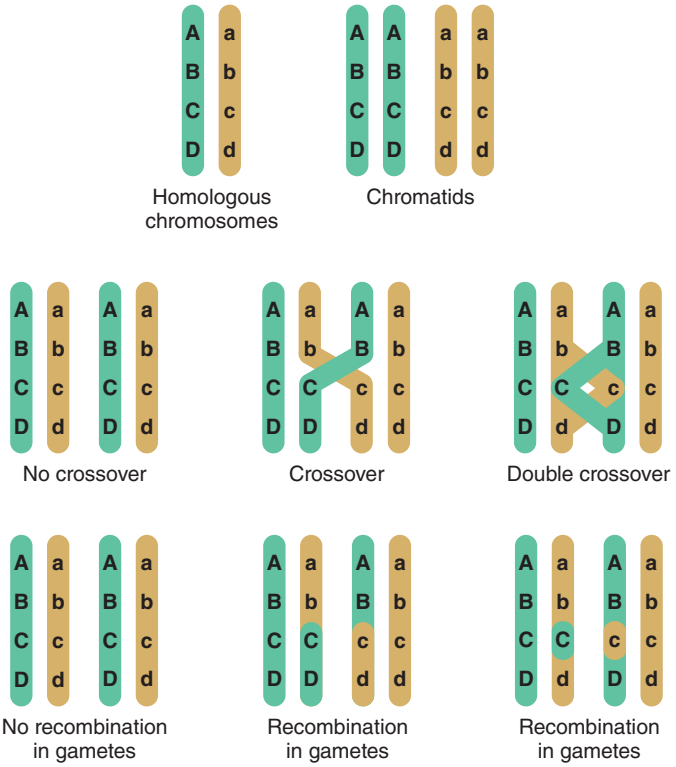

FIGURE 466-6 Crossing-over and genetic recombination. During chiasma formation, either of the two sister chromatids on one chromosome pairs with one of the chromatids of the homologous chromosome. Genetic recombination occurs through crossing-over and results in recombinant and nonrecombinant chromosome segments in the gametes. Together with the random segregation of the maternal and paternal chromosomes, recombination contributes to genetic diversity and forms the basis of the concept of linkage.

TABLE 466-2 Selected Examples of Diseases Caused by Mutations and Rearrangements in Transcription Factors

TRANSCRIPTION FACTOR CLASS	EXAMPLE	ASSOCIATED DISORDER
Nuclear receptors	Androgen receptor	Complete or partial androgen insensitivity (recessive missense mutations) Spinobulbar muscular atrophy (CAG repeat expansion)
Zinc finger proteins	WT1	WAGR syndrome: *W*ilms' tumor, *a*niridia, *g*enitourinary malformations, mental *r*etardation
Basic helix-loop-helix	MITF	Waardenburg's syndrome type 2A
Homeobox	IPF1	Maturity onset of diabetes mellitus type 4 (heterozygous mutation/ haploinsufficiency) Pancreatic agenesis (homozygous mutation)
Leucine zipper	Retina leucine zipper (NRL)	Autosomal dominant retinitis pigmentosa
High mobility group (HMG) proteins	SRY	Sex reversal
Forkhead	HNF4α, HNF1α, HNF1β	Maturity onset of diabetes mellitus types 1, 3, 5
Paired box	PAX3	Waardenburg's syndrome types 1 and 3
T-box	TBX5	Holt-Oram syndrome (thumb anomalies, atrial or ventricular septum defects, phocomelia)
Cell cycle control proteins	P53	Li-Fraumeni syndrome, other cancers
Co-activators	CREB binding protein (CREBBP)	Rubinstein-Taybi syndrome
General transcription factors	TATA-binding protein (TBP)	Spinocerebellar ataxia 17 (CAG expansion)
Transcription elongation factor	VHL	von Hippel–Lindau syndrome (renal cell carcinoma, pheochromocytoma, pancreatic tumors, hemangioblastomas) Autosomal dominant inheritance, somatic inactivation of second allele (Knudson two-hit model)
Runt	RUNX1	Familial thrombocytopenia with propensity to acute myelogenous leukemia
Chimeric proteins due to translocations	PML-RAR	Acute promyelocytic leukemia t(15;17)(q22;q11.2-q12) translocation

Abbreviations: CREB, cAMP responsive element–binding protein; HNF, hepatocyte nuclear factor; PML, promyelocytic leukemia; RAR, retinoic acid receptor; SRY, sex-determining region Y; VHL, von Hippel–Lindau.

it will remain inactive, and this information is transmitted with each cell division. The *X-inactive specific transcript* (*Xist*) gene encodes a large noncoding RNA that mediates the silencing of the X chromosome from which it is transcribed by coating it with *Xist* RNA. The inactive X chromosome is highly methylated and has low levels of histone acetylation. While the majority of X-chromosomal genes are silenced by X-inactivation, ~15% escape inactivation and are expressed.

Epigenetic gene inactivation also occurs on selected chromosomal regions of autosomes, a phenomenon referred to as *genomic imprinting*. Through this mechanism, a small subset of genes is only expressed in a monoallelic fashion. Imprinting is heritable and leads to the preferential expression of one of the parental alleles, which deviates from the usual biallelic expression seen for the majority of genes. Remarkably, imprinting can be limited to a subset of tissues. Imprinting is mediated through DNA methylation of one of the alleles. The epigenetic marks on imprinted genes are maintained throughout life, but during zygote formation, they are activated or inactivated in a sex-specific manner (imprint reset) **(Fig. 466-8)**, which allows a differential expression pattern in the fertilized egg and the subsequent mitotic divisions. Appropriate expression of imprinted genes is important for normal development and cellular functions. Imprinting defects and uniparental disomy, which is the inheritance of two chromosomes or chromosomal regions from the same parent, are the cause of several developmental disorders such as Beckwith-Wiedemann syndrome, Silver-Russell syndrome, Angelman's syndrome, and Prader-Willi syndrome (see below). Monoallelic loss-of-function mutations in the *GNAS1* gene lead to Albright's hereditary osteodystrophy (AHO). Paternal transmission of *GNAS1* mutations leads to an isolated AHO phenotype (pseudopseudohypoparathyroidism), whereas maternal transmission leads to AHO in combination with hormone resistance to parathyroid hormone, thyrotropin, and gonadotropins (pseudohypoparathyroidism type IA). These phenotypic differences are explained by tissue-specific imprinting of the *GNAS1* gene, which is expressed primarily from the maternal allele in the thyroid, gonadotropes, and the proximal renal tubule. In most other tissues, the *GNAS1* gene is expressed biallelically. In patients with isolated renal resistance to parathyroid hormone (pseudohypoparathyroidism type IB), defective imprinting of the *GNAS1* gene results in decreased $G_s\alpha$ expression in the proximal renal tubules. Rett's syndrome is an X-linked dominant disorder resulting in developmental regression and stereotypic hand movements in affected girls. It is caused by mutations in the *MECP2* gene, which encodes a methyl-binding protein. The ensuing aberrant methylation results in abnormal gene expression in neurons, which are otherwise normally developed.

Remarkably, epigenetic differences also occur among monozygotic twins. Although twins are epigenetically indistinguishable during the early years of life, older monozygotic twins exhibit differences in the overall content and genomic distribution of DNA methylation and histone acetylation, which would be expected to alter gene expression in various tissues.

In cancer, the epigenome is characterized by simultaneous losses and gains of DNA methylation in different genomic regions, as well as repressive histone modifications. Hyper- and hypomethylation are associated with mutations in genes that control DNA methylation. Hypomethylation is thought to remove normal control mechanisms that prevent expression of repressed DNA regions. It is also associated with genomic instability. Hypermethylation, in contrast, results in the silencing of CpG islands in promoter regions of genes, including tumor-suppressor genes. Epigenetic alterations are considered to be more easily reversible compared to genetic changes; modification of the epigenome with demethylating agents and histone deacetylases is being used in the treatment of various malignancies.

TRANSMISSION OF GENETIC DISEASE

Origins and Types of Mutations The term *mutation* or *variant* is used to designate the process of generating genetic variations as well as the outcome of these alterations. A *mutation* can be defined as any change in the primary nucleotide sequence of DNA regardless of its functional consequences, although it often has a negative connotation. The more neutral term *variation* is now increasingly used to describe sequence changes and is recommended by several professional organizations and guidelines instead of *mutation*. Some variations may be lethal, others are less deleterious, and some may confer an evolutionary advantage. Variations can occur in the germline (sperm or oocytes); these can be transmitted to progeny. Alternatively, variations can occur during embryogenesis or in somatic tissues. Variations that occur during development lead to *mosaicism*, a situation in which tissues are composed of cells with different genetic constitutions. If the germline is mosaic, a mutation can be transmitted to some progeny but not others, which sometimes leads to confusion in assessing the pattern of inheritance. Somatic mutations that do not affect cell survival can sometimes be detected because of variable phenotypic effects in tissues (e.g., pigmented lesions in McCune-Albright syndrome). Other somatic mutations are associated with neoplasia because they confer a growth advantage to cells. Epigenetic events may also influence gene expression or facilitate genetic damage. With the exception of triplet

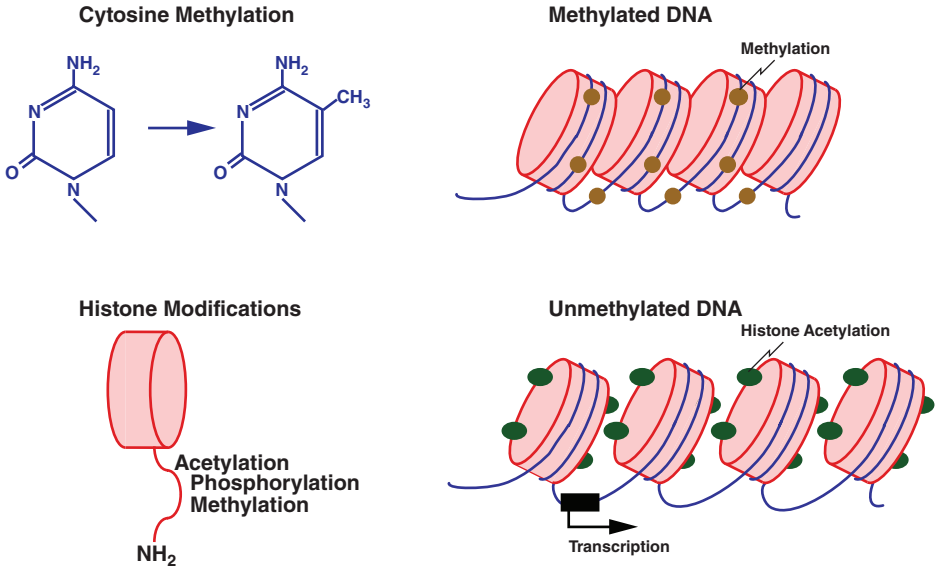

FIGURE 466-7 Epigenetic modifications of DNA and histones. Methylation of cytosine residues is associated with gene silencing. Methylation of certain genomic regions is inherited (imprinting), and it is involved in the silencing of one of the two X chromosomes in females (X-inactivation). Alterations in methylation can also be acquired, e.g., in cancer cells. Covalent posttranslational modifications of histones play an important role in altering DNA accessibility and chromatin structure and hence in regulating transcription. Histones can be reversibly modified in their amino-terminal tails, which protrude from the nucleosome core particle, by acetylation of lysine, phosphorylation of serine, methylation of lysine and arginine residues, and sumoylation. Acetylation of histones by histone acetylases (HATs), e.g., leads to unwinding of chromatin and accessibility to transcription factors. Conversely, deacetylation by histone deacetylases (HDACs) results in a compact chromatin structure and silencing of transcription.

nucleotide repeats, which can expand (see below), variations are usually stable.

Mutations are structurally diverse—they can involve the entire genome, as in triploidy (one extra set of chromosomes), or gross numerical or structural alterations in chromosomes or individual genes. Large deletions may affect a portion of a gene or an entire gene, or, if several genes are involved, they may lead to a *contiguous gene syndrome*. Unequal crossing-over between homologous genes can result in fusion gene mutations, as illustrated by color blindness. Variations involving single nucleotides are referred to as *point mutations*. Substitutions are called *transitions* if a purine is replaced by another purine base (A ↔ G) or if a pyrimidine is replaced by another pyrimidine (C ↔ T). Changes from a purine to a pyrimidine, or vice versa, are referred to as *transversions*. If the DNA sequence change occurs in a coding region and alters an amino acid, it is called a *missense mutation*. Depending on the functional consequences of such a missense mutation, amino acid substitutions in different regions of the protein can lead to distinct phenotypes.

Variations can occur in all domains of a gene **(Fig. 466-9)**. A point mutation occurring within the coding region leads to an amino acid substitution if the codon is altered **(Fig. 466-10)**. Point mutations that introduce a premature stop codon result in a truncated or missing protein. Large deletions may affect a portion of a gene or an entire gene, whereas small deletions and insertions alter the reading frame if they do not represent a multiple of three bases. These "frameshift" mutations, also designated as *amphigoric* amino acid changes, lead to an entirely altered carboxy terminus. Mutations in intronic sequences or in exon junctions may destroy or create splice donor or splice acceptor sites. Variations may also be found in the regulatory sequences of genes, resulting in reduced or enhanced gene transcription.

Certain DNA sequences are particularly susceptible to mutagenesis. Successive pyrimidine residues (e.g., T-T or C-C) are subject to the formation of ultraviolet light–induced photoadducts. If these pyrimidine dimers are not repaired by the nucleotide excision repair pathway, mutations will be introduced after DNA synthesis. The dinucleotide C-G, or CpG, is also a hot spot for a specific type of mutation. In this case, methylation of the cytosine is associated with an enhanced rate of deamination to uracil, which is then replaced with thymine. This C → T transition (or G → A on the opposite strand) accounts for at least one-third of point mutations associated with polymorphisms and mutations. In addition to the fact that certain types of mutations (C → T or G → A) are relatively common, the nature of the genetic code also results in overrepresentation of certain amino acid substitutions.

Polymorphisms are sequence variations that have a frequency of at least 1%. Usually, they do not result in a perceptible phenotype, but because allele frequency and functional consequences are often not known, the term *variation* is now increasingly recommended for the description of these sequence changes. Often, they consist of single base-pair substitutions that do not alter the protein coding sequence because of the degenerate nature of the genetic code (synonymous polymorphism), although it is possible that some might alter mRNA stability, translation, or the amino acid sequence (nonsynonymous polymorphism) (Fig. 466-10). The detection of sequence variants poses a practical problem because it is often unclear whether it creates a change with functional consequences or a benign variation. In this situation, the sequence alteration is also described as *variant of unknown significance (VUS)*.

MUTATION RATES Mutations represent an important cause of genetic diversity as well as disease. Mutation rates are difficult to determine in humans because many mutations are silent and because testing is often not adequate to detect the phenotypic consequences. Mutation rates vary in different genes but are estimated to occur at a rate of ~10^{-10}/bp per cell division. Germline mutation rates (as opposed to somatic mutations) are relevant in the transmission of genetic disease. Because the population of oocytes is established very early in development, only ~20 cell divisions are required for completed oogenesis, whereas spermatogenesis involves ~30 divisions by the time of puberty and 20 cell divisions each year thereafter. Consequently, the probability of acquiring new point mutations is much greater in the male germline than the female germline, in which rates of aneuploidy are increased. Thus, the incidence of new point mutations in spermatogonia increases with paternal age (e.g., achondrodysplasia, Marfan's syndrome, neurofibromatosis). It is estimated that about 1 in 10 sperm carries a new deleterious mutation. The rates for new mutations are calculated most readily for autosomal dominant and X-linked disorders and are ~10^{-5}–10^{-6}/locus per generation. Because most monogenic diseases are relatively rare, new mutations account for a significant fraction of cases. This is important in the context of genetic counseling, because a new mutation can be transmitted to the affected individual but does not necessarily imply that the parents are at risk to transmit the disease to other children. An exception to this is when the new mutation occurs early in germline development, leading to *gonadal mosaicism*.

UNEQUAL CROSSING-OVER Normally, DNA recombination in germ cells occurs with remarkable fidelity to maintain the precise junction sites for the exchanged DNA sequences (Fig. 466-6). However, mispairing of homologous sequences leads to unequal crossover, with gene duplication on one of the chromosomes and gene deletion on the other chromosome. A significant fraction of growth hormone (*GH*) gene deletions, for example, involve unequal crossing-over **(Chap. 379)**. The *GH* gene is a member of a large gene cluster that includes a GH variant gene as well as several structurally related chorionic somatomammotropin genes and pseudogenes (highly homologous but functionally inactive relatives of a normal gene). Because such gene clusters contain multiple homologous DNA sequences arranged in tandem, they are particularly

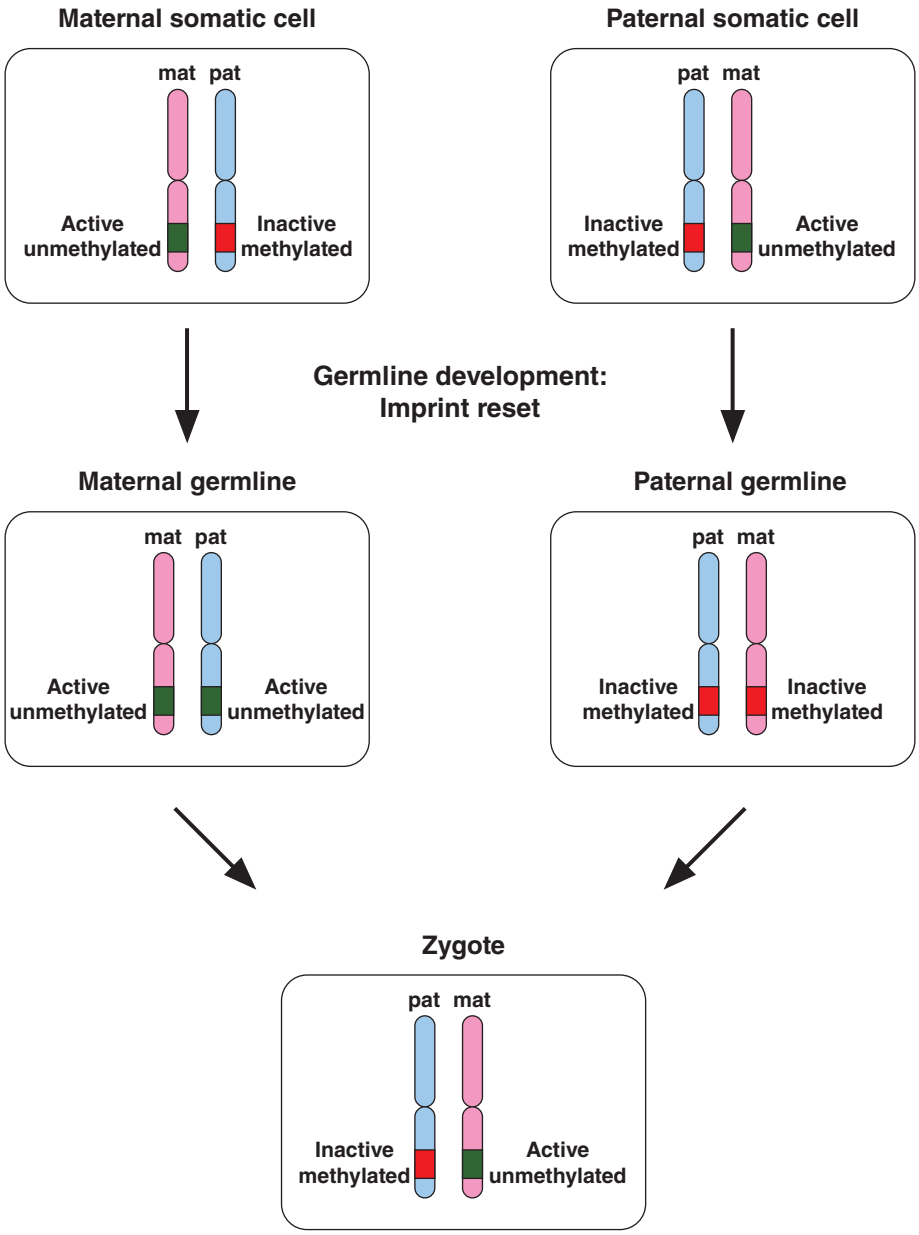

FIGURE 466-8 A few genomic regions are imprinted in a parent-specific fashion. The unmethylated chromosomal regions are actively expressed, whereas the methylated regions are silenced. In the germline, the imprint is reset in a parent-specific fashion: both chromosomes are unmethylated in the maternal (mat) germline and methylated in the paternal (pat) germline. In the zygote, the resulting imprinting pattern is identical with the pattern in the somatic cells of the parents.

prone to undergo recombination and, consequently, gene duplication or deletion. On the other hand, duplication of the *PMP22* gene because of unequal crossing-over results in increased gene dosage and type IA Charcot-Marie-Tooth disease. Unequal crossing-over resulting in deletion of *PMP22* causes a distinct neuropathy called *hereditary neuropathy with liability to pressure palsies* (HNPP) **(Chap. 446)**.

Glucocorticoid-remediable aldosteronism (GRA) is caused by a gene fusion or rearrangement involving the genes that encode aldosterone synthase (*CYP11B2*) and steroid 11β-hydroxylase (*CYP11B1*), normally arranged in tandem on chromosome 8q. These two genes are 95% identical, predisposing to gene duplication and deletion by unequal crossing-over. The rearranged gene product contains the regulatory regions of 11β-hydroxylase fused to the coding sequence of aldosterone synthetase. Consequently, the latter enzyme is expressed in the adrenocorticotropic hormone (ACTH)–dependent zona fasciculata of the adrenal gland, resulting in overproduction of mineralocorticoids and hypertension **(Chap. 386)**.

Gene conversion refers to a nonreciprocal exchange of homologous genetic information. It has been used to explain how an internal portion of a gene is replaced by a homologous segment copied from another allele or locus; these genetic alterations may range from a few nucleotides to a few thousand nucleotides. As a result of gene conversion, it is possible for short DNA segments of two chromosomes to be identical, even though these sequences are distinct in the parents. A practical consequence of this phenomenon is that nucleotide substitutions can occur during gene conversion between related genes, often altering the function of the gene. In disease states, gene conversion often involves intergenic exchange of DNA between a gene and a related pseudogene. For example, the 21-hydroxylase gene (*CYP21A2*) is adjacent to a nonfunctional pseudogene (*CYP21A1P*). Many of the nucleotide substitutions that are found in the *CYP21A2* gene in patients with congenital adrenal hyperplasia correspond to sequences that are present in the *CYP21A1P* pseudogene, suggesting gene conversion as one cause of mutagenesis. In addition, mitotic gene conversion has been suggested as a mechanism to explain revertant mosaicism in which an inherited mutation is "corrected" in certain cells. For example, patients with autosomal recessive generalized atrophic benign epidermolysis bullosa have acquired reverse mutations in one of the two mutated *COL17A1* alleles, leading to clinically unaffected patches of skin.

INSERTIONS AND DELETIONS Although many instances of insertions and deletions occur as a consequence of unequal crossing-over, there is also evidence for internal duplication, inversion, or deletion of DNA sequences. The fact that certain deletions or insertions appear to occur repeatedly as independent events indicates that specific regions within the DNA sequence predispose to these errors. For example, certain regions of the *DMD* gene, which encodes dystrophin, appear to be hot spots for deletions and result in muscular dystrophy **(Chap. 449)**. Some regions within the human genome are rearrangement hot spots and lead to CNVs.

ERRORS IN DNA REPAIR Because mutations caused by defects in DNA repair accumulate as somatic cells divide, these types of mutations are particularly important in the context of neoplastic disorders. Several genetic disorders involving DNA repair enzymes underscore their importance. Patients with xeroderma pigmentosum have defects in DNA damage recognition or in the nucleotide excision and repair pathway **(Chap. 76)**. Exposed skin is dry and pigmented and is extraordinarily sensitive to the mutagenic effects of ultraviolet irradiation. More than 10 different genes have been shown to cause the different forms of xeroderma pigmentosum.

Ataxia-telangiectasia is a multisystem disorder that includes progressive neurodegenerative cerebellar ataxia, immunologic defects, telangiectatic lesions, lymphomas and leukemias, and hypersensitivity to ionizing radiation **(Chap. 439)**. The discovery of the ataxia-telangiectasia mutated (*ATM*) gene revealed that it is homologous to genes involved in DNA repair and control of cell cycle checkpoints. Mutations in the *ATM* gene give rise to defects in meiosis as well as increasing susceptibility to damage from ionizing radiation. Fanconi's anemia is also associated with an increased risk of multiple acquired genetic abnormalities. It is characterized by diverse congenital anomalies and

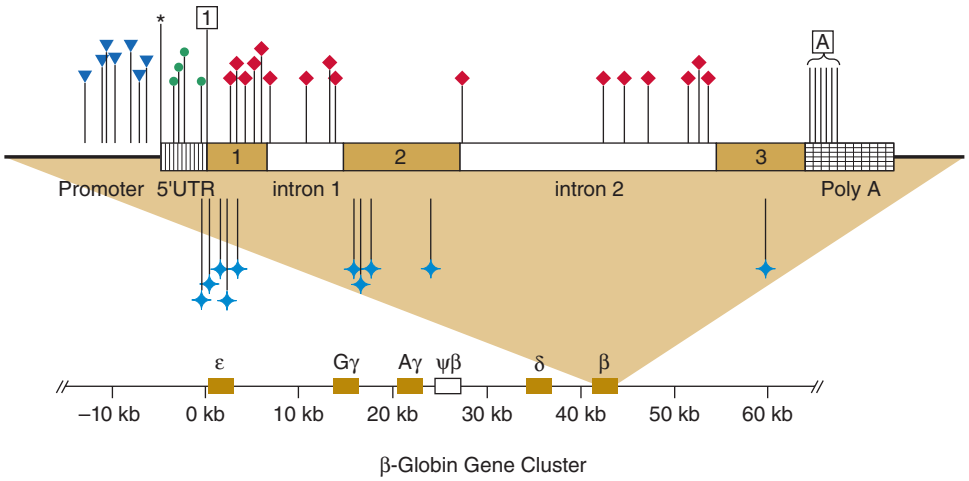

FIGURE 466-9 Point mutations causing β thalassemia as example of allelic heterogeneity. The β-*globin* gene is located in the globin gene cluster. Point mutations can be located in the promoter, the CAP site, the 5′-untranslated region, the initiation codon, each of the three exons, the introns, or the polyadenylation signal. Many mutations introduce missense or nonsense mutations, whereas others cause defective RNA splicing. Not shown here are deletion mutations of the β-*globin* gene or larger deletions of the globin locus that can also result in thalassemia. ▼, promoter mutations; *, CAP site; ●, 5′UTR; 1, initiation codon; ◆, defective RNA processing; ✦, missense and nonsense mutations; A, Poly A signal.

a strong predisposition to develop aplastic anemia and acute myelogenous leukemia **(Chap. 104)**. Cells from these patients are susceptible to chromosomal breaks caused by a defect in genetic recombination. It can be caused by mutations in the multiple genes forming the Fanconi's anemia pathway, which is involved in DNA repair and replication. HNPCC (Lynch syndrome) is characterized by autosomal dominant transmission of colon cancer, young age (<50 years) of presentation, predisposition to lesions in the proximal large bowel, and associated malignancies such as uterine cancer and ovarian cancer. HNPCC is predominantly caused by mutations in one of several different mismatch repair (MMR) genes including MutS homologue 2 (*MSH2*), MutL homologue 1 and 6 (*MLH1, MLH6*), *MSH6*, *PMS1*, and *PMS2* **(Chap. 81)**. These proteins are involved in the detection of nucleotide mismatches and in the recognition of slipped-strand trinucleotide repeats. Germline mutations in these genes lead to microsatellite instability and a high mutation rate in colon cancer. Genetic screening tests for this disorder are now being used for families considered to be at risk. Recognition of HNPCC allows early screening with colonoscopy and the implementation of prevention strategies using nonsteroidal anti-inflammatory drugs.

UNSTABLE DNA SEQUENCES *Trinucleotide repeats* may be unstable and expand beyond a critical number. Mechanistically, the expansion is thought to be caused by unequal recombination and slipped mispairing. A premutation represents a small increase in trinucleotide copy number. In subsequent generations, the expanded repeat may increase further in length and result in an increasingly severe phenotype, a process called *dynamic mutation* (see below for discussion of anticipation). Trinucleotide expansion was first recognized as a cause of the fragile X syndrome, one of the most common causes of intellectual disability. Other disorders arising from a similar mechanism include Huntington's disease, X-linked spinobulbar muscular atrophy, and myotonic dystrophy. Malignant cells are also characterized by genetic instability, indicating a breakdown in mechanisms that regulate DNA repair and the cell cycle.

Functional Consequences of Mutations Functionally, mutations can be broadly classified as gain-of-function and loss-of-function mutations. Gain-of-function mutations are typically dominant (e.g., they result in phenotypic alterations when a single allele is affected). Inactivating mutations are usually recessive, and an affected individual is homozygous or compound heterozygous (e.g., carrying two different mutant alleles of the same gene) for the disease-causing mutations. Alternatively, mutation in a single allele can result in *haploinsufficiency*, a situation in which one normal allele is not sufficient to maintain a normal phenotype. Haploinsufficiency is a commonly observed mechanism in diseases associated with mutations in transcription factors (Table 466-2). Remarkably, the clinical features among patients with an identical mutation often vary significantly. One mechanism underlying this variability consists in the influence of modifying

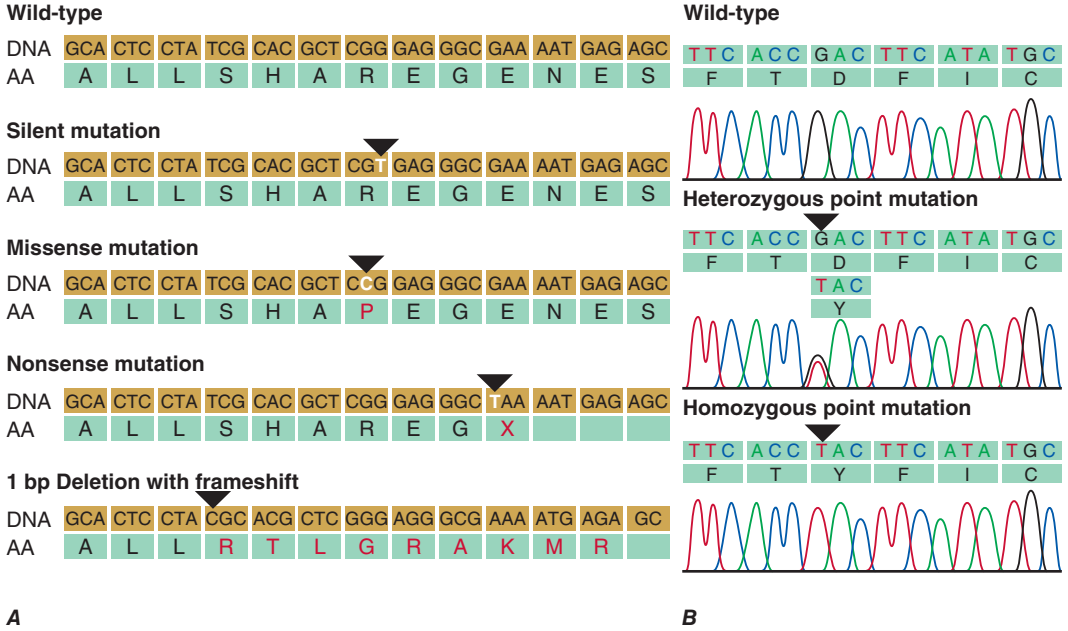

FIGURE 466-10 ***A.*** Examples of mutations (now commonly referred to as *variations*). The coding strand is shown with the encoded amino acid sequence. ***B.*** Chromatograms of sequence analyses after amplification of genomic DNA by polymerase chain reaction.

genes. Haploinsufficiency can also affect the expression of rate-limiting enzymes. For example, haploinsufficiency in enzymes involved in heme synthesis can cause porphyrias **(Chap. 416)**.

An increase in dosage of a gene product may also result in disease, as illustrated by the duplication of the *DAX1* gene in dosage-sensitive sex reversal **(Chap. 390)**. Mutation in a single allele can also result in loss of function due to a dominant-negative effect. In this case, the mutated allele interferes with the function of the normal gene product by one of several different mechanisms: (1) a mutant protein may interfere with the function of a multimeric protein complex, as illustrated by mutations in type 1 collagen (*COL1A1*, *COL1A2*) genes in osteogenesis imperfecta **(Chap. 413)**; (2) a mutant protein may occupy binding sites on proteins or promoter response elements, as illustrated by thyroid hormone resistance β, a disorder in which inactivated thyroid hormone receptor β binds to target genes and functions as an antagonist of normal receptors **(Chap. 382)**; or (3) a mutant protein can be cytotoxic as in α_1 antitrypsin deficiency **(Chap. 292)** or autosomal dominant neurohypophyseal diabetes insipidus **(Chap. 381)**, in which the abnormally folded proteins are trapped within the endoplasmic reticulum and ultimately cause cellular damage.

Genotype and Phenotype

• **ALLELES, GENOTYPES, AND HAPLOTYPES** An observed trait is referred to as a *phenotype*; the genetic information defining the phenotype is called the *genotype*. Alternative forms of a gene or a genetic marker are referred to as *alleles*. Alleles may be polymorphic variants of nucleic acids that have no apparent effect on gene expression or function. In other instances, these variants may have subtle effects on gene expression, thereby conferring adaptive advantages associated with genetic diversity. On the other hand, allelic variants may reflect mutations that clearly alter the function of a gene product. The common Glu6Val (E6V) sickle cell mutation in the *β-globin* gene and the ΔF508 deletion of phenylalanine (F) in the *CFTR* gene are examples of allelic variants of these genes that result in disease. Because each individual has two copies of each chromosome (one inherited from the mother and one inherited from the father), an individual can have only two alleles at a given locus. However, there can be many different alleles in the population. The normal or common allele is usually referred to as *wild type*. When alleles at a given locus are identical, the individual is *homozygous*. Inheriting identical copies of a mutant allele occurs in many autosomal recessive disorders, particularly in circumstances of consanguinity or isolated populations. If the alleles are different on the maternal and the paternal copy of the gene, the individual is *heterozygous* at this locus (Fig. 466-10). If two different mutant alleles are inherited at a given locus, the individual is said to be a *compound heterozygote*. *Hemizygous* is used to describe males with a mutation in an X chromosomal gene or a female with a loss of one X chromosomal locus.

Genotypes describe the specific alleles at a particular locus. For example, there are three common alleles (E2, E3, E4) of the apolipoprotein E (*APOE*) gene. The genotype of an individual can therefore be described as *APOE3/4* or *APOE4/4* or any other variant. These designations indicate which alleles are present on the two chromosomes in the *APOE* gene at locus 19q13.2. In other cases, the genotype might be assigned arbitrary numbers (e.g., 1/2) or letters (e.g., B/b) to distinguish different alleles.

A *haplotype* refers to a group of alleles that are closely linked together at a genomic locus (Fig. 466-4). Haplotypes are useful for tracking the transmission of genomic segments within families and for detecting evidence of genetic recombination, if the crossover event occurs between the alleles (Fig. 466-6). As an example, various alleles of the histocompatibility locus antigens (HLA) at the major histocompatibility complex (MHC) on chromosome 6 are used to establish haplotypes associated with certain disease states. For example, 21-hydroxylase deficiency, complement deficiency, and hemochromatosis are each associated with specific HLA haplotypes. It is now recognized that these genes lie in close proximity to the HLA locus, which explains why HLA associations were identified even before the disease genes were cloned and localized. In other cases, specific HLA associations with diseases such as ankylosing spondylitis (HLA-B27) or type 1 diabetes mellitus (HLA-DR4) reflect the role of specific HLA allelic variants in susceptibility to these autoimmune diseases. The characterization of common SNP haplotypes in numerous populations from different parts of the world has provided the necessary tools for association studies designed to detect genes involved in the pathogenesis of complex disorders (Table 466-1). The presence or absence of certain haplotypes can also be relevant for the customized choice of medical therapies (pharmacogenomics) or may have value for preventive strategies.

Genotype-phenotype correlation describes the association of a specific mutation and the resulting phenotype. The phenotype may differ depending on the location or type of the mutation in some genes. For example, in von Hippel–Lindau disease, an autosomal dominant multisystem disease that can include renal cell carcinoma, hemangioblastomas, and pheochromocytomas, among others, the phenotype varies greatly and the identification of the specific mutation can be clinically useful in order to predict the phenotypic spectrum.

ALLELIC HETEROGENEITY *Allelic heterogeneity* refers to the fact that different mutations in the same genetic locus can cause an identical or similar phenotype. For example, many different mutations of the β-globin locus can cause β thalassemia **(Table 466-3)** (Fig. 466-9). In essence, allelic heterogeneity reflects the fact that many different mutations are capable of altering protein structure and function. For this reason, maps of inactivating mutations in genes usually show a near-random distribution. Exceptions include (1) a founder effect, in which a particular mutation that does not affect reproductive capacity can be traced to a single individual; (2) "hot spots" for mutations, in which the nature of the DNA sequence predisposes to a recurring mutation; and (3) localization of mutations to certain domains that are particularly critical for protein function. Allelic heterogeneity creates a practical problem for genetic testing because one must often examine the entire genetic locus for mutations, because these can differ in each patient. For example, ~2000 variants have been identified in the *CFTR* gene to date, although some of them are very rare and some may not be disease-causing (Fig. 466-3). Mutational analysis may initially focus on a panel of mutations that are particularly frequent (often taking the ethnic background of the patient into account), but a negative result does not exclude the presence of a mutation elsewhere in the gene. One should also be aware that mutational analyses tend to focus on the coding region of a gene without considering regulatory and intronic regions. Because disease-causing mutations may be located outside the coding regions, negative results need to be interpreted with caution. The advent of more comprehensive sequencing technologies now greatly facilitates concomitant mutational analyses of several genes after targeted enrichment or even mutational analysis of the whole exome or genome. However, comprehensive sequencing can result in significant diagnostic challenges because the detection of a sequence alteration is not always sufficient to establish that it has a causal role (variants of unknown significance [VUS]).

PHENOTYPIC HETEROGENEITY *Phenotypic heterogeneity* occurs when more than one phenotype is caused by allelic mutations (e.g., by different mutations in the same gene) (Table 466-3). For example, laminopathies are monogenic multisystem disorders that result from mutations in the *LMNA* gene, which encodes the nuclear lamins A and C. Multiple autosomal dominant and recessive disorders are caused by mutations in the *LMNA* gene. They include several forms of lipodystrophies, Emery-Dreifuss muscular dystrophy, progeria syndromes, a form of neuronal Charcot-Marie-Tooth disease (type 2B1), and a group of overlapping syndromes. Remarkably, hierarchical cluster analysis has revealed that the phenotypes vary depending on the position of the mutation (*genotype-phenotype correlation*). Similarly, identical mutations in the *FGFR2* gene can result in very distinct phenotypes: Crouzon's syndrome (craniofacial synostosis) or Pfeiffer's syndrome (acrocephalopolysyndactyly).

LOCUS OR NONALLELIC HETEROGENEITY AND PHENOCOPIES *Nonallelic* or *locus heterogeneity* refers to the situation in which a similar disease phenotype results from mutations at different genetic loci (Table 466-3). This often occurs when more than one gene product

TABLE 466-3 Selected Examples of Phenotypic Heterogeneity and Locus Heterogeneity

Phenotypic Heterogeneity

GENE, PROTEIN	PHENOTYPE	INHERITANCE	OMIM
LMNA, Lamin A/C	Emery-Dreifuss muscular dystrophy (AD)	AD	181350
	Familial partial lipodystrophy Dunnigan	AD	151660
	Hutchinson-Gilford progeria	AD	176670
	Atypical Werner's syndrome	AD	150330
	Dilated cardiomyopathy 1A	AD	115200
	Familial atrial fibrillation 3	AD	607554
	Charcot-Marie-Tooth type 2B1	AR	605588
KRAS	Noonan's syndrome	AD	163950
	Cardio-facio-cutaneous syndrome 1	AD	115150

Locus Heterogeneity

PHENOTYPE	GENE	CHROMOSOMAL LOCATION	PROTEIN
Familial hypertrophic cardiomyopathy	*MYH7*	14q11.2	Myosin heavy chain beta
Genes encoding sarcomeric proteins	*TNNT2*	1q32.1	Troponin-T2
	TPM1	15q22.2	Tropomyosin alpha
	MYBPC3	11p11q	Myosin-binding protein C
	TNNC1	19q13.4	Troponin 1
	MYL2	12q24.11	Myosin light chain 2
	MYL3	3p21.31	Myosin light chain 3
	TTN	2q31.2	Cardiac titin
	ACTC	15q14	Cardiac alpha actin
	MYH6	14q11.2	Myosin heavy chain alpha
	MYLK2	20q11.21	Myosin light-peptide kinase
	CAV3	3p25	Caveolin 3
Genes encoding nonsarcomeric proteins	*MT-T1*	Mitochondrial	tRNA isoleucine
	MT-TG	Mitochondrial	tRNA glycine
	PRKAG2	7q36.1	AMP-activated protein kinase γ2 subunit
	DMPK	19q13.32	Myotonin protein kinase (myotonic dystrophy)
	FRDA	9q21.11	Frataxin (Friedreich's ataxia)
Polycystic kidney disease	*PKD1*	16p13.3	Polycystin 1 (AD)
	PKD2	4q22.1	Polycystin 2 (AD)
	PKHD1	6p21.1-p12.2	Fibrocystin/polyductin (AR)
Noonan's syndrome	*PTPN11*	12q24.13	Protein-tyrosine phosphatase 2c
	KRAS	12p12.1	KRAS

Abbreviations: AD, autosomal dominant; AR, autosomal recessive; OMIM, Online Mendelian Inheritance in Man.

produces different subunits of an interacting complex or when different genes are involved in the same genetic cascade or physiologic pathway. For example, osteogenesis imperfecta can arise from mutations in two different procollagen genes (*COL1A1* or *COL1A2*) that are located on different chromosomes and can involve multiple other genes **(Chap. 413)**. The effects of inactivating mutations in these two genes are similar because the protein products comprise different subunits of the helical collagen fiber. Similarly, muscular dystrophy syndromes can be caused by mutations in various genes, consistent with the fact that it can be transmitted in an X-linked (Duchenne or Becker), autosomal dominant (limb-girdle muscular dystrophy type 1), or autosomal recessive (limb-girdle muscular dystrophy type 2) manner **(Chap. 449)**. Mutations in the X-linked *DMD* gene, which encodes dystrophin, are the most common cause of muscular dystrophy. This feature reflects the large size of the gene as well as the fact that the phenotype is expressed in hemizygous males because they have only a single copy of the X chromosome. Dystrophin is associated with a large protein complex linked to the membrane-associated cytoskeleton in muscle. Mutations in several different components of this protein complex can also cause muscular dystrophy syndromes. Although the phenotypic features of some of these disorders are distinct, the phenotypic spectrum caused by mutations in different genes overlaps, thereby leading to nonallelic heterogeneity. It should be noted that mutations in dystrophin are also associated with allelic heterogeneity. For example, mutations in the *DMD* gene can cause either Duchenne's or the less severe Becker's muscular dystrophy, depending on the severity of the protein defect.

Recognition of nonallelic heterogeneity is important for several reasons: (1) the ability to identify disease loci in linkage studies is reduced by including patients with similar phenotypes but different genetic disorders; (2) genetic testing is more complex because several different genes need to be considered along with the possibility of different mutations in each of the candidate genes; and (3) novel information is gained about how genes or proteins interact, providing unique insights into molecular physiology.

Phenocopies refer to circumstances in which nongenetic conditions mimic a genetic disorder. For example, features of toxin- or drug-induced neurologic syndromes can resemble those seen in Huntington's disease, and vascular causes of dementia share phenotypic features with familial forms of Alzheimer's dementia **(Chap. 431)**. As in nonallelic heterogeneity, the presence of phenocopies has the potential to confound linkage studies and genetic testing. Patient history and subtle

differences in phenotype can often provide clues that distinguish these disorders from related genetic conditions.

VARIABLE EXPRESSIVITY AND INCOMPLETE PENETRANCE The same genetic mutation may be associated with a phenotypic spectrum in different affected individuals, thereby illustrating the phenomenon of *variable expressivity*. This may include different manifestations of a disorder variably involving different organs (e.g., multiple endocrine neoplasia [MEN]), the severity of the disorder (e.g., cystic fibrosis), or the age of disease onset (e.g., Alzheimer's dementia). MEN 1 illustrates several of these features. In this autosomal dominant tumor syndrome, affected individuals carry an inactivating germline mutation that is inherited in an autosomal dominant fashion. After somatic inactivation of the alternate allele (loss of heterozygosity; Knudson two-hit model), patients can develop tumors of the parathyroid gland, endocrine pancreas, the pituitary gland and dermatologic lesions **(Chap. 388)**. However, the pattern of tumors in the different glands, the age at which tumors develop, and the types of hormones produced vary among affected individuals, even within a given family. In this example, the phenotypic variability arises, in part, because of the requirement for a second somatic mutation in the normal copy of the *MEN1* gene, as well as the large array of different cell types that are susceptible to the effects of *MEN1* gene mutations. In part, variable expression reflects the influence of modifier genes, or genetic background, on the effects of a particular mutation. Even in identical twins, in whom the genetic constitution is essentially the same, one can occasionally see variable expression of a genetic disease.

Interactions with the environment can also influence the course of a disease. For example, the manifestations and severity of hemochromatosis can be influenced by iron intake **(Chap. 414)**, and the course of phenylketonuria is affected by exposure to phenylalanine in the diet **(Chap. 420)**. Other metabolic disorders, such as hyperlipidemias and porphyria, also fall into this category. Many mechanisms, including genetic effects and environmental influences, can therefore lead to variable expressivity. In genetic counseling, it is particularly important to recognize this variability, because one cannot always predict the course of disease, even when the mutation is known.

Penetrance refers to the proportion of individuals with a mutant genotype that express the phenotype. If all carriers of a mutant express the phenotype, penetrance is complete, whereas it is said to be *incomplete* or *reduced* if some individuals do not exhibit features of the phenotype. Dominant conditions with incomplete penetrance are characterized by skipping of generations with unaffected carriers transmitting the mutant gene. For example, hypertrophic obstructive cardiomyopathy (HCM) caused by mutations in the *myosin-binding protein C* gene is a dominant disorder with clinical features in only a subset of patients who carry the mutation **(Chap. 259)**. Patients who have the mutation but no evidence of the disease can still transmit the disorder to subsequent generations. In many conditions with postnatal onset, the proportion of gene carriers who are affected varies with age. Thus, when describing penetrance, one has to specify age. For example, for disorders such as Huntington's disease or familial amyotrophic lateral sclerosis, which present later in life, the rate of penetrance is influenced by the age at which the clinical assessment is performed. *Imprinting* can also modify the penetrance of a disease. For example, in patients with AHO, mutations in the $G_s\alpha$ subunit (*GNAS1* gene) are expressed clinically only in individuals who inherit the mutation from their mother **(Chap. 410)**.

SEX-INFLUENCED PHENOTYPES Certain mutations affect males and females quite differently. In some instances, this is because the gene resides on the X or Y sex chromosomes (X-linked disorders and Y-linked disorders). As a result, the phenotype of mutated X-linked genes will be expressed fully in males but variably in heterozygous females, depending on the degree of X-inactivation and the function of the gene. For example, most heterozygous female carriers of factor VIII deficiency (hemophilia A) are asymptomatic because sufficient factor VIII is produced to prevent a defect in coagulation **(Chap. 116)**. On the other hand, some females heterozygous for the X-linked lipid storage defect caused by α-galactosidase A deficiency (Fabry's disease) experience mild manifestations of painful neuropathy, as well as other features of the disease **(Chap. 418)**. Because only males have a Y chromosome, mutations in genes such as *SRY*, which causes male-to-female sex reversal, or *DAZ* (deleted in azoospermia), which causes abnormalities of spermatogenesis, are unique to males **(Chap. 390)**.

Other diseases are expressed in a sex-limited manner because of the differential function of the gene product in males and females. Activating mutations in the luteinizing hormone receptor cause dominant male-limited precocious puberty in boys **(Chap. 391)**. The phenotype is unique to males because activation of the receptor induces testosterone production in the testis, whereas it is functionally silent in the immature ovary. Biallelic inactivating mutations of the follicle-stimulating hormone (FSH) receptor cause primary ovarian failure in females because the follicles do not develop in the absence of FSH action. In contrast, affected males have a more subtle phenotype, because testosterone production is preserved (allowing sexual maturation) and spermatogenesis is only partially impaired **(Chap. 391)**. In congenital adrenal hyperplasia, most commonly caused by 21-hydroxylase deficiency, cortisol production is impaired and ACTH stimulation of the adrenal gland leads to increased production of androgenic precursors **(Chap. 386)**. In females, the increased androgen level causes ambiguous genitalia, which can be recognized at the time of birth. In males, the diagnosis may be made on the basis of adrenal insufficiency at birth, because the increased adrenal androgen level does not alter sexual differentiation, or later in childhood, because of the development of precocious puberty. Hemochromatosis is more common in males than in females, presumably because of differences in dietary iron intake and losses associated with menstruation and pregnancy in females **(Chap. 414)**.

Chromosomal Disorders *Chromosomal disorders* and the techniques used for their characterization have been discussed in detail in a chapter in previous editions of this textbook. Chromosomal or cytogenetic disorders are caused by numerical (aneuploidy) or structural aberrations (deletions, duplications, translocations, inversions, dicentric and ring chromosomes, Robertsonian translocations) in chromosomes. They occur in ~1% of the general population, in 8% of stillbirths, and in close to 50% of spontaneously aborted fetuses. Indications for cytogenetic and cytogenomic chromosome analyses are summarized in **Table 466-4**. *Contiguous gene syndromes* (e.g., large deletions affecting several genes) have been useful for identifying the location of new disease-causing genes. Because of the variable size of gene deletions in different patients, a systematic comparison of phenotypes and locations of deletion breakpoints allows positions of particular genes to be mapped within the critical genomic region.

TABLE 466-4 Indications for Cytogenetic and Cytogenomic Analysis across the Life Span

TIMING OF TESTING	INDICATIONS FOR TESTING
Prenatal	Advanced maternal age Abnormalities on ultrasound Increased risk for genetic disorder on maternal serum screen
Neonatal and childhood	Multiple congenital anomalies Intellectual disability Autism Developmental delay Failure to thrive Short stature Disorders of sexual development History of familial chromosomal alteration Cancer
Adult	Infertility Recurrent miscarriage Familial cancer

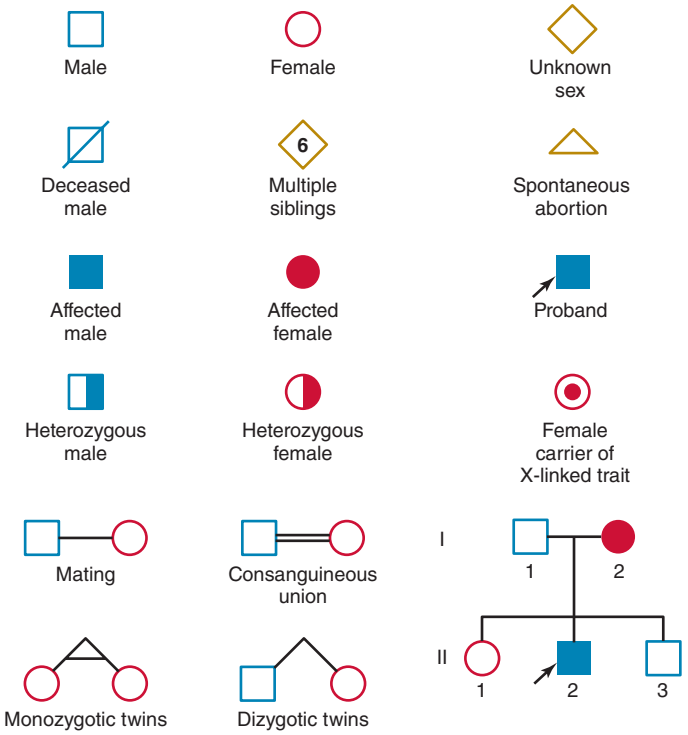

FIGURE 466-11 Standard pedigree symbols.

Monogenic Mendelian Disorders Monogenic human diseases are frequently referred to as *Mendelian disorders* because they obey the principles of genetic transmission originally set forth in Gregor Mendel's classic work. The continuously updated OMIM catalogue lists several thousand of these disorders and provides information about the clinical phenotype, molecular basis, allelic variants, and pertinent animal models (Table 466-1). The mode of inheritance for a given phenotypic trait or disease is determined by pedigree analysis. All affected and unaffected individuals in the family are recorded in a pedigree using standard symbols **(Fig. 466-11)**. The principles of allelic segregation, and the transmission of alleles from parents to children, are illustrated in **Fig. 466-12**. One dominant (A) allele and one recessive (a) allele can display three Mendelian modes of inheritance: autosomal dominant, autosomal recessive, and X-linked. About 65% of human monogenic disorders are autosomal dominant, 25% are autosomal recessive, and 5% are X-linked. Genetic testing is now available for many of these disorders and plays an important role in clinical medicine **(Chap. 467)**.

AUTOSOMAL DOMINANT DISORDERS In autosomal dominant disorders, mutations in a single allele are sufficient to cause the disease. In contrast to recessive disorders, in which disease pathogenesis is relatively straightforward because there is a biallelic loss of gene function, dominant disorders can be caused by various disease mechanisms, many of which are unique to the function of the genetic pathway

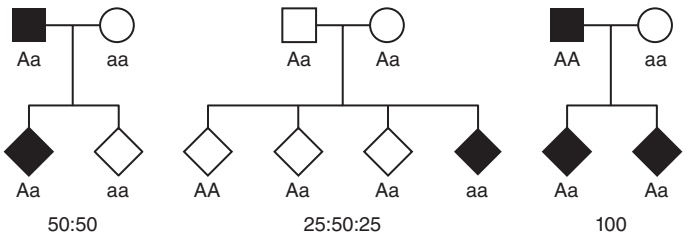

FIGURE 466-12 Segregation of alleles. Segregation of genotypes in the offspring of parents with one dominant (A) and one recessive (a) allele. The distribution of the parental alleles to their offspring depends on the combination present in the parents. Filled symbols = affected individuals.

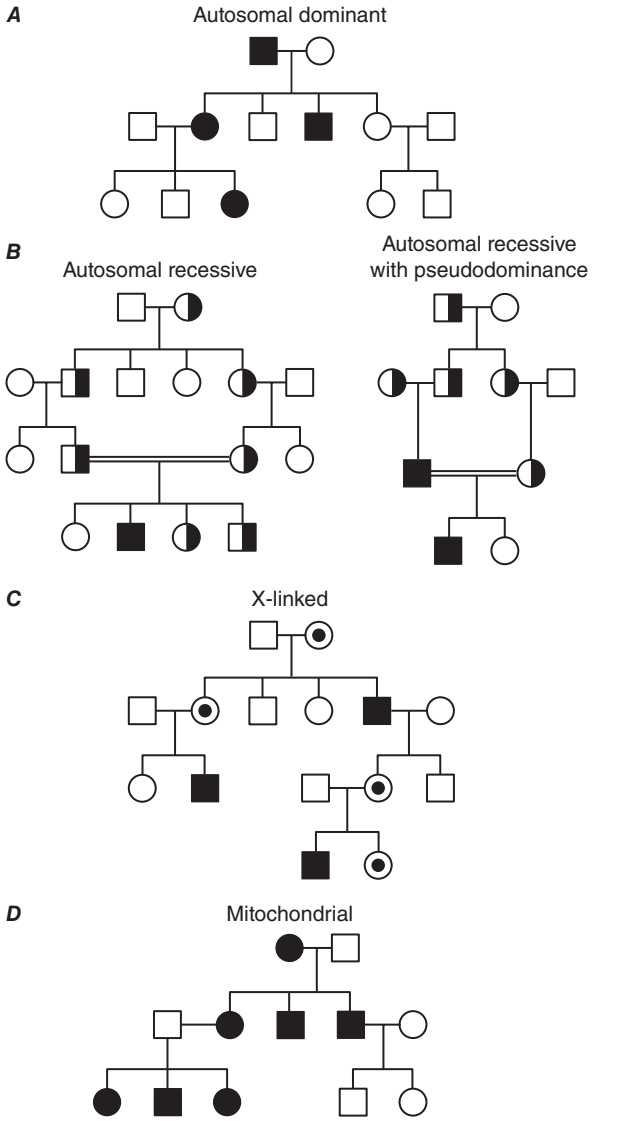

FIGURE 466-13 ***A.*** Dominant, ***B.*** recessive, ***C.*** X-linked, and ***D.*** mitochondrial (matrilinear) inheritance.

involved. Mechanistically, the mutation may confer constitutive activation (gain of function), exert a dominant negative effect, or result in loss of function and haploinsufficiency.

In autosomal dominant disorders, individuals are affected in successive generations; the disease does not occur in the offspring of unaffected individuals. Males and females are affected with equal frequency because the defective gene resides on one of the 22 autosomes **(Fig. 466-13*A*)**. Autosomal dominant mutations alter one of the two alleles at a given locus. Because the alleles segregate randomly at meiosis, the probability that an offspring will be affected is 50%. Unless there is a new germline mutation, an affected individual has an affected parent. Children with a normal genotype do not transmit the disorder. Due to differences in penetrance or expressivity (see above), the clinical manifestations of autosomal dominant disorders may be variable. Because of these variations, it is sometimes challenging to determine the pattern of inheritance.

It should be recognized, however, that some individuals acquire a mutated gene from an unaffected parent due to de novo germline mutations. They occur more frequently during later cell divisions in gametogenesis, which explains why siblings are rarely affected. As noted before, new germline mutations occur more frequently in fathers of advanced age. For example, the average age of fathers with new germline mutations that cause Marfan's syndrome is ~37 years, whereas fathers who transmit the disease by inheritance have an average age of ~30 years.

AUTOSOMAL RECESSIVE DISORDERS In recessive disorders, the mutated alleles result in a complete or partial loss of function. They frequently involve enzymes in metabolic pathways, receptors, or proteins in signaling cascades. In an autosomal recessive disease, the affected individual, who can be of either sex, is a homozygote or compound heterozygote for a single-gene defect. With a few important exceptions, autosomal recessive diseases are rare and often occur in the context of parental consanguinity. The relatively high frequency of certain recessive disorders such as sickle cell anemia, cystic fibrosis, and thalassemia, is partially explained by a selective biologic advantage for the heterozygous state (see below). Although heterozygous carriers of a defective allele are usually clinically normal, they may display subtle differences in phenotype that only become apparent with more precise testing or in the context of certain environmental influences. In sickle cell anemia, for example, heterozygotes are normally asymptomatic. However, in situations of dehydration or diminished oxygen pressure, sickle cell crises can also occur in heterozygotes **(Chap. 98)**.

In most instances, an affected individual is the offspring of heterozygous parents. In this situation, there is a 25% chance that the offspring will have a normal genotype, a 50% probability of a heterozygous state, and a 25% risk of homozygosity for the recessive alleles **(Figs.** 466-10 and **466-13*B*)**. In the case of one unaffected heterozygous and one affected homozygous parent, the probability of disease increases to 50% for each child. In this instance, the pedigree analysis mimics an autosomal dominant mode of inheritance (*pseudodominance*). In contrast to autosomal dominant disorders, new mutations in recessive alleles are rarely manifest because they usually result in an asymptomatic carrier state.

X-LINKED DISORDERS Males have only one X chromosome; consequently, a daughter always inherits her father's X chromosome in addition to one of her mother's two X chromosomes. A son inherits the Y chromosome from his father and one maternal X chromosome. Thus, the characteristic features of X-linked inheritance are (1) the absence of father-to-son transmission and (2) the fact that all daughters of an affected male are obligate carriers of the mutant allele **(Fig. 466-13*C*)**. The risk of developing disease due to a mutant X-chromosomal gene differs in the two sexes. Because males have only one X chromosome, they are hemizygous for the mutant allele; thus, they are more likely to develop the mutant phenotype, regardless of whether the mutation is dominant or recessive. A female may be either heterozygous or homozygous for the mutant allele, which may be dominant or recessive. The terms *X-linked dominant* and *X-linked recessive* are therefore only applicable to expression of the mutant phenotype in women. In addition, the expression of X-chromosomal genes is influenced by X chromosome inactivation.

Y-LINKED DISORDERS The Y chromosome has a relatively small number of genes. One such gene, the sex-region determining Y factor (*SRY*), which encodes the testis-determining factor (*TDF*), is crucial for normal male development. Normally, there is infrequent exchange of sequences on the Y chromosome with the X chromosome. The *SRY* region is adjacent to the pseudoautosomal region, a chromosomal segment on the X and Y chromosomes with a high degree of homology. A crossing-over event occasionally involves the *SRY* region with the distal tip of the X chromosome during meiosis in the male. Translocations can result in XY females with the Y chromosome lacking the *SRY* gene or XX males harboring the *SRY* gene on one of the X chromosomes **(Chap. 390)**. Point mutations in the *SRY* gene may also result in individuals with an XY genotype and an incomplete female phenotype. Most of these mutations occur de novo. Men with oligospermia/azoospermia frequently have microdeletions on the long arm of the Y chromosome that involve one or more of the azoospermia factor (*AZF*) genes.

Exceptions to Simple Mendelian Inheritance Patterns

MITOCHONDRIAL DISORDERS Mendelian inheritance refers to the transmission of genes encoded by DNA contained in the nuclear chromosomes. In addition, each mitochondrion contains several copies of a small circular chromosome **(Chap. 468)**. The mitochondrial DNA (mtDNA) is ~16.5 kb and encodes transfer and ribosomal RNAs and 13 core proteins that are components of the respiratory chain involved in oxidative phosphorylation and ATP generation. The mitochondrial genome does not recombine and is inherited through the maternal line because sperm does not contribute significant cytoplasmic components to the zygote. A noncoding region of the mitochondrial chromosome, referred to as D-loop, is highly polymorphic. This property, together with the absence of mtDNA recombination, makes it a valuable tool for studies tracing human migration and evolution, and it is also used for specific forensic applications.

Inherited mitochondrial disorders are transmitted in a matrilineal fashion; all children from an affected mother will inherit the disease, but it will not be transmitted from an affected father to his children **(Fig. 466-13*D*)**. Alterations in the mtDNA that involves enzymes required for oxidative phosphorylation lead to reduction of ATP supply, generation of free radicals, and induction of apoptosis. Several syndromic disorders arising from mutations in the mitochondrial genome are known in humans, and they affect both protein-coding and tRNA genes. The broad clinical spectrum often involves (cardio) myopathies and encephalopathies because of the high dependence of these tissues on oxidative phosphorylation. The age of onset and the clinical course are highly variable because of the unusual mechanisms of mtDNA transmission, which replicates independently from nuclear DNA. During cell replication, the proportion of wild-type and mutant mitochondria can drift among different cells and tissues. The resulting heterogeneity in the proportion of mitochondria with and without a mutation is referred to as *heteroplasmia* and underlies the phenotypic variability that is characteristic of mitochondrial diseases.

Acquired somatic mutations in mitochondria are thought to be involved in several age-dependent degenerative disorders affecting predominantly muscle and the peripheral and central nervous system (e.g., Alzheimer's and Parkinson's diseases). Establishing that an mtDNA alteration is causal for a clinical phenotype is challenging because of the high degree of polymorphism in mtDNA and the phenotypic variability characteristic of these disorders. Certain pharmacologic treatments may have an impact on mitochondria and/or their function. For example, treatment with the antiretroviral compound azidothymidine (AZT) causes an acquired mitochondrial myopathy through depletion of muscular mtDNA.

MOSAICISM Mosaicism refers to the presence of two or more genetically distinct cell lines in the tissues of an individual. It results from a mutation that occurs during embryonic, fetal, or extrauterine development. The developmental stage at which the mutation arises will determine whether germ cells and/or somatic cells are involved. Chromosomal mosaicism results from nondisjunction at an early embryonic mitotic division, leading to the persistence of more than one cell line, as exemplified by some patients with Turner's syndrome **(Chap. 390)**. Somatic mosaicism is characterized by a patchy distribution of genetically altered somatic cells. The McCune-Albright syndrome, for example, is caused by activating mutations in the stimulatory G protein α ($G_s\alpha$) that occur early in development **(Chap. 410)**. The clinical phenotype varies depending on the tissue distribution of the mutation; manifestations include ovarian cysts that secrete sex steroids and cause precocious puberty, polyostotic fibrous dysplasia, café-au-lait skin pigmentation, GH-secreting pituitary adenomas, and hypersecreting autonomous thyroid nodules.

X-INACTIVATION, IMPRINTING, AND UNIPARENTAL DISOMY According to traditional Mendelian principles, the parental origin of a mutant gene is irrelevant for the expression of the phenotype. There are, however, important exceptions to this rule. *X-inactivation* prevents the expression of most genes on one of the two X chromosomes in every cell of a female. Gene inactivation through genomic imprinting occurs on selected chromosomal regions of autosomes and leads to inheritable preferential expression of one of the parental alleles. It is of pathophysiologic importance in disorders where the transmission of disease is dependent on the sex of the transmitting parent and, thus, plays an important role in the expression of certain genetic disorders. Two classic examples are the Prader-Willi syndrome and Angelman's

syndrome. Prader-Willi syndrome is characterized by diminished fetal activity, obesity, hypotonia, intellectual disability, short stature, and hypogonadotropic hypogonadism. Deletions of the paternal copy of the Prader-Willi locus located on the short arm of chromosome 15 result in a contiguous gene syndrome involving missing paternal copies of the *necdin* and *SNRPN* genes, among others. In contrast, patients with Angelman's syndrome, characterized by intellectual disability, seizures, ataxia, and hypotonia, have deletions involving the maternal copy of this region on chromosome 15. These two syndromes may also result from *uniparental disomy*. In this case, the syndromes are not caused by deletions on chromosome 15 but by the inheritance of either two maternal chromosomes (Prader-Willi syndrome) or two paternal chromosomes (Angelman's syndrome). Lastly, the two distinct phenotypes can also be caused by an imprinting defect that impairs the resetting of the imprint during zygote development (defect in the father leads to Prader-Willi syndrome; defect in the mother leads to Angelman's syndrome).

Imprinting and the related phenomenon of allelic exclusion may be more common than currently documented, because it is difficult to examine levels of mRNA expression from the maternal and paternal alleles in specific tissues or in individual cells. Genomic imprinting, or uniparental disomy, is involved in the pathogenesis of several other disorders and malignancies. For example, hydatidiform moles contain a normal number of diploid chromosomes, but they are all of paternal origin. The opposite situation occurs in ovarian teratomata, with 46 chromosomes of maternal origin. Expression of the imprinted gene for insulin-like growth factor 2 (IGF-2) is involved in the pathogenesis of the cancer-predisposing Beckwith-Wiedemann syndrome (BWS). These children show somatic overgrowth with organomegalies and hemihypertrophy, and they have an increased risk of embryonal malignancies such as Wilms' tumor. Normally, only the paternally derived copy of the *IGF2* gene is active, and the maternal copy is inactive. BWS can be caused by several genetic defects that result in overactivity of IGF-2, or a missing active copy of CDKN1C, that result in inhibition of cell proliferation. They include paternal uniparental disomy (UPD) of chromosome 11, aberrant methylation of this region, maternal chromosomal rearrangements, or deletions within the locus.

Alterations of the epigenome through gain and loss of DNA methylation and altered histone modifications play an important role in the pathogenesis of malignancies.

SOMATIC MUTATIONS Cancer can be considered a genetic disease at the cellular level **(Chap. 71)**. Cancers are monoclonal in origin, indicating that they have arisen from a single precursor cell with one or several mutations in genes controlling growth (proliferation or apoptosis) and/or differentiation. These acquired somatic mutations are restricted to the tumor and its metastases and are not found in the surrounding normal tissue. The molecular alterations include dominant gain-of-function mutations in oncogenes, recessive loss-of-function mutations in tumor-suppressor genes and DNA repair genes, gene amplification, and chromosome rearrangements. Chromothripsis refers to a mutational process including multiple clustered chromosomal rearrangements in close vicinity, for example, after injury by ionizing radiation. Rarely, a single mutation in certain genes may be sufficient to transform a normal cell into a malignant cell. In most cancers, however, the development of a malignant phenotype requires several genetic alterations for the gradual progression from a normal cell to a cancerous cell, a phenomenon termed *multistep carcinogenesis*. Genome-wide analyses of cancers using deep sequencing often reveal somatic rearrangements resulting in fusion genes and mutations in multiple genes (Table 466-1 and **Fig. 466-14**). Comprehensive sequence analyses, now also possible through single-cell sequencing (SCS), provide insight into the evolution and genetic heterogeneity within malignancies; these include intratumoral heterogeneity among the cells of the primary tumor, intermetastatic and intrametastatic heterogeneity, and interpatient differences. These analyses further support the notion of cancer as an ongoing process of clonal evolution, in which successive rounds of clonal selection within the primary tumor and metastatic lesions result in diverse genetic and epigenetic alterations that require targeted (personalized) therapies (precision medicine). The heterogeneity of mutations within a tumor can also lead to resistance to targeted therapies because cells with mutations that are resistant to the therapy, even if they are a minor part of the tumor population, will be selected as the more sensitive cells are eliminated.

Telomeres, repeats of conserved sequences, protect the ends the chromosomes from DNA damage or fusion with neighboring chromosomes. Telomere length shortens with age. Most human tumors express telomerase, an enzyme formed of a protein and an RNA component, which adds telomere repeats at the ends of chromosomes during replication. This mechanism impedes shortening of the telomeres and is associated with enhanced replicative capacity in cancer cells.

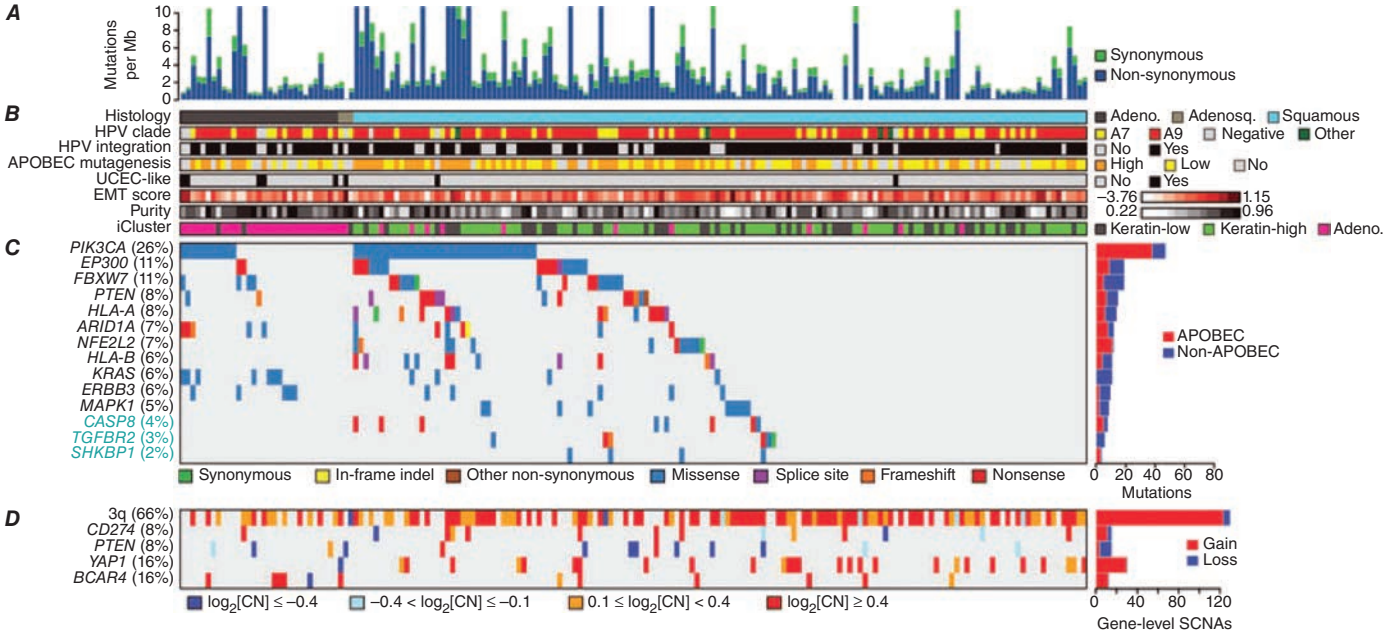

FIGURE 466-14 Somatic alterations in cervical cancer. ***A.*** Cervical carcinoma samples ordered by histology and mutation frequency; ***B.*** clinical and molecular platform features; ***C.*** significantly mutated genes (SMGs); and ***D.*** select somatic copy number alterations. SMGs are ordered by the overall mutation frequency and color-coded by mutation type. Adeno, adenocarcinomas; Adenosq, adenosquamous cancers; CN, copy number; SCNAs, somatic copy number alterations; Squamous, squamous cell carcinomas. *(From The Cancer Genome Atlas Research Network. Integrated genomic and molecular characterization of cervical cancer. Nature 543:378–384, 2017. Permission for reproduction granted through a Creative Commons CC-BY [CC BY 4.0] license.)*

Telomerase inhibitors provide a strategy for treating advanced human cancers.

In many cancer syndromes, there is frequently an inherited *predisposition* to tumor formation. In these instances, a germline mutation is inherited in an autosomal dominant fashion inactivating one allele of an autosomal tumor-suppressor gene. If the second allele is inactivated by a somatic mutation or by epigenetic silencing in a given cell, this will lead to neoplastic growth (Knudson two-hit model). Thus, the defective allele in the germline is transmitted in a dominant mode, although tumorigenesis results from a biallelic loss of the tumor-suppressor gene in an affected tissue. The classic example to illustrate this phenomenon is retinoblastoma, which can occur as a sporadic or hereditary tumor. In sporadic retinoblastoma, both copies of the retinoblastoma (*RB*) gene are inactivated through two somatic events. In hereditary retinoblastoma, one mutated or deleted *RB* allele is inherited in an autosomal dominant manner and the second allele is inactivated by a subsequent somatic mutation. This two-hit model applies to other inherited cancer syndromes such as MEN 1 **(Chap. 388)** and neurofibromatosis types 1 and 2 **(Chap. 90)**. In contrast, in the autosomal dominant MEN 2 syndrome, the predisposition for tumor formation in various organs is caused by a gain-of-function mutation in a single allele of the *RET* gene **(Chap. 388)**.

NUCLEOTIDE REPEAT EXPANSION DISORDERS Several diseases are associated with an increase in the number of nucleotide repeats above a certain threshold **(Table 466-5)**. The repeats are sometimes located within the coding region of the genes, as in Huntington's disease or the X-linked form of spinal and bulbar muscular atrophy (SBMA; Kennedy's syndrome). In other instances, the repeats probably alter gene regulatory sequences. If an expansion is present, the DNA fragment is unstable and tends to expand further during cell division. The length of the nucleotide repeat often correlates with the severity of the disease. When repeat length increases from one generation to the next, disease manifestations may worsen or be observed at an earlier age; this phenomenon is referred to as *anticipation*. In Huntington's disease, for example, there is a correlation between age of onset and length of the triplet codon expansion **(Chap. 424)**. Anticipation has also been documented in other diseases caused by dynamic mutations in trinucleotide repeats (Table 466-5). The repeat number may also vary in a tissue-specific manner. In myotonic dystrophy, the CTG repeat may be tenfold greater in muscle tissue than in lymphocytes **(Chap. 449)**.

Complex Genetic Disorders The expression of many common diseases such as cardiovascular disease, hypertension, diabetes, asthma, psychiatric disorders, and certain cancers is determined by a combination of genetic background, environmental factors, and lifestyle. A trait is called *polygenic* if multiple genes contribute to the phenotype or *multifactorial* if multiple genes are assumed to interact with environmental factors. Genetic models for these complex traits need to account for genetic heterogeneity and interactions with other genes and the environment. Complex genetic traits may be influenced by modifier genes that are not linked to the main gene involved in the pathogenesis of the trait. This type of gene-gene interaction, or *epistasis*, plays an important role in polygenic traits that require the simultaneous presence of variations in multiple genes to result in a pathologic phenotype.

Type 2 diabetes mellitus provides a paradigm for considering a multifactorial disorder, because genetic, nutritional, and lifestyle factors are intimately interrelated in disease pathogenesis **(Table 466-6)** **(Chap. 403)**. The identification of genetic variations and environmental factors that either predispose to or protect against disease is essential for predicting disease risk, designing preventive strategies, and developing novel therapeutic approaches. The study of rare monogenic diseases may provide insight into some of the genetic and molecular mechanisms important in the pathogenesis of complex diseases. For example, the identification of the genes causing monogenic forms of permanent neonatal diabetes mellitus or maturity-onset diabetes defined them as *candidate genes* in the pathogenesis of diabetes mellitus type 2 (Tables 466-2 and 466-6) **(Fig. 466-15)**. Genome scans have identified numerous genes and loci that may be associated with susceptibility to development of diabetes mellitus in certain populations **(Fig. 466-16)**. Efforts to identify susceptibility genes require very large sample sizes, and positive results may depend on ethnicity, ascertainment criteria, and statistical analysis. Association studies analyzing the potential influence of (biologically functional) SNPs and SNP haplotypes on a particular phenotype have revealed new insights into the genes involved in the pathogenesis of these common disorders. Large variants ([micro]deletions, duplications, and inversions) present in the human population also contribute to the pathogenesis of complex disorders, but their contributions remain poorly understood.

Linkage and Association Studies There are two primary strategies for mapping genes that cause or increase susceptibility to human disease: (1) classic linkage can be performed based on a known genetic model or, when the model is unknown, by studying pairs of affected relatives; or (2) disease genes can be mapped using allelic association studies **(Table 466-7)**.

GENETIC LINKAGE *Genetic linkage* refers to the fact that genes are physically connected, or linked, to one another along the chromosomes. Two fundamental principles are essential for understanding the concept of linkage: (1) when two genes are close together on a chromosome, they are usually transmitted together, unless a recombination

TABLE 466-5 Selected Trinucleotide Repeat Disorders

DISEASE	LOCUS	REPEAT	TRIPLET LENGTH (NORMAL/DISEASE)	INHERITANCE	GENE PRODUCT
X-chromosomal spinobulbar muscular atrophy (SBMA)	Xq12	CAG	11–34/40–62	XR	Androgen receptor
Fragile X syndrome (FRAXA)	Xq27.3	CGG	6–50/200–300	XR	FMR-1 protein
Fragile X syndrome (FRAXE)	Xq28	GCC	6–25/>200	XR	FMR-2 protein
Dystrophia myotonica (DM)	19q13.32	CTG	5–30/200–1000	AD, variable penetrance	Myotonin protein kinase
Huntington's disease (HD)	4p16.3	CAG	6–34/37–180	AD	Huntingtin
Spinocerebellar ataxia type 1 (SCA1)	6p22.3	CAG	6–39/40–88	AD	Ataxin 1
Spinocerebellar ataxia type 2 (SCA2)	12q24.12	CAG	15–31/34–400	AD	Ataxin 2
Spinocerebellar ataxia type 3 (SCA3); Machado-Joseph disease (MD)	14q32.12	CAG	13–36/55–86	AD	Ataxin 3
Spinocerebellar ataxia type 6 (SCA6, CACNAIA)	19p13	CAG	4–16/20–33	AD	Alpha 1A voltage-dependent L-type calcium channel
Spinocerebellar ataxia type 7 (SCA7)	3p14.1	CAG	4–19/37 to >300	AD	Ataxin 7
Spinocerebellar ataxia type 12 (SCA12)	5q32	CAG	6–26/66–78	AD	Protein phosphatase 2A
Dentatorubral pallidoluysian atrophy (DRPLA)	12p13.31	CAG	7–23/49–75	AD	Atrophin 1
Friedreich's ataxia (FRDA1)	9q21.11	GAA	7–22/200–900	AR	Frataxin

Abbreviations: AD, autosomal dominant; AR, autosomal recessive; XR, X-linked recessive.

TABLE 466-6 Genes and Loci Involved in Mono- and Polygenic Forms of Diabetes

DISORDER	GENES OR SUSCEPTIBILITY LOCUS	CHROMOSOMAL LOCATION	OTHER FACTORS
Monogenic permanent neonatal diabetes mellitus	*KCNJ11* (inwardly rectifying potassium channelKir6.2)	11p15.1	AD
	GCK (glucokinase)	7p13	AR
	INS (insulin)	11p15.5	AR, hyperproinsulinemia
	ABCC8 (ATP-binding cassette, subfamily c, member 8; sulfonylurea receptor)	11p15.1	AD or AR
	GLIS3 (GLIS family zinc finger protein 3)	9p24.2	AR, diabetes, congenital hypothyroidism
Maturity-onset diabetes of the young (MODY): monogenic forms of diabetes mellitus			
MODY 1	*HNF4α* (hepatocyte nuclear factor 4α)	20q13.12	AD inheritance
MODY 2	*GCK* (glucokinase)	7p13	
MODY 3	*HNF1α* (hepatocyte nuclear factor 1α)	12q24.31	
MODY 4	*IPF1* (insulin receptor substrate)	13q12.2	
MODY 5 (renal cysts, diabetes)	*HNF1β* (hepatocyte nuclear factor 1β)	17q12	
MODY 6	*NeuroD1* (neurogenic differentiation factor 1)	2q31.3	
MODY 7	*KLF1* (Kruppel-like factor 1)	19p13.13	
MODY 8	*CEL* (carboxyl ester lipase)	9q34.13	
MODY 9	*PAX4* (paired box transcription factor 4)	7q32.1	
MODY 10	*INS* (insulin)	11p15.5	
MODY 11	*BLK* (B-lymphocyte-specific tyrosine kinase)	8p23.1	
Diabetes mellitus type 2; loci and genes linked and/or associated with susceptibility for diabetes mellitus type 2	Genes and loci identified by linkage/association studies		Heavily influenced by diet, energy expenditure, obesity

event separates them (Figs. 466-6); and (2) the odds of a crossover, or recombination event, between two linked genes is proportional to the distance that separates them. Thus, genes that are farther apart are more likely to undergo a recombination event than genes that are very close together. The detection of chromosomal loci that segregate with a disease by linkage can be used to identify the gene responsible for the disease (*positional cloning*) and to predict the odds of disease gene transmission in genetic counseling.

Polymorphic variants are essential for linkage studies because they provide a means to distinguish the maternal and paternal chromosomes in an individual. On average, 1 out of every 1000 bp varies from one person to the next. Although this degree of variation seems low (99.9% identical), it means that >3 million sequence differences exist between any two unrelated individuals and the probability that the sequence at such loci will differ on the two homologous chromosomes is high (often >70–90%). These sequence variations include variable number of tandem repeats (VNTRs), short tandem repeats (STRs), and SNPs. Most STRs, also called *polymorphic microsatellite markers*, consist of di-, tri-, or tetranucleotide repeats that can be characterized readily using the polymerase chain reaction (PCR). Characterization of SNPs, using DNA chips or beads, permits comprehensive analyses of genetic variation, linkage, and association studies. Although these sequence variations often have no apparent functional consequences, they provide much of the basis for variation in genetic traits.

In order to identify a chromosomal locus that segregates with a disease, it is necessary to characterize polymorphic DNA markers from affected and unaffected individuals of one or several pedigrees. One can then assess whether certain marker alleles cosegregate with the disease. Markers that are closest to the disease gene are less likely to undergo recombination events and therefore receive a higher linkage score. Linkage is expressed as an lod (logarithm of odds) score—the ratio of the probability that the disease and marker loci are linked rather than unlinked. Lod scores of +3 (1000:1) are generally accepted as supporting linkage, whereas a score of −2 is consistent with the absence of linkage.

ALLELIC ASSOCIATION, LINKAGE DISEQUILIBRIUM, AND HAPLOTYPES *Allelic association* refers to a situation in which the frequency of an allele is significantly increased or decreased in individuals affected by a particular disease in comparison to controls. Linkage and

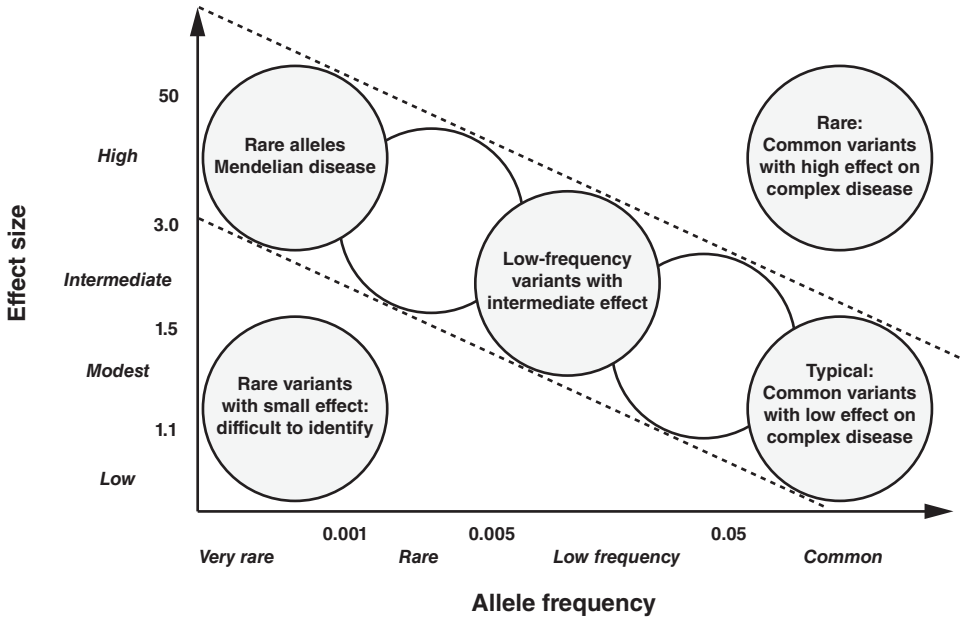

FIGURE 466-15 Relationship between allele frequency and effect size in monogenic and polygenic disorders. In classic Mendelian disorders, the allele frequency is typically low but has a high impact (single-gene disorder). This contrasts with polygenic disorders that require the combination of multiple low-impact alleles that are frequently quite common in the general population.

association differ in several aspects. Genetic linkage is demonstrable in families or sibships. Association studies, on the other hand, compare a population of affected individuals with a control population. Association studies can be performed as case-control studies that include unrelated affected individuals and matched controls or as family-based studies that compare the frequencies of alleles transmitted or not transmitted to affected children.

Allelic association studies are particularly useful for identifying susceptibility genes in complex diseases. When alleles at two loci occur more frequently *in combination* than would be predicted (based on known allele frequencies and recombination fractions), they are said to be in *linkage disequilibrium*. Evidence for linkage disequilibrium can be helpful in mapping disease genes because it suggests that the two loci are tightly linked.

Detecting the genetic factors contributing to the pathogenesis of common complex disorders is challenging. In many instances, these are low-penetrance alleles (e.g., variations that individually have a subtle effect on disease development, and they can only be identified by unbiased GWAS) (Catalog of Published Genome-Wide Association Studies; Table 466-1) (Fig. 466-16). Most variants occur in noncoding or regulatory sequences but do not alter protein structure. The analysis of complex disorders is further complicated by ethnic differences in disease prevalence, differences in allele frequencies in known susceptibility genes among different populations, locus and allelic heterogeneity, gene-gene and gene-environment interactions, and the possibility of phenocopies. Catalogues of human variation and genotype data (HapMap, International Genome Sample Resource) have greatly facilitated GWAS for the characterization of complex disorders. Adjacent SNPs are inherited together as blocks, and these blocks can be identified by genotyping selected marker SNPs, so-called *Tag SNPs*, thereby reducing cost and workload (Fig. 466-4). The availability of this information permits the characterization of a limited number of SNPs to identify the set of haplotypes present in an individual (e.g., in cases and controls). This, in turn, permits performing GWAS by searching for associations of certain haplotypes with a disease phenotype of interest, an essential step for unraveling the genetic factors contributing to complex disorders.

POPULATION GENETICS In population genetics, the focus changes from alterations in an individual's genome to the distribution pattern of different genotypes in the population. In a case where there are only two alleles, A and a, the frequency of the genotypes will be $p^2 + 2pq + q^2 = 1$, with p^2 corresponding to the frequency of AA, $2pq$ to the frequency of Aa, and q^2 to aa. When the frequency of an allele is known, the frequency of the genotype can be calculated. Alternatively, one can determine an allele frequency if the genotype frequency has been determined.

Allele frequencies vary among ethnic groups and geographic regions. For example, heterozygous mutations in the *CFTR* gene are relatively common in populations of European origin but are rare in the African population. Allele frequencies may vary because certain allelic variants confer a selective advantage. For example, heterozygotes for the sickle cell mutation, which is particularly common in West Africa, are more resistant to malaria infection because the erythrocytes of heterozygotes provide a less favorable environment for *Plasmodium* parasites. Although homozygosity for the sickle cell mutation is associated with severe anemia and sickle crises, heterozygotes have a higher probability of survival because of the reduced morbidity and mortality from malaria; this phenomenon has led to an increased frequency of the mutant allele. Recessive conditions are more prevalent in geographically isolated populations because of the more restricted gene pool.

APPROACH TO THE PATIENT

Inherited Disorders

For the practicing clinician, the family history remains an essential step in recognizing the possibility of a hereditary predisposition to disease. When taking the history, it is useful to draw a detailed pedigree of the first-degree relatives (e.g., parents, siblings, and children), because they share 50% of genes with the patient. Standard symbols for pedigrees are depicted in Fig. 466-11. The family history should include information about ethnic background, age, health status, and deaths, including infants. Next, the physician should explore whether there is a family history of the same or related illnesses to the current problem. An inquiry focused on commonly occurring disorders such as cancers, heart disease, and diabetes mellitus should follow. Because of the possibility of age-dependent expressivity and penetrance, the family history will need intermittent updating. If the findings suggest a genetic disorder, the clinician should assess whether some of the patient's relatives may be at risk of carrying or transmitting the disease. In this circumstance, it is useful to confirm and extend the pedigree based on input from several family members. This information may form the

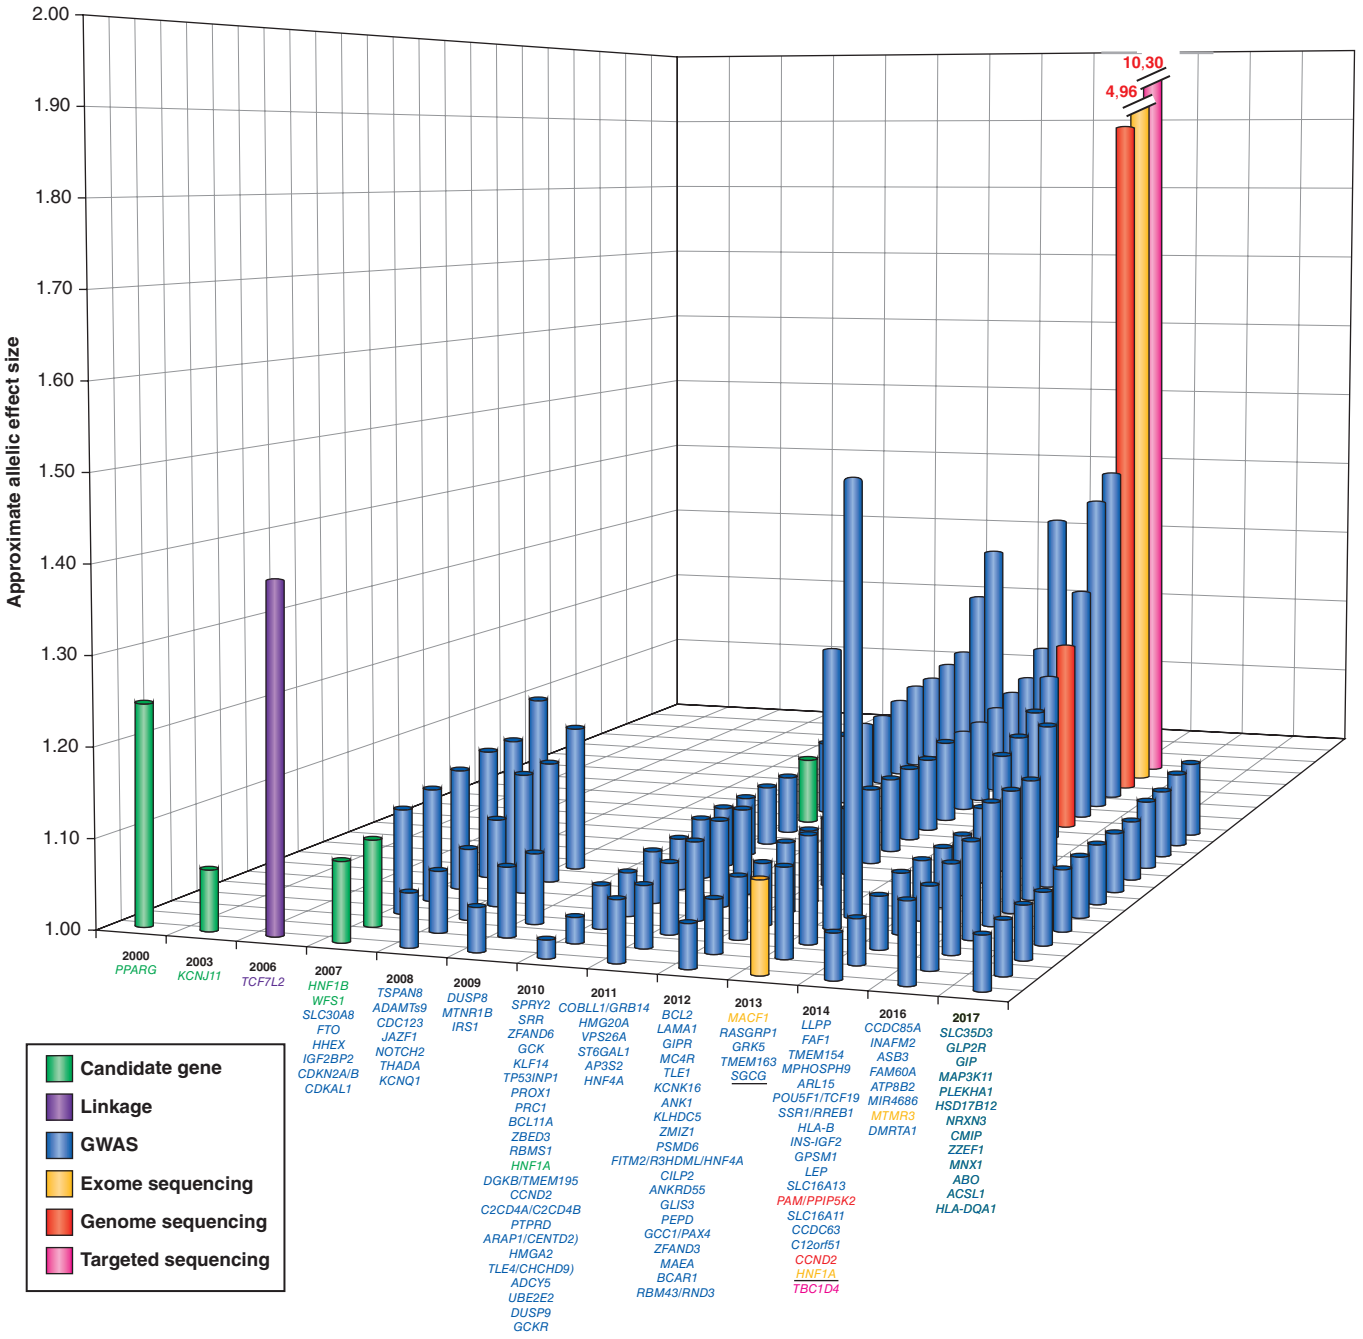

FIGURE 466-16 Loci and genes associated with diabetes mellitus type 2. Loci are listed by year of identification, and the color indicates discovery method. Gene names indicate the locus and do not necessarily imply that the gene itself is causally involved. Approximate allelic effect sizes were either derived from the discovery cohort or, if available, from the DIAGRAM (Diabetes Genetics Replication and Meta-analysis consortium) European ancestry meta-analysis and the Asian ancestry meta-analysis. Gene names that are underlined denote identification in population isolates. *(The data have been graciously provided by Dr. Miriam Udler and Dr. Jose Florez, Harvard Medical School, Boston.)*

basis for genetic counseling, carrier detection, early intervention, and disease prevention in relatives of the index patient **(Chap. 467)**.

In instances where a diagnosis at the molecular level may be relevant, it is important to identify an appropriate laboratory that can perform the appropriate test. Genetic testing is available for a large number of monogenic disorders through commercial laboratories. For uncommon disorders, the test may only be performed in a specialized research laboratory. Approved laboratories offering testing for inherited disorders can be identified in continuously updated online resources (e.g., Genetic Testing Registry; Table 466-1). If genetic testing is considered, the patient and the family should be counseled about the potential implications of positive results, including psychological distress and the possibility of discrimination. The patient or caretakers should be informed about the meaning of a negative result, technical limitations, and the possibility of false-negative and inconclusive results. For these reasons, genetic testing should only be performed after obtaining *informed consent*. Published ethical guidelines address the specific aspects that should be considered when testing children and adolescents. Genetic testing should usually be limited to situations in which the results may have an impact on medical management.

IDENTIFYING THE DISEASE-CAUSING GENE

Precision medicine aims to enhance the quality of medical care through the use of genotypic analysis (DNA testing) to identify genetic predisposition to disease, to select more specific pharmacotherapy, and to design individualized medical care based on genotype. Genotype can be deduced by analysis of protein

AFKEBOOKS SINCE 2013

TABLE 466-7 Genetic Approaches for Identifying Disease Genes

METHOD	INDICATIONS AND ADVANTAGES	LIMITATIONS
Linkage Studies		
Classical linkage analysis (parametric methods)	Analysis of monogenic traits Suitable for genome scan Control population not required Useful for multifactorial disorders in isolated populations	Difficult to collect large informative pedigrees Difficult to obtain sufficient statistical power for complex traits
Allele-sharing methods (nonparametric methods)	Suitable for identification of susceptibility genes in polygenic and multifactorial disorders	Difficult to collect sufficient number of subjects
Affected sib and relative pair analyses	Suitable for genome scan	Difficult to obtain sufficient statistical power for complex traits
Sib pair analysis	Control population not required if allele frequencies are known Statistical power can be increased by including parents and relatives	Reduced power compared to classical linkage, but not sensitive to specification of genetic mode
Association Studies		
Case-control studies	Suitable for identification of susceptibility genes in polygenic and multifactorial disorders	Requires large sample size and matched control population
Linkage disequilibrium	Suitable for testing specific allelic variants of known candidate loci	False-positive results in the absence of suitable control population
Transmission disequilibrium test (TDT)	Facilitated by comprehensive catalogs of genotypes and variants	Candidate gene approach does not permit detection of novel genes and pathways
Whole-genome association studies	Does not necessarily need relatives	Susceptibility genes can vary among different populations
Next-Generations Sequencing Technologies		
Whole exome or genome sequencing	Unbiased approach, analysis can be performed without reference sequences from parents or siblings	Requires appropriate bioinformatics, may have low sensitivity if CNV analysis is not included, detects numerous VUS, can lead to the detection of unrelated deleterious alleles
Targeted sequencing of gene panels	Captures multiple candidate genes and loci with hybridization techniques followed by deep sequencing	Permits analyses of multiple candidate genes in parallel; facilitates molecular characterization of disorders with locus heterogeneity

Abbreviations: CNV, copy number variation; VUS, variants of unknown significance.

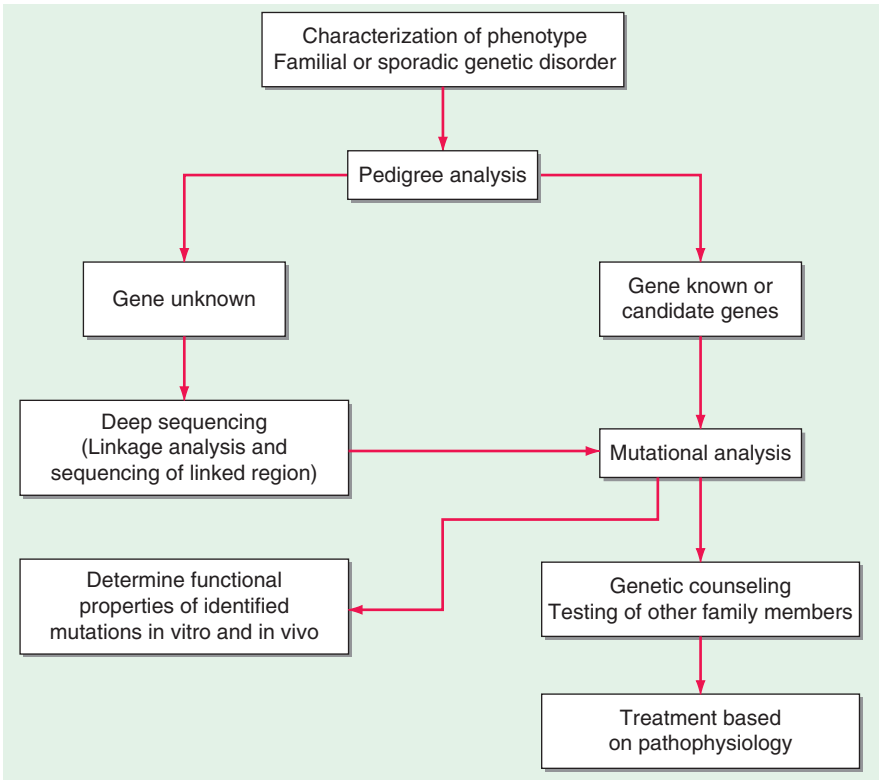
(e.g., hemoglobin, apoprotein E), mRNA, or DNA. Many (pathogenic) variants can be readily identified by DNA analyses; technical advances in RNA sequencing now add increasing depth to genetic and genomic investigations (e.g., for the detection of gene fusions or aberrant gene expression patterns).

DNA testing is performed by mutational analysis or linkage studies in individuals at risk for a genetic disorder known to be present in a family. Mass screening programs require tests of high sensitivity and specificity to be cost-effective. The benefits and risks of screening newborns with genomic sequencing remain uncertain, and the potential impact on surveillance, preventative health care, and personalized treatment options is currently being explored (BabySeq Project). Prerequisites for the success of genetic screening programs include the following: that the disorder is potentially serious; that it can be influenced at a presymptomatic stage by changes in behavior, diet, and/or pharmaceutical manipulations; and that the screening does not result in any harm or discrimination. Screening in Jewish populations for the autosomal recessive neurodegenerative storage disease Tay-Sachs has reduced the number of affected individuals. In contrast, screening for sickle cell trait/disease in African Americans has led to unanticipated problems of discrimination by health insurers and employers. Mass screening programs harbor additional potential problems. For example, screening for the most common genetic alteration in cystic fibrosis, the ΔF508 mutation with a frequency of ~70% in northern Europe, is feasible and seems to be effective. One has to keep in mind, however, that there is pronounced allelic heterogeneity and that the *CFTR* gene can be affected by ~2000 other mutations. The search for these less common mutations would substantially increase costs but not the effectiveness of the screening program as a whole. Next-generation genome sequencing permits comprehensive and cost-effective mutational analyses after selective enrichment of candidate genes. For example, tests that sequence all the common genes causing hereditary deafness or hereditary pheochromocytomas are commercially available. Occupational screening programs aim to detect individuals with increased risk for certain professional activities (e.g., α_1 antitrypsin deficiency and smoke or dust exposure). Integrating genomic data into electronic medical records is evolving and can provide significant decision support at the point of care, for example, by providing the clinician with genomic data and decision algorithms for the prescription of drugs that are subject to pharmacogenetic influences.

Mutational Analyses DNA sequence analysis is widely used as a diagnostic tool and has significantly enhanced diagnostic accuracy. It is used for determining carrier status and for prenatal testing in monogenic disorders. Numerous techniques, discussed in previous versions of this chapter, are available for the detection of mutations. Analyses of large alterations in the genome are possible using classic methods such as karyotype analysis, cytogenetics, fluorescent in situ hybridization (FISH), and array- or bead-based techniques that search for multiple single exon deletions or duplications.

More discrete sequence alterations rely heavily on the use of PCR, which allows rapid gene amplification and analysis. Moreover, PCR makes it possible to perform genetic testing and mutational analysis with small amounts of DNA extracted from leukocytes or even from single cells, buccal cells, or hair roots. DNA sequencing can be performed directly on PCR products. Sequencing of the whole genome or exome, of selected chromosomes, or of numerous candidate genes in a single run is now possible with NGS platforms and has transformed the characterization of patients with rare disorders and advanced malignancies. Analysis of cell-free DNA (cfDNA; also referred to as "liquid biopsy") present in body fluids is playing a growing role for minimally invasive diagnostics and disease monitoring. Genomic tests are also widely used for the detection of pathogens and for the identification of viral or bacterial sequence variations.

The integration of genomic tests into clinical medicine is associated with a number of ongoing challenges related to costs, variable sensitivities of the tests, bioinformatics analyses, storage and sharing of data, and the difficulty of interpreting all genetic variants identified with comprehensive testing. The discovery of incidental (or secondary) findings that are unrelated to the indication for the sequencing analysis, but indicators of other disorders of potential relevance for patient care can pose a difficult ethical dilemma. It can



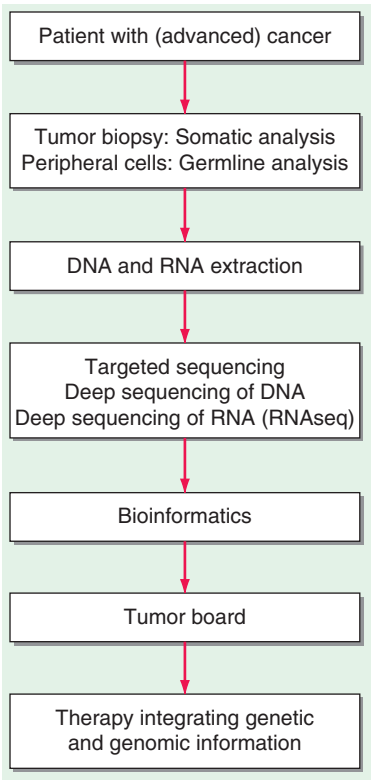


FIGURE 466-17 Approach to genetic disease.

lead to the detection of undiagnosed medically actionable genetic conditions but can also reveal deleterious mutations that cannot be influenced, as numerous sequence variants are of unknown significance.

A general algorithm for the approach to mutational analysis in patients with a suspected genetic disorder and (advanced) malignancies is outlined in **Fig. 466-17**. The importance of a detailed characterization of the clinical phenotype cannot be overemphasized. This is the step where one should also consider the possibility of genetic heterogeneity and phenocopies. If obvious candidate genes are suggested by the phenotype, they can be analyzed directly. After identification of a mutation, it is essential to demonstrate that it segregates with the phenotype. The functional characterization of novel mutations is labor intensive and may require analyses in vitro or in transgenic models in order to document the relevance of the genetic alteration.

Prenatal diagnosis of numerous genetic diseases in instances with a high risk for certain disorders is possible by direct DNA analysis. *Amniocentesis* involves the removal of a small amount of amniotic fluid, usually at 16 weeks of gestation. Cells can be collected and submitted for karyotype analyses, FISH, and mutational analysis of selected genes (Table 466-4). The main indications for amniocentesis include advanced maternal age (>35 years), presence of an abnormality of the fetus on ultrasound examination, an abnormal serum "quad" test (α fetoprotein, β human chorionic gonadotropin, inhibin-A, and unconjugated estriol), a family history of chromosomal abnormalities, or a Mendelian disorder amenable to genetic testing. Prenatal diagnosis can also be performed by *chorionic villus sampling* (CVS), in which a small amount of the chorion is removed by a transcervical or transabdominal biopsy. Chromosomes and DNA obtained from these cells can be submitted for cytogenetic and mutational analyses. CVS can be performed earlier in gestation (weeks 9–12) than amniocentesis, an aspect that may be of relevance when termination of pregnancy is a consideration. Later in pregnancy, beginning at ~18 weeks of gestation, percutaneous umbilical blood sampling (PUBS; cordocentesis) permits collection of fetal blood for analysis. Prenatal cfDNA allows DNA analyses from the mother and fetus from a maternal blood sample to screen for certain chromosomal abnormalities and fetal sex. These approaches enable screening for clinically relevant and deleterious alleles inherited from the parents, as well as for de novo germline mutations, and they have the potential to identify genetic disorders in the prenatal setting.

In combination with in vitro fertilization (IVF) techniques, it is possible to perform genetic diagnoses in a single cell removed from the four- to eight-cell embryo or to analyze the first polar body from an oocyte. Preconceptual diagnosis thereby avoids therapeutic abortions but is costly and labor intensive. It should be emphasized that excluding a specific disorder by any of these approaches is never equivalent to the assurance of having a normal child. Postnatal indications for cytogenetic analyses in infants or children include multiple congenital anomalies, suspicion of a known cytogenetic syndrome, developmental delay, dysmorphic features, autism, short stature, and disorders of sexual development, among others (Table 466-4).

Mutations in certain cancer susceptibility genes such as *BRCA1* and *BRCA2* may identify individuals with an increased risk for the development of malignancies and result in risk-reducing interventions. The detection of cytogenetic alterations and mutations is an important diagnostic and prognostic tool in leukemias, and it has also transformed the management of solid tumors. In addition to providing diagnostic information, mutational analysis can inform the choice of targeted therapies ("actionable mutations") and characterize the mutational load, which is emerging as an important indicator of sensitivity to immune checkpoint inhibitors, and can be used for surveillance.

The demonstration of the presence or absence of mutations and polymorphisms is also relevant for the rapidly evolving field of pharmacogenomics, including the identification of differences in drug treatment response or metabolism as a function of genetic background

Gene therapy through the introduction of a normal gene or the ability to make site-specific modifications to the human genome has, so far, limited clinical application. However, several gene

transfer methods have now been approved for clinical use, for example, for the treatment of Leber congenital amaurosis, B-cell acute lymphoblastic leukemia, spinal muscular atrophy, and hereditary transthyretin-mediated amyloidosis. Moreover, CRISPR-Cas9 genome editing is currently being investigated in clinical trials as a novel therapeutic approach for selected genetic disorders **(Chap. 470)**.

ETHICAL ISSUES

Determination of the association of genetic defects with disease, comprehensive data of an individual's genome, and studies of genetic variation raise many ethical and legal issues. Genetic information is generally regarded as sensitive information that should not be readily accessible without explicit consent (*genetic privacy*). The disclosure of genetic information may risk possible discrimination by insurers or employers. The scientific components of the Human Genome Project have been paralleled by efforts to examine ethical, social, and legal implications. An important milestone emerging from these endeavors is the Genetic Information Nondiscrimination Act (GINA), signed into law in 2008, which aims to protect asymptomatic individuals against the misuse of genetic information for health insurance and employment. It does not, however, protect the symptomatic individual. Provisions of the U.S. Patient Protection and Affordable Care Act, effective in 2014, have, in part, filled this gap and prohibit exclusion from, or termination of, health insurance based on personal health status. Potential threats to the maintenance of genetic privacy consist of the emerging integration of genomic data into electronic medical records, compelled disclosures of health records, and direct-to-consumer genetic testing.

It is widely accepted that identifying disease-causing genes can lead to improvements in diagnosis, treatment, and prevention. However, the information gleaned from genotypic results can have quite different impacts, depending on the availability of strategies to modify the course of disease. For example, the identification of mutations that cause MEN 2 or hemochromatosis allows specific interventions for affected family members. On the other hand, at present, the identification of an Alzheimer's or Huntington's disease gene does not currently alter therapy and outcomes. Most genetic disorders are likely to fall into an intermediate category where the opportunity for prevention or treatment is significant but limited. However, the progress in this area is unpredictable, as underscored by the finding that angiotensin II receptor blockers appear to slow disease progression in Marfan's syndrome. Genetic test results can generate anxiety in affected individuals and family members. Comprehensive sequence analyses are particularly challenging because most individuals can be expected to harbor several serious recessive gene mutations. Moreover, the sensitivity of comprehensive sequence analyses is not always greater, for example, if CNV analysis is not integrated but can be associated with higher costs. Genetic manipulation and patient selection for gene therapy approaches have aroused ethical controversy and safety concerns that remain unresolved.

The impact of genetic testing on health care costs remains unclear. It does vary among disorders and depends on the availability of effective therapeutic modalities, and there are significant differences among health care systems. A significant problem arises from the marketing of genetic testing directly to consumers by commercial companies. The validity of these tests is, in part, not well defined, and there are persisting concerns about the lack of appropriate regulatory oversight, the accuracy and confidentiality of genetic information, the availability of counseling, and the handling of these results.

Many issues raised by the genome project are familiar, in principle, to medical practitioners. For example, an asymptomatic patient with increased low-density lipoprotein (LDL) cholesterol, high blood pressure, or a strong family history of early myocardial infarction is known to be at increased risk of coronary heart disease. In such cases, it is clear that the identification of risk factors and an appropriate intervention are beneficial. Likewise, patients with phenylketonuria, cystic fibrosis, or sickle cell anemia are often identified as having a genetic disease early in life. These precedents can be helpful for adapting policies that relate to genetic information.

One confounding aspect of the rapid expansion of information is that our ability to make clinical decisions often lags behind initial insights into genetic mechanisms of disease. For example, when genes that predispose to breast cancer such as *BRCA1* are described, they generate tremendous public interest in the potential to predict disease, but many years of clinical research are still required to rigorously establish genotype and phenotype correlations.

Genomics may contribute to improvements in global health by providing a better understanding of pathogens and diagnostics and through contributions to drug development. There is, however, persisting concern about the development of a "genomics divide" because of the costs associated with these developments and uncertainty as to whether these advances will be accessible to the populations of developing countries faced with pressing health needs associated with poverty, infectious diseases, and the relative lack of essential infrastructure. The World Health Organization's "Human Genomics in Global Health Initiative" aims to address these issues and inequities surrounding genomic medicine.

Whether related to informed consent, participation in research, or the management of a genetic disorder that affects an individual or his or her family, there is a great need for more information about fundamental principles of genetics. The pervasive nature of the role of genetics in medicine makes it important for physicians and other health care professionals to become more informed about genetics and to provide advice and counseling in conjunction with trained genetic counselors **(Chap. 467)**. Therefore, the application of screening and prevention strategies does require continuing patient and physician education, changes in health care financing, and legislation to protect patient's rights.

Acknowledgment

Selected sections and Table 466-4 have been integrated from the chapter on Chromosome Disorders by Dr. Nancy B. Spinner and Dr. Laura K. Conlin, published in the 19th edition of Harrison's Principles in Internal Medicine. The data and concept for Figure 466-16 have been graciously provided by Dr. Miriam Udler and Dr. Jose Florez, Massachusetts General Hospital and Harvard Medical School, Boston.

467 The Practice of Genetics in Clinical Medicine

Susan M. Domchek, J. Larry Jameson, Susan Miesfeldt

APPLICATIONS OF MOLECULAR GENETICS IN CLINICAL MEDICINE

Genetic testing for inherited abnormalities associated with disease risk is increasingly used in the practice of clinical medicine. Germline alterations include chromosomal abnormalities, specific gene mutations (also called pathogenic variants) with autosomal dominant or recessive patterns of transmission **(Chap. 466)**, and single nucleotide polymorphisms (SNPs) with small relative risks associated with disease. Germline alterations are responsible for disorders beyond classic Mendelian conditions with genetic susceptibility to common adult-onset diseases such as asthma, hypertension, diabetes mellitus, macular degeneration, and a number of types of cancer. For many of these diseases, there is a complex interplay of genes (often multiple) and environmental factors that affect lifetime risk, age of onset, disease severity, and treatment options.

The expansion of human genetic knowledge is changing our understanding of pathophysiology and influencing our classification of diseases. Awareness of genetic etiology can have an impact on clinical management, including prevention and screening for or treatment of a range of diseases. Primary care physicians are relied upon to help patients navigate testing and treatment options. Consequently, they must understand the genetic basis for a large number of genetically influenced diseases, incorporate personal and family history to determine the risk for a specific pathogenic variant, and be positioned to provide counseling. Even if patients are seen by genetic specialists who assess genetic risk and coordinate testing, primary care providers should offer information to their patients regarding the indications, limitations, risks, and benefits of genetic counseling and testing. They must also be prepared to offer risk-based management following genetic risk assessment. Given the pace of genetics, this is an increasingly difficult task. The field of clinical genetics has rapidly transitioned from single-gene testing to multigene panel testing, with techniques such as whole exome and genome sequencing on the horizon, increasing the complexity of test selection and interpretation, as well as patient education and medical decision-making.

COMMON ADULT-ONSET GENETIC DISORDERS

INHERITANCE PATTERNS

Adult-onset hereditary diseases follow multiple patterns of inheritance. Some are autosomal dominant conditions. These include many common cancer susceptibility syndromes such as hereditary breast and ovarian cancer (due to germline *BRCA1* and *BRCA2* pathogenic variants) and Lynch syndrome (caused by germline mutations in the mismatch repair genes *MLH1*, *MSH2*, *MSH6*, and *PMS2*). In both of these examples, inherited pathogenic variants are associated with a high penetrance (lifetime risk) of cancer, although penetrance is incomplete (risk is not 100%). In other conditions, although there is autosomal dominant transmission, penetrance is lower, thereby making the disorders more difficult to recognize. For example, germline mutations in *CHEK2* increase the risk of breast cancer but with a moderate lifetime risk in the range of 20–30%, as opposed to 50–70% for mutations in *BRCA1* or *BRCA2*. Other adult-onset hereditary diseases are transmitted in an autosomal recessive fashion where two mutant alleles are necessary to cause full expression of disease. Examples include hemochromatosis and *MUTYH*-associated polyposis. There are more pediatric-onset autosomal recessive disorders, such as lysosomal storage diseases and cystic fibrosis.

The genetic risk for many adult-onset disorders is multifactorial. Risk can be conferred by genetic factors at a number of loci (polygenic), which individually have very small effects (usually with relative risks of <1.5). These risk loci (generally SNPs) combine with other genes and environmental factors in ways that are not well understood. Despite our incomplete understanding of gene-environment interactions, data suggest that a healthy lifestyle can mitigate risk associated with elevated polygenic risk diseases, such as cardiovascular disease. SNP panels are available to assess risk of disease, but the optimal way of using this information in the clinical setting to improve patient outcomes remains uncertain.

Many diseases have multiple patterns of inheritance, adding to the complexity of evaluating patients and families for these conditions. For example, colon cancer can be associated with a single germline mutation in a mismatch repair gene (Lynch syndrome; autosomal dominant), biallelic mutations in *MUTYH* (autosomal recessive), or multiple SNPs (polygenic). Many more individuals will have SNP risk alleles than germline pathogenic variants in high-penetrance genes, but cumulative lifetime risk of colon cancer related to the former is modest, whereas the risk related to the latter is significant. Personal and family histories provide important insights into the possible mode of inheritance.

FAMILY HISTORY

When two or more first-degree relatives are affected with asthma, cardiovascular disease, type 2 diabetes, breast cancer, colon cancer, or melanoma, the relative risk for disease among close relatives ranges from two- to fivefold, underscoring the importance of family history for these prevalent disorders. In most situations, the key to assessing the inherited risk for common adult-onset diseases is the collection and interpretation of a detailed personal and family medical history in conjunction with a directed physical examination.

Family history should be recorded in the form of a pedigree, conveying health-related data on first- and second-degree relatives. When such pedigrees suggest inherited disease, they should be expanded to include additional family members. The determination of risk for an asymptomatic individual will vary depending on the size of the family, the number of unaffected relatives, the types of diagnoses, and the ages of disease onset. For example, a woman with two first-degree relatives with breast cancer is at greater risk for a specific Mendelian disorder if she has a total of 3 female first-degree relatives (with only 1 unaffected) than if she has a total of 10 female first-degree relatives (with 8 unaffected). Factors such as adoption and limited family structure (few women in a family or multiple early deaths unrelated to the target disease) should to be taken into consideration in the interpretation of a pedigree. Additional considerations include young age of disease onset (e.g., a 30-year-old nonsmoking woman with a myocardial infarction), unusual diseases (e.g., male breast cancer or medullary thyroid cancer), and the finding of multiple potentially related diseases in an individual (e.g., a woman with a history of both colon and endometrial cancer). Some adult-onset diseases are more prevalent in certain ethnic groups.

For instance, 2.5% of individuals of Ashkenazi Jewish ancestry carry one of three founder mutations in *BRCA1* and *BRCA2*. Factor V Leiden mutations are much more common in Caucasians than in Africans or Asians.

Additional variables that should be documented are nonhereditary risk factors among those with disease (such as cigarette smoking and myocardial infarction; asbestos exposure and lung disease; and mantle radiation and breast cancer). Significant associated environmental exposures or lifestyle factors decrease the likelihood of a specific genetic disorder. In contrast, the absence of nonhereditary risk factors typically associated with a disease raises concern about a genetic association. A personal or family history of deep-vein thrombosis in the absence of known environmental or medical risk factors suggests a hereditary thrombotic disorder. The physical examination may also provide important clues about the risk for a specific inherited disorder. A patient presenting with xanthomas at a young age should prompt consideration of familial hypercholesterolemia. The presence of trichilemmomas in a woman with breast cancer raises concern for Cowden syndrome, associated with *PTEN* mutations.

Recall of family history is often inaccurate. This is especially so when the history is remote and families lose contact or separate geographically. It can be helpful to ask patients to fill out family history forms before or after their visits, because this provides them with an opportunity to contact relatives. Ideally, this information should be embedded in electronic health records and updated intermittently. Attempts should be made to confirm the illnesses reported in the family history before making important and, in certain circumstances, irreversible management decisions. This process is often labor intensive and ideally involves interviews of additional family members or review of medical records (including pathology reports) and death certificates.

Although many inherited disorders will be suggested by the clustering of relatives with the same or related conditions, it is important to note that disease penetrance is incomplete for most genetic disorders. As a result, the pedigree obtained in such families may not exhibit a clear Mendelian inheritance pattern because not all family members carrying the disease-associated alleles will manifest clinical evidence of the condition. Furthermore, genes associated with some of these disorders often exhibit variable disease expression. For example, the breast cancer–associated gene *BRCA2* can predispose to several different malignancies in the same family, including cancers of the breast, ovary, pancreas, skin (melanoma), and prostate. For common diseases such as breast cancer, some family members without the susceptibility allele (or genotype) may develop breast cancer (or phenotype) sporadically. Such *phenocopies* represent another confounding variable in the pedigree analysis.

Some of the aforementioned features of the family history are illustrated in **Fig. 467-1**. In this example, the proband (the individual serving as the starting point for genetic assessment in a family), a 36-year-old woman (IV-1), has a strong history of breast and ovarian cancer on the paternal side of her family. The early age of onset and the co-occurrence of breast and ovarian cancer in this family suggest the possibility of an inherited mutation in *BRCA1* or *BRCA2*, associated with the hereditary breast and ovarian cancer syndrome. However, without genetic testing, it is unclear whether her father harbors such a pathogenic variant and transmitted it to her. After appropriate genetic counseling of the proband and her family, the most informative and cost-effective approach to DNA analysis in this family is to test the cancer-affected 42-year-old living cousin for the presence of a *BRCA1* or *BRCA2* mutation. If a pathogenic variant is found, then it is possible to test for this particular alteration in other family members, if they so desire. In the example shown, if the proband's cousin has a *BRCA1* pathogenic variant, testing for this alteration (single site testing) would be an option for the proband's father. If he tests positive, there is a 50:50 probability that the mutation was transmitted to her, and genetic testing can be used to establish the absence or presence of this alteration. In contrast, if he tests negative for the known familial *BRCA1* mutation (a true-negative result), the proband and her brother are not at risk for having inherited this variant from their father.

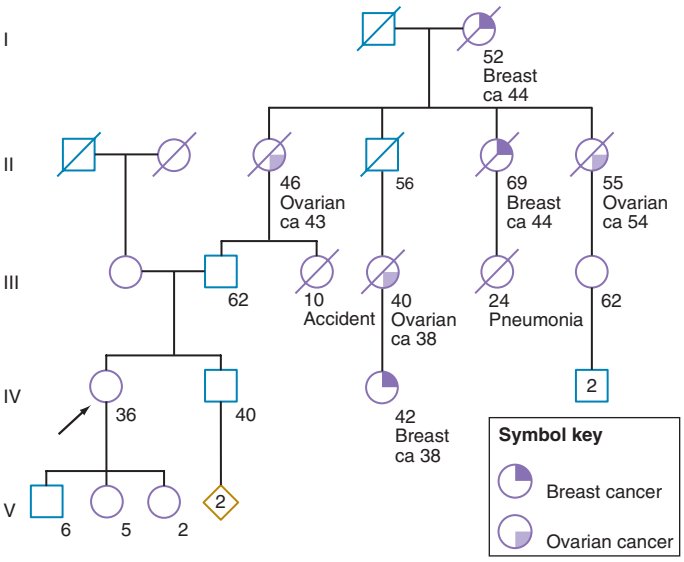

FIGURE 467-1 A 36-year-old woman (*arrow*) seeks consultation because of her family history of cancer. The patient expresses concern that the multiple cancers in her relatives imply an inherited predisposition to develop cancer. The family history is recorded, and records of the patient's relatives confirm the reported diagnoses.

GENETIC TESTING FOR ADULT-ONSET DISORDERS

A critical first step before initiating genetic testing is to ensure that the correct clinical diagnosis has been made, whether it is based on family history, characteristic physical findings, pathology, or biochemical testing. Such careful clinical assessment can define the phenotype. In the traditional model of genetic testing, testing is directed initially toward the most probable genes (determined by the phenotype), which prevents unnecessary testing. Many disorders exhibit the feature of locus heterogeneity, which refers to the fact that mutations in different genes can cause phenotypically similar disorders. For example, osteogenesis imperfecta **(Chap. 413)**, long QT syndrome **(Chap. 252)**, muscular dystrophy **(Chap. 449)**, and hereditary predisposition to breast **(Chap. 79)** or colon **(Chap. 81)** cancer can each be caused by pathogenic variants in a number of distinct genes. The patterns of disease transmission, disease risk, clinical course, and treatment may differ significantly depending on the specific gene affected. Historically, the choice of which gene to test has been determined by unique clinical and family history features and the relative prevalence of candidate genetic disorders. However, rapid changes in genetic testing techniques, as discussed below, are impacting this paradigm. It is now technically and financially feasible to sequence many genes (or even the whole exome) at one time. The incorporation of expanded testing for germline mutations has rapidly evolved both within the clinic as well as through direct-to-consumer marketing of genetic and genomic tests.

METHODOLOGIC APPROACHES TO GENETIC TESTING

Genetic testing is regulated and performed in much the same way as other specialized laboratory tests. In the United States, genetic testing laboratories are Clinical Laboratory Improvement Amendments (CLIA) approved to ensure that they meet quality and proficiency standards. A useful information source for various genetic tests is *www.genetests.org*. It should be noted that many tests need to be ordered through specialized laboratories.

Genetic testing is performed largely by DNA sequence analysis for mutations, although genotype can also be deduced through the study of RNA or protein (e.g., apolipoprotein E, hemoglobin S, and immunohistochemistry). For example, universal Lynch syndrome screening of colorectal and uterine cancers via immunohistochemical analysis for absence of expression of mismatch repair proteins is recommended by the National Comprehensive Cancer Network. The determination of DNA sequence alterations relies heavily on the use of polymerase chain

reaction (PCR), which allows rapid amplification and analysis of the gene of interest. In addition, PCR enables genetic testing on minimal amounts of DNA extracted from a wide range of tissue sources including leukocytes (obtained from blood), leukocytes and mucosal epithelial cells (obtained via saliva or buccal swabs), and tumors (obtained from biopsies or archival tissues). Amplified DNA can be analyzed directly by DNA sequencing, or it can be hybridized to DNA chips or blots to detect the presence of normal and altered DNA sequences. Direct DNA sequencing is frequently used for determination of hereditary disease susceptibility and prenatal diagnosis. Analyses of large alterations (e.g., deletions, duplications, rearrangements, translocations) of the genome are possible using cytogenetics, fluorescent in situ hybridization (FISH), Southern blotting, or multiplex ligation-dependent probe amplification (MLPA).

Massively parallel sequencing (also called *next-generation sequencing*) has significantly altered the approach to genetic testing for adult-onset hereditary susceptibility disorder. This technology encompasses high-throughput approaches to DNA analysis that can reliably examine many genes at one time. Technically, this involves sequencing of millions of small fragments of DNA in parallel. Through bioinformatics, these fragments are pieced together by mapping the individual sequence reads to the human reference genome, a very different process than traditional Sanger sequencing, which is time-consuming and expensive.

Multiplex panels for inherited susceptibility are commercially available and include testing of a number of genes that have been associated with the condition of interest. For example, panels are available for Brugada syndrome, hypertrophic cardiomyopathy, and Charcot-Marie-Tooth neuropathy. For many syndromes, this type of panel testing may make sense. However, in other situations, the clinical utility of panel testing is evolving and may be dependent on the particular composition of the panel. Currently available breast cancer susceptibility panels contain close to 30 genes, with larger multicancer panels available. Some of the genes included in the larger multicancer panels have no known association with breast cancer or have only a modest associated risk, and the clinical utility is uncertain. An additional problem of sequencing many genes, rather than focusing on leading candidate genes, is the identification of one or more variants of uncertain significance (VUS), discussed below, or an unexpected yet clinically relevant result.

Whole exome sequencing (WES) is also now commercially available, although largely used in individuals with syndromes unexplained by traditional genetic testing. As cost declines, WES may be more widely used. Whole genome sequencing is also commercially available. Although it may be quite feasible to sequence the entire genome, there are many issues in doing so, including the daunting task of analyzing the vast amount of data generated. Other issues include (1) the optimal way in which to obtain informed consent, (2) interpretation of frequent sequence variations of uncertain significance, (3) interpretation of alterations in genes with unclear relevance to specific human pathology, and (4) management of unexpected but clinically significant genetic findings.

Testing strategies are evolving as a result of these new genetic testing platforms. As the costs of multiplex gene panels and WES continue to fall and as interpretation and understanding of the clinical relevance of such test results improve, there has been a shift to more extensive panel-based genetic testing in the clinic. For example, in the past, a 30-year-old woman with breast cancer but no family history of cancer and no syndromic features would undergo *BRCA1/2* testing and would be offered *TP53* testing in light of her early-onset disease (notably, a reasonable number of individuals offered *TP53* testing for Li-Fraumeni syndrome in the past declined because mutations are associated with extremely high cancer risks—including childhood cancers—in multiple organs and means to mitigate risk are evolving). Without features consistent with other high-risk, breast cancer–related conditions such as Cowden syndrome, the woman would not have been routinely offered *PTEN* analysis (associated with Cowden syndrome) or testing for other breast cancer–associated genes including *PALB2*, *CHEK2*, and *ATM*. It is now possible to synchronously analyze all of the aforementioned genes, along with genes such as *BRIP, RAD51C,* and *RAD51D* (which are associated with moderate ovarian cancer risk but unclear risk for other cancers, including breast cancer), for a nominally higher cost than *BRCA1/2* testing alone. Concerns about such panels include appropriate consent strategies related to unclear findings, including one or more VUSs, unanticipated results, and the uncertain clinical utility of some of the genes included on the panel **(Fig. 467-2)**.

DIRECT-TO-CONSUMER GENETIC TESTING

Historically, genetic testing occurred entirely, or predominantly, in the context of clinical care. However, technologic advances combined with shifts in social norms have created an increasingly complex landscape for genetic information, and patients come to providers with a wide range of information.

Clinician-directed genetic testing is based on the individual's personal or family medical history. Results are disclosed by the clinician with a management plan formulated based on results, within the context of the individual's personal and family medical history. Consumer-directed genetic testing differs in that the individual electively requests the tests to be performed by a direct-to-consumer (DTC) company and submits the sample directly. DTC tests are analyzed through proprietary technology, with results communicated directly to the consumer.

DTC testing can include assays for disease risk or disease carrier status; however, they often place a greater emphasis on ancestry or physical traits and characteristics, such as obesity, nutrition, taste, or hair loss. From a clinical utility standpoint, such testing companies most often examine sets of SNPs, common "hot spots" in genes associated

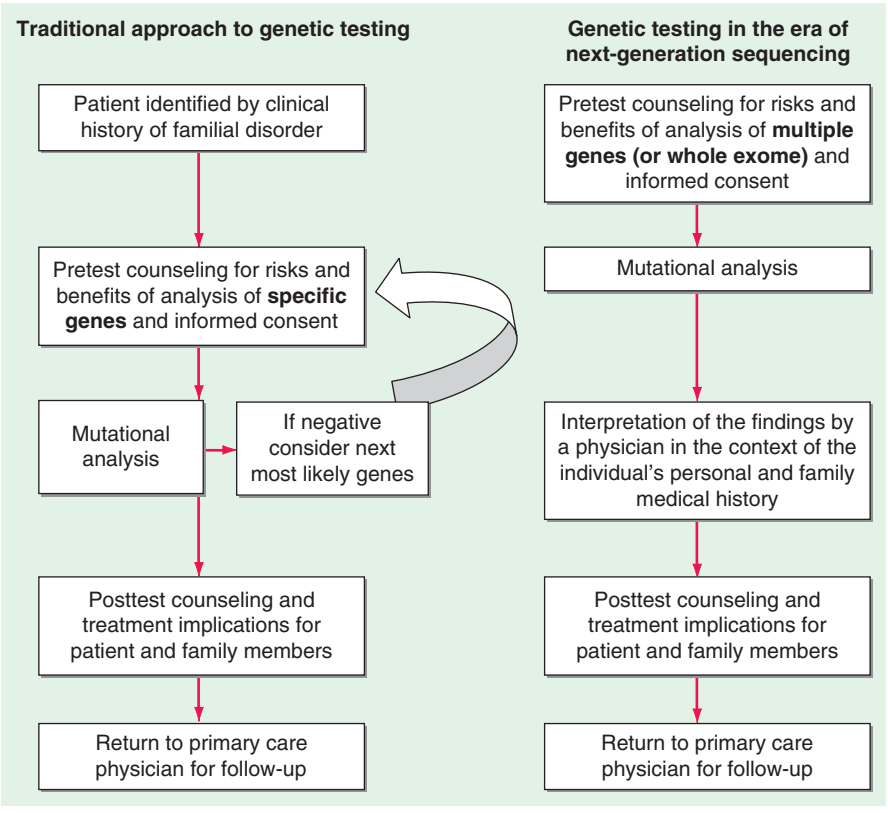

FIGURE 467-2 Approach to genetic testing.

TABLE 467-1 Summary of American College of Medical Genetics and Genomics Position Statement on Direct-to-Consumer Genetic Testing

The clinical laboratory must:	• Be accredited by the CLIA (Clinical Laboratory Improvement Amendments) program, the state, and/or other applicable accrediting agencies with this accreditation indicated on test result reports
Appropriately trained professionals should order, interpret, and disclose test result to avoid:	• Inadequate or lack of informed consent • Testing without appropriate indications • Selection of inadequate testing methods or incorrect test • Misinterpretation of results leading to improper clinical management
The individual undergoing testing should be adequately informed of:	• What the test can or cannot determine about their health or health risk • The potential for receiving results that neither confirm nor exclude the possibility of disease • Potential unexpected results, unrelated to the indication for testing • The potential impact of a given genetic test result on relatives
Professionals will review and provide information about:	• The validity and utility of a genetic test, including the limitations of a given test • Privacy issues to include review of who will have access to test results, the processes in place to protect results, and disposition of DNA samples once analysis is complete • Personal or family implications for life, long-term care, or disability insurance • Whether data generated will be shared with third parties

with specific diseases; however, SNP analysis does not provide a definitive risk/no risk answer. In contrast, clinical genetic testing thoroughly interrogates specific genes known be associated with an individual disease or disease risk. Quality standards between DTC and clinical laboratories vary greatly. In the United States, clinical genetic testing labs meet established strict quality standards discernible as CLIA certification and College of American Pathologists (CAP) accreditation. Some DTC labs are granted U.S. Food and Drug Administration (FDA) approval for the tests offered but are not CLIA/CAP certified. The FDA mandates that "results obtained from the tests should not be used for diagnosis or to inform treatment decisions. Users should consult a health care professional with questions or concerns about results." Recommendations from the American College of Medical Genetics and Genomics are summarized in **Table 467-1**.

A third, hybrid model has been developed by commercial genetic testing laboratories, particularly focused on analysis for cancer and cardiovascular disease risk. Here, after an individual initiates the testing process, either their own physician or a physician provided by the company orders the test. Many of these tests are similar to those offered to a patient in the clinical setting; however, the order and results remain separate from the medical record unless integrated by the patient's primary or specialist physician or other health care provider.

Limitations to the accuracy and interpretation of genetic testing exist. In addition to technical errors, genetics tests are sometimes designed to detect only the most common pathogenic variants. In addition, genetic testing has evolved over time. For example, it was not possible to obtain commercially available, comprehensive, large genomic rearrangement testing for *BRCA1* and *BRCA2* until 2006. Therefore, a negative result must be qualified by the possibility that the individual may have a variant that was not detectable in the test. In addition, the individual may have a pathogenic variant in another untested cancer-associated gene or in a gene not yet reported to be associated with elevated disease risk. As such, unless there is a known mutation in the family, a negative result in an individual with a suggestive personal or family history is typically classified as an uninformative negative. In this circumstance, medical management decisions should be based on personal and family history. For example, a woman with a strong family history of breast cancer who receives an uninformative negative panel-based genetic test result may still be eligible for high-risk care, including consideration of MRI-based breast cancer screening and the option of chemoprevention, in addition to close clinical surveillance and mammograms.

The finding of a VUS is another limitation to genetic testing. A VUS (also termed *unclassified variant*) is a sequence variation in a gene where the effect of the alteration on the function of the protein is not known. Many of these variants are single nucleotide substitutions (also called missense mutations) that result in a single amino acid change. Although many VUSs will ultimately be reclassified as benign variants, some will prove to be functionally important. As more genes are sequenced (e.g., in a multiplex panel or through WES), the percentage of individuals found to have one or more VUSs increases significantly. The finding of a VUS is difficult for patients and providers alike and complicates decisions regarding medical management. In this setting, until there is further reclassification of the variant, ongoing screening, surveillance, and care is typically determined based on personal and family history.

Clinical utility is an important consideration because genetic testing for susceptibility to chronic diseases is increasingly integrated into the practice of medicine. In some situations, there is proven clinical utility to genetic testing with significant evidence-based changes in medical management options and recommendations based on results. For example, there is clear evidence that risk-reducing bilateral salpingo-oophorectomy benefits women with a documented *BRCA1/2* mutation, relative to both ovarian and breast cancer–related risk. However, in many cases, the discovery of disease-associated genes has outpaced studies that assess how such information should be used in the clinical management of the patient and family. This is particularly true for moderate- and low-penetrance pathogenic variants. Therefore, predictive genetic testing should be approached with caution and offered to individuals who have been adequately counseled and have provided informed consent.

Predictive genetic testing falls into two distinct categories. Presymptomatic testing applies to diseases where a specific genetic alteration is associated with a near 100% likelihood of developing disease. In contrast, predisposition testing predicts a risk for disease that is <100%. For example, presymptomatic testing is available for those at risk for Huntington's disease, whereas predisposition testing is considered for those at risk for hereditary colon cancer. It is important to note that for the majority of adult-onset disorders, testing is only predictive. Test results cannot reveal with confidence whether, when, or how the disease will manifest itself. For example, not everyone with the apolipoprotein ε4 allele will develop Alzheimer's disease, and individuals without this genetic marker can still develop the disorder.

The optimal testing strategy for a family is to initiate testing in a (target) disease-affected family member first. Identification of a mutation can direct the testing of other at-risk family members (whether symptomatic or not). In the absence of additional familial or environmental risk factors, individuals who test negative for the mutation found in the affected family member can be informed that they are at general population risk for that particular disease. Furthermore, they can be reassured that they are not at risk for passing the mutation on to their children. On the other hand, asymptomatic family members who test positive for the known mutation must be informed that they are at increased risk for disease development and for transmitting the alteration to their children.

Pretest counseling and education are important, as is an assessment of the patient's ability to understand and cope with test results. Genetic testing has implications for entire families, and thus, individuals interested in pursuing genetic testing must consider how test results might impact their relationships with relatives, partners, spouses, and children. In families with a known genetic mutation, those who test positive must consider the impact of their carrier status on their present and future lifestyles; those who test negative may manifest survivor guilt. Parents who are found to have a disease-associated mutation often express considerable anxiety and despair as they address the issue

of risk to their children. In addition, some individuals consider options such as preimplantation genetic testing (PGT) in their reproductive decision-making.

When a condition does not manifest until adulthood, clinicians and parents are faced with the question of whether at-risk children should be offered genetic testing and, if so, at what age. Although the matter is debated, several professional organizations have cautioned that genetic testing for adult-onset disorders should not be offered to children. Many of these conditions have no known interventions in childhood to prevent disease; consequently, such information can pose significant psychosocial risk to the child. In addition, there is concern that testing during childhood violates a child's right to make an informed decision regarding testing upon reaching adulthood. On the other hand, testing should be offered in childhood for disorders that may manifest early in life, especially when management options are available. For example, children with multiple endocrine neoplasia 2 (MEN 2) may develop medullary thyroid cancer early in life and should be considered for prophylactic thyroidectomy **(Chap. 388)**. Similarly, children with familial adenomatous polyposis (FAP) due to a mutation in *APC* may develop polyps in their teens with progression to invasive cancer in the twenties, and therefore, colonoscopy screening is started between the ages of 10 and 15 years **(Chap. 81)**.

INFORMED CONSENT

Informed consent for genetic testing begins with education and counseling. The patient should understand the risks, benefits, and limitations of genetic testing, as well as the potential implications of test results. Informed consent should include a written document, drafted clearly and concisely in a language and format that is understandable to the patient. Because molecular genetic testing of an asymptomatic individual often allows prediction of future risk, the patient should understand all potential long-term medical, psychological, and social implications of testing. There have long been concerns about the potential for genetic discrimination. The Genetic Information Nondiscrimination Act (GINA) was passed in 2008 and provides some protections related to job and health insurance discrimination. It is important to explore with patients the potential impact of genetic test results on future health as well as disability and life insurance coverage. Patients should understand that alternatives remain available if they decide not to pursue genetic testing, including the option of delaying testing to a later date. The option of DNA banking should be presented so that samples are readily available for future use by family members, if needed.

FOLLOW-UP CARE AFTER TESTING

Depending on the nature of the genetic disorder, posttest interventions may include (1) cautious surveillance and awareness; (2) specific medical interventions such as enhanced screening, chemoprevention, or risk-reducing surgery; (3) risk avoidance; and (4) referral to support services. For example, patients with known deleterious mutations in *BRCA1* or *BRCA2* are strongly encouraged to undergo risk-reducing salpingo-oophorectomy at an appropriate age and are offered intensive breast cancer screening as well as the option of risk-reducing mastectomy. In addition, such women may wish to take chemoprevention with tamoxifen, raloxifene, or exemestane. Those with more limited medical management and prevention options, such as patients with Huntington's disease, should be offered continued follow-up and supportive services, including physical and occupational therapy and social services or support groups as indicated. Specific interventions will change as research continues to enhance our understanding of the medical management of these genetic conditions and more is learned about the functions of the gene products involved.

Individuals who test negative for a mutation in a disease-associated gene identified in an affected family member must be reminded that they may still be at risk for the disease. This is of particular importance for common diseases such as diabetes mellitus, cancer, and coronary artery disease. For example, a woman who finds that she does not carry the disease-associated mutation in *BRCA1* previously discovered in the family should be reminded that she still requires the same breast cancer screening recommended for the general population.

GENETIC COUNSELING AND EDUCATION

Genetic counseling is the process of helping people understand and adapt to the medical, psychological, and familial implications of genetic contributions to disease. This process integrates the following: interpretation of family and medical histories to assess the chance of disease occurrence or recurrence; education about the natural history of the condition, inheritance pattern, testing, management, prevention, support resources, and research; and counseling to promote informed choices in view of risk assessment, family goals, and ethical and religious values. Genetic counseling should be distinguished from genetic testing and risk-based medical screening and care, though genetic counselors are involved in these later issues.

Genetic risk assessment is complex and often involves elements of uncertainty. Genetic counseling can be useful in a wide range of situations **(Table 467-2)**. The roles of the genetic counselor include the following:

1. Gather and document a detailed family history.
2. Educate patients about general genetic principles related to disease risk, both for themselves and for others in the family.
3. Assess and enhance the patient's ability to cope with the genetic information offered.
4. Discuss how nongenetic factors may relate to the ultimate expression of disease.
5. Address medical management issues.
6. Assist in determining the role of genetic testing for the individual and the family.
7. Ensure the patient is aware of the indications, process, risks, benefits, and limitations of the various genetic testing options.
8. Assist the patient, family, and referring physician in the interpretation of the test results.
9. Ensure that the patient has the resources necessary to alert relatives to their risk, particularly in the face of a positive genetic test result.
10. Address the reproductive implications of a positive genetic test result, including the risk for a recessive disorder as well as discussion of reproductive options, including gamete donation or preimplantation genetic testing (PGT).
11. Refer the patient and other at-risk family members for additional medical and support services, if necessary.

The principles of voluntary and informed decision-making and protection of the individual's privacy and confidentiality are core principles in the practice of genetic counseling. Genetic counseling is generally offered in a *nondirective, noncoercive* manner, wherein patients learn to understand how their values factor into a particular medical decision. Nondirective counseling is particularly appropriate when there are no data demonstrating a clear benefit associated with a particular intervention or when an intervention is considered experimental. For example, nondirective genetic counseling is used when a person is deciding whether to undergo genetic testing for Huntington's disease. At this time, there is no clear benefit (in terms of medical outcome) to an at-risk individual undergoing genetic testing for this disease because its course cannot be altered by therapeutic interventions. However, testing can have an important impact on the individual's perception of advanced care planning and his or her interpersonal relationships and plans for childbearing. Therefore, the decision to pursue testing rests on the individual's belief system and values. On the other hand, a more

directive approach is appropriate when a condition can be treated. In a family with FAP, colon cancer screening and prophylactic colectomy should be recommended for known *APC* mutation carriers. The counselor and clinician following this family must ensure that the at-risk family members have access to the resources necessary to adhere to these recommendations.

Genetic education is central to an individual's ability to make an informed decision regarding testing options and treatment. An adequate knowledge of patterns of inheritance will allow patients to understand the probability of disease risk for themselves and other family members. It is also important to impart the concepts of disease penetrance and expression. For most complex adult-onset genetic disorders, asymptomatic patients should be advised that a positive test result does not always translate into future disease development. In addition, the role of nongenetic factors, such as environmental exposures and lifestyle, must be discussed in the context of multifactorial disease risk and disease prevention. Finally, patients should understand the natural history of the disease as well as the potential options for intervention, including screening, prevention, and in certain circumstances, pharmacologic treatment or prophylactic surgery.

THERAPEUTIC INTERVENTIONS BASED ON GENETIC RISK FOR DISEASE

Specific treatments are available for a number of genetic disorders. Strategies for the development of therapeutic interventions have a long history in childhood metabolic diseases; however, these principles have been applied in the diagnosis and management of adult-onset diseases as well (Table 467-3). Hereditary hemochromatosis is usually caused

TABLE 467-3 Examples of Genetic Testing and Possible Interventions

GENETIC DISORDER	INHERITANCE	GENES	INTERVENTIONS
Oncologic			
Lynch syndrome (HNPCC)	AD	*MLH1, MSH2, MSH6, PMS2*	Early endoscopic screening; risk-reducing surgery
Familial adenomatous polyposis	AD	*APC*	Early and frequent endoscopy; prophylactic colectomy; chemoprevention
Hereditary breast and ovarian cancer	AD	*BRCA1, BRCA2*	Risk-reducing salpingo-oophorectomy; intensified breast surveillance including breast MRI; risk-reducing mastectomy
Hereditary diffuse gastric cancer	AD	*CDH1*	Prophylactic gastrectomy; enhanced breast cancer surveillance
Hematologic			
Factor V Leiden	AD	*F5*	Avoidance of thrombogenic risk factors
Hemophilia A	XL	*F8*	Factor VIII replacement
Hemophilia B	XL	*F9*	Factor IX replacement
Glucose-6-phosphate dehydrogenase deficiency	XL	*G6PD*	Avoidance of oxidant drugs and certain foods
Cardiovascular			
Hypertrophic cardiomyopathy	AD	>10 genes including *MYBPC3, MYH7, TNNT2, TPM1*	Echocardiographic screening; pharmacologic intervention; myomectomy
Long QT syndrome	AD, AR	>10 genes including *KCNQ1, SCN5A, KCNE1, KCNE2*	Electrocardiographic screening; pharmacologic intervention; implantable cardiac defibrillator devices
Marfan's syndrome	AD	*FBN1*	Echocardiographic screening; prophylactic beta blockers; aortic valve replacement as indicated
Gastrointestinal			
Familial Mediterranean fever	AR	*MEFV*	Colchicine
Hemochromatosis	AR	*HFE*	Phlebotomy
Pulmonary			
α_1 Antitrypsin deficiency	AR	*SERPINA1*	Avoidance of smoking and occupational and environmental toxins
Cystic fibrosis	AR	*CFTR*	Chest physiotherapy; agents to promote airway secretion clearance; *CFTR* modulators; lung transplantation
Endocrine			
Neurohypophyseal diabetes insipidus	AD	*AVP*	Replace vasopressin
Familial hypocalciuric hypercalcemia	AD	*CASR*	Avoidance of parathyroidectomy; calcimimetics
Multiple endocrine neoplasia type 2	AD	*RET*	Prophylactic thyroidectomy; screening for pheochromocytoma and hyperparathyroidism
Renal			
Polycystic kidney disease	AD, AR	*PKD1, PKD2, PKHD1*	Prevention of hypertension; prevention of urinary tract infections; kidney transplantation
Nephrogenic diabetes insipidus	XL, AR	*AVPR2, AQP2*	Fluid replacement; thiazides with or without amiloride
Neurologic			
Malignant hyperthermia	AD	*RYR1, CACNA1S*	Avoidance of precipitating anesthetics
Hyperkalemic periodic paralysis	AD	*SCN4A*	Diet rich in calcium and low in potassium; thiazides or acetazolamide
Duchenne's and Becker's muscular dystrophy	XL	*DMD*	Corticosteroids; physical therapy
Wilson's disease	AR	*ATP7B*	Zinc, trientine

Abbreviations: AD, autosomal dominant; AR, autosomal recessive; HNPCC, hereditary nonpolyposis colorectal cancer; MRI, magnetic resonance imaging; XL, X-linked.

by mutations in *HFE* (although other genes have been less commonly associated) and manifests as a syndrome of iron overload, which can lead to liver disease, skin pigmentation, diabetes mellitus, arthropathy, impotence in males, and cardiac issues **(Chap. 414)**. When identified early, the disorder can be managed effectively with therapeutic phlebotomy. Therefore, when the diagnosis of hemochromatosis has been made in a proband, it is important to counsel other family members in order to minimize the impact of the disorder.

Preventative measures and therapeutic interventions are not restricted to metabolic disorders. Identification of familial forms of long QT syndrome, associated with ventricular arrhythmias, allows early electrocardiographic testing and the use of prophylactic antiarrhythmic therapy, overdrive pacemakers, or defibrillators. Individuals with familial hypertrophic cardiomyopathy can be screened by ultrasound, treated with beta blockers or other drugs, and counseled about the importance of avoiding strenuous exercise and dehydration. Those with Marfan's syndrome can be treated with beta blockers or angiotensin II receptor blockers and monitored for the development of aortic aneurysms.

The field of pharmacogenetics identifies genes that alter drug metabolism or confer susceptibility to toxic drug reactions. Pharmacogenetics seeks to individualize drug therapy in an attempt to improve treatment outcomes and reduce toxicity. Examples include thiopurine methyltransferase (TPMT) deficiency, dihydropyrimidine dehydrogenase deficiency, malignant hyperthermia, and glucose-6-phosphate deficiency. Despite successes in this area, it is not always clear how to incorporate pharmacogenetics into clinical care. For example, although there is an association with *CYP2C6* and *VKORC1* genotypes and warfarin dosing, there is no evidence that incorporating genotyping into clinical practice improves patient outcomes compared with clinical algorithms.

The identification of germline abnormalities that increase the risk of specific types of cancer is rapidly changing clinical management. Identifying family members with mutations that predispose to FAP or Lynch syndrome leads to recommendations of early cancer screening and prophylactic surgery, as well as consideration of chemoprevention and attention to healthy lifestyle habits. Similar principles apply to familial forms of melanoma as well as cancers of the breast, ovary, and thyroid. In addition to increased screening and prophylactic surgery, the identification of germline mutations associated with cancer may also lead to the development of targeted therapeutics, for example, the FDA has approved multiple poly-ADP ribose polymerase (PARP) inhibitors for *BRCA1/2*-associated breast, ovarian, pancreatic, and prostate cancers.

Although the role of genetic testing in the clinical setting continues to evolve, such testing holds the promise of allowing early and more targeted interventions that can reduce morbidity and mortality. Rapid technologic advances are changing the ways in which genetic testing is performed. As genetic testing becomes less expensive and technically easier to perform, it is anticipated that there will be an expansion of its use. This will present challenges but also opportunities. It is critical that physicians and other health care professionals keep current with advances in genetic medicine in order to facilitate appropriate referral for genetic counseling and judicious use of genetic testing, as well as to provide state-of-the-art, evidence-based care for affected or at-risk patients and their relatives.

468 Mitochondrial DNA and Heritable Traits and Diseases

Karl L. Skorecki, Bruce H. Cohen

Mitochondria are cytoplasmic organelles whose major function is to generate ATP by the process of oxidative phosphorylation under aerobic conditions. This process is mediated by the respiratory electron transport chain (ETC) multiprotein enzyme complexes I–V and the two electron carriers, coenzyme Q_{10} (CoQ_{10}) and cytochrome c, located in the inner mitochondrial membrane. Other cellular processes to which mitochondria make a major contribution include apoptosis (programmed cell death) and additional cell type–specific functions **(Table 468-1)**. The efficiency of the mitochondrial ETC in ATP production is the major determinant of overall body energy balance and thermogenesis. In addition, mitochondria are the predominant source of reactive oxygen species (ROS), whose rate of production is a delicate balance between health and disease and relates to the coupling of ATP production to oxygen consumption. Given the centrality of oxidative phosphorylation to the normal activities of almost all cells, it is not surprising that mitochondrial dysfunction can affect almost any organ system **(Fig. 468-1)**. Until recently, it was thought that disruption of energy production was the source of the pathophysiology in those with mitochondrial dysfunction, but recent evidence suggests that free radical production and the redox state of the mitochondria may play a role

as well. Thus, physicians in many disciplines might encounter patients with mitochondrial diseases and should be aware of their existence and characteristics.

The integrated activity of an estimated 1500 gene products is required for normal mitochondrial biogenesis, function, maintenance, and integrity. Aside from the 37 genes that comprise the mitochondrial DNA (mtDNA) molecule, the remaining 1400+ gene products are encoded by nuclear genes (referred to as nDNA) and thus follow the rules and patterns of nuclear genomic inheritance **(Chap. 466)**. These nuclear-encoded proteins are synthesized in the cell cytoplasm and imported to their location of activity within the mitochondria through a complex biochemical process. This process includes unfolding of the nuclear-encoded protein, attachment to a chaperone protein that shuttles it through a specific channel to a specific mitochondrial location, and detachment from the chaperone followed by assembly with other mtDNA- and nDNA-encoded proteins. In addition, the mitochondria contain their own small genome consisting of numerous copies (polyploidy) per mitochondrion of a circular, double-strand mtDNA molecule comprising 16,569 nucleotides. This mtDNA sequence (also known as the "mitogenome") might represent the remnants of endosymbiotic prokaryotes from which mitochondria are thought to have originated. The mtDNA sequence contains a total of 37 genes, of which 13 encode mitochondrial protein components of the ETC **(Fig. 468-2)**. The remaining 22 tRNA- and 2 rRNA-encoding genes are mitochondria-specific and dedicated to the process of translating the 13 mtDNA-encoded proteins. The mtDNA itself replicates constantly, independent of cell division, and requires its own unique polymerase, referred to as polymerase gamma (polγ), which is encoded by the nuclear gene *POLG*, disorders of which are discussed in **Chaps. 449 and 467**. However, mutations in *POLG* can disrupt the endonuclease function of polγ, resulting in somatic mutations in the mtDNA that endure with future replication. Unless this mutation occurs and repopulates in an oocyte, it is not heritable. This dual nuclear and mitochondrial genetic control of mitochondrial function results in unique and diagnostically challenging patterns of inheritance. The current chapter focuses on heritable traits and diseases related to the mtDNA component of the dual genetic control of mitochondrial function. The reader is referred to **Chaps. 449 and 466** for consideration of mitochondrial disease originating from mutations in the nuclear genome. The former include (1) disorders due to mutations in nuclear genes directly encoding structural components or assembly factors of the oxidative phosphorylation complexes, (2) disorders due to mutations in nuclear genes encoding proteins indirectly related to oxidative phosphorylation, (3) mtDNA depletion syndromes (MDSs) characterized by a reduction of mtDNA copy number in affected tissues without mutations or rearrangements in the mtDNA, and (4) disorders due to mutations in nuclear genes that disrupt normal mitochondrial dynamics (biosynthesis, mitophagy, fission, and fusion).

The classic physical structure of the mitochondria is that of a thread-like organelle, which under fixed conditions, such as observed with immunohistochemical stains or electron microscopy, has a submarine shape and measures about 1 μm in length. However, in the living state, mitochondrial shape is highly variable based on the cell type and manifests a complex and ever-changing syncytial form, with continuous appearance and disappearance of budding structures (representing mitochondrial fission) and reorganization of separate mitochondria (representing mitochondrial fusion). Although we often think of the *mitochondrial number* in an individual cell, in fact, the more accurate concept in a living cell is probably mitochondrial volume.

Although the presence of mitochondria has been known for >150 years, the first knowledge of their respiratory function was proposed ~100 years ago, and the initial description of an illness linked to mitochondrial dysfunction was only made in 1962. The presence of mtDNA was noted in the 1960s, and it was not until 1988 when the first mutations in the mtDNA causing human illness were described. These included the demonstration of a large-scale mtDNA deletion

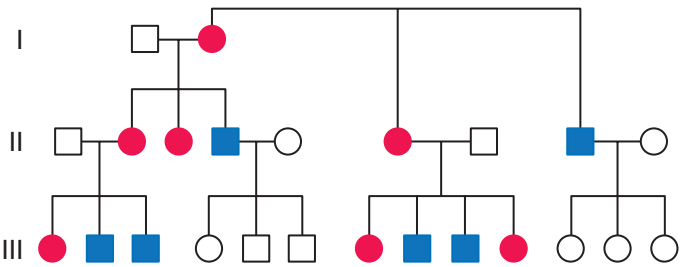

FIGURE 468-2 Maternal inheritance of mitochondrial DNA (mtDNA) disorders and heritable traits. Affected women (*filled circles*) transmit the trait to their children. Affected men (*filled squares*) do not transmit the trait to any of their offspring.

causing Kearns-Sayre syndrome (KSS) and the discovery of a point mutation in *ND4*, an mtDNA-encoded complex I gene, causing Leber's hereditary optic neuropathy (LHON). Following these two discoveries, >400 pathogenic mtDNA mutations or deletions have been reported to cause human disease.

MITOCHONDRIAL DNA STRUCTURE AND FUNCTION

As a result of its circular structure and extranuclear location, the replication and transcription mechanisms of mtDNA differ from the corresponding mechanisms in the nuclear genome, whose nucleosomal packaging and structure are more complex. Specifically, mitochondria have their own transcription system, and the mtDNA itself replicates independently of cellular replication. Because each cell contains many copies of mtDNA and because the number of mitochondria can vary during the lifetime of each cell, mtDNA copy number is not directly coordinated with the cell cycle. Thus, vast differences in mtDNA copy number are observed between different cell types and tissues and during the lifetime of a cell. Another important feature of the mtDNA replication process is a reduced stringency of proofreading and replication error correction, leading to a greater degree of sequence variation compared to the nuclear genome. Some of these sequence variants are silent polymorphisms that do not have the potential for a phenotypic or pathogenic effect, whereas others may be considered pathogenic mutations. There are some mutations that may be considered ecogenetic, as they typically remain silent, meaning they do not cause disease, unless an external event occurs. One classic example is seen in a common (1:800) mutation in the mitochondrial 12S rRNA gene, m.A1555G, which is associated with hearing loss but is rapidly exacerbated by exposure to normal dosages of an aminoglycoside. Because mtDNA replication is independent of cellular replication, the percentage of mutant mtDNA copies tend to increase with age in cells that are terminally differentiated (nonreplicative) at birth such as neurons and myocytes, which may explain some features of mitochondrial dysfunction with aging.

With respect to transcription, initiation can occur on both strands and proceeds through the production of an intronless polycistronic precursor RNA, which is then processed to produce the 13 individual mRNA and 24 individual tRNA and rRNA products. The 37 mtDNA genes comprise fully 93% of the 16,569 nucleotides of the mtDNA in what is known as the *coding region*. The *control region*, which is contained in the D-loop, consists of ~1.1 kilobases (kb) of noncoding DNA and is thought to have an important role in replication and transcription initiation.

MATERNAL INHERITANCE AND LACK OF RECOMBINATION

In contrast to homologous pair recombination that takes place in the nucleus, mtDNA molecules do not undergo recombination, such that mutational events represent the only source of mtDNA genetic diversification. Moreover, it is only the maternal DNA that is transmitted to the offspring. The fertilized oocyte degrades mtDNA carried from the sperm in a complex process involving the ubiquitin proteasome system and autophagy that takes place on the inner membrane of the oocyte. Thus, although mothers transmit their mtDNA to both their sons and daughters, only the daughters can transmit the inherited mtDNA to future generations. Accordingly, mtDNA sequence variation and associated phenotypic traits and diseases are inherited exclusively along maternal lines, meaning both sons and daughters have equal chances of having symptomatic disease, with the only significant exception being LHON, as described below.

The phenotypic expression, including age of onset and the exact pattern of organ dysfunction, of a pathogenic mtDNA mutation may vary greatly, even within families. Because of this complex relationship between mtDNA mutations and disease expression, sometimes it is difficult to recognize the maternal pattern of inheritance at the clinical or pedigree level. However, evidence of paternal transmission can almost certainly exclude an mtDNA genetic origin of phenotypic variation or disease; conversely, a disease affecting both sexes without evidence of paternal transmission strongly suggests a heritable mtDNA disorder (Fig. 468-2).

MULTIPLE COPY NUMBER (POLYPLOIDY), HIGH MUTATION RATE, HETEROPLASMY, AND MITOTIC SEGREGATION

Each aerobic cell in the body has multiple mitochondria, often numbering many hundreds or more in cells with extensive energy production requirements. Furthermore, the number of copies of mtDNA within each mitochondrion varies from several to hundreds; this is true of both somatic as well as germ cells, including oocytes in females. In the case of somatic cells, this means that the impact of most newly acquired somatic mtDNA mutations is likely to be very small in terms of total cellular or organ system function; however, because of the manyfold higher mutation rate during mtDNA replication, numerous different mutations may accumulate with aging of the organism. It has been proposed that the total cumulative burden of acquired somatic mtDNA mutations with age may result in an overall perturbation of mitochondrial function, contributing to age-related reduction in the efficiency of oxidative phosphorylation and increased production of damaging ROS. Because mtDNA (and nDNA) mutations may result in electron leak within the ETC, the ROS damage may rise above the normal baseline in some with specific mutations, resulting in increased susceptibility to somatic mtDNA damage and disease expression. The accumulation of such acquired somatic mtDNA mutations with aging may contribute to age-related diseases, such as metabolic syndrome and diabetes, cancer, and neurodegenerative and cardiovascular disease in any given individual. However, somatic mutations are not carried forward to the next generation, and the hereditary impact of mtDNA mutagenesis requires separate consideration of events in the female germline.

The multiple mtDNA copy number within each cell, including the maternal germ cells, results in the phenomenon of heteroplasmy, in contrast to much greater uniformity (homoplasy) of somatic nuclear DNA sequence. Heteroplasmy for a given mtDNA sequence variant or mutation arises as a result of the coexistence within a cell, tissue, or individual of mtDNA molecules bearing more than one version of the sequence variant **(Fig. 468-3)**. The importance of the heteroplasmy phenomena to the understanding of mtDNA-related mitochondrial diseases is critical. The coexistence of mutant and nonmutant (wild-type) mtDNA and the variation of the mutant load, which can be thought of as the percentage of mutant mtDNA molecules within a specific cell, tissue, organ, or organism, contribute to the expression of a phenotype among individuals from the same maternal sibship. At the level of the oocyte, the percentage of mtDNA molecules bearing each version of the polymorphic sequence variant or mutation depends on stochastic events related to partitioning of mtDNA molecules during the process of oogenesis itself. Thus, oocytes differ from each other in the degree of heteroplasmy for that sequence variant or mutation. In turn, the heteroplasmic state is carried forward to the zygote and to the organism as a whole, to varying degrees, depending on mitotic segregation of mtDNA molecules during organ system development and maintenance. For this reason, in vitro fertilization, followed by preimplantation genetic diagnosis (PGD), is not as predictive of the genetic health of the offspring in the case of mtDNA mutations as in the case of mutations and subsequent diseases occurring in the nuclear genome. Similarly, the impact of somatic mtDNA mutations acquired during development and subsequently also shows an enormous spectrum of variability. In general, a higher mutant load will result in a more severe and earlier phenotypic presentation. However, measuring heteroplasmy in one tissue (lymphocytes from blood or urine sediment containing kidney and bladder epithelial cells, for example) may not represent the percentage of mutant heteroplasmy in the tissue or organs most affected, such as the cardiac atrioventricular node or brain. Furthermore, the threshold of mutant heteroplasmy that results in clinical illness may vary depending on the specific mutation.

Mitotic segregation refers to the unequal distribution of wild-type and mutant versions of mtDNA molecules during all cell divisions that occur during prenatal development and subsequently throughout

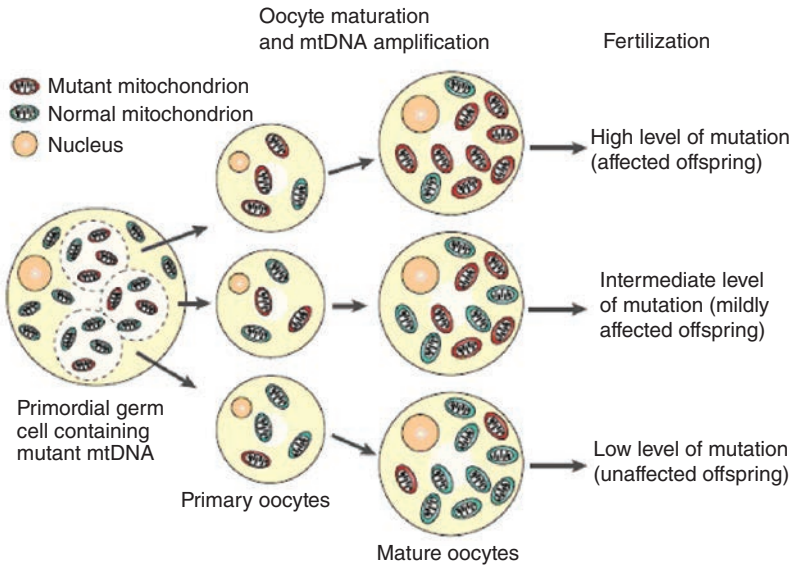

FIGURE 468-3 Heteroplasmy and the mitochondrial genetic bottleneck. During the production of primary oocytes, a selected number of mitochondrial DNA (mtDNA) molecules are transferred into each oocyte. Oocyte maturation is associated with the rapid replication of this mtDNA population. This restriction-amplification event can lead to a random shift of mtDNA mutational load between generations and is responsible for the variable levels of mutated mtDNA observed in affected offspring from mothers with pathogenic mtDNA mutations. Mitochondria that contain mutated mtDNA are shown in *red,* and those with normal mtDNA are shown in *green. (Reproduced with permission from R Taylor, D Turnbull: Mitochondrial DNA mutations in human disease. Nat Rev Genetics 6:389, 2005.)*

the lifetime of an individual. The phenotypic effect or disease impact will be a function not only of the inherent disruptive effect (pathogenicity) on the mtDNA-encoded gene (coding region mutations) or integrity of the mtDNA molecule (control region mutations) but also of its distribution among the multiple copies of mtDNA in the various mitochondria, cells, and tissues of the affected individual. Thus, one consequence can be the generation of a bottleneck due to the marked decline in given sets of mtDNA variants, pathogenic and nonpathogenic, consequent to such mitotic segregation. It is postulated that the main effects of this bottleneck occur between the primordial germ cell state and the primary oocyte stage of development. Heterogeneity arises from differences in the degree of heteroplasmy among oocytes of the transmitting female, together with subsequent, probably random, mitotic segregation of the pathogenic mutation during tissue and organ development and throughout the lifetime of the individual offspring. The actual expression of disease might then depend on a threshold percentage of mitochondria whose function is disrupted by mtDNA mutations. This in turn confounds hereditary transmission patterns and hence genetic diagnosis of pathogenic heteroplasmic mutations. Generally, if the proportion of mutant mtDNA is <60%, the individual is unlikely to be affected, whereas proportions exceeding 90% cause clinical disease. One notable exception is LHON, in which these mutations are present either in 100% mutant homoplasmy, which causes the disease expression, or 100% wild-type homoplasmy. It is not understood why this specific phenotype and the several known mtDNA alleles that result in LHON behave in this manner.

HOMOPLASMIC VARIANTS AND HUMAN mtDNA PHYLOGENY

In contrast to classic mtDNA diseases, most of which begin in childhood and are the result of heteroplasmic mutations as noted above, during the course of human evolution, certain mtDNA sequence variants have drifted to a state of homoplasmy, wherein all of the mtDNA molecules in the organism contain the new sequence variant. This arises due to a "bottleneck" effect followed by genetic drift during the very process of oogenesis itself (Fig. 468-3). In other words, during certain stages of oogenesis, the mtDNA copy number becomes so substantially reduced that the particular mtDNA species bearing the novel or derived sequence variant may become the increasingly predominant, and eventually exclusive, version of the mtDNA for that particular nucleotide site. All of the offspring of a woman bearing an mtDNA sequence variant or mutation that has become homoplasmic will also be homoplasmic for that variant and will transmit the sequence variant forward in subsequent generations.

Considerations of reproductive fitness limit the evolutionary or population emergence of pathogenic homoplasmic mutations that are lethal or cause severe disease in infancy or childhood. Thus, with a number of notable exceptions (e.g., mtDNA mutations causing LHON; see below), most homoplasmic mutations are considered to be neutral markers of human evolution, which are useful and interesting in the population genetics analysis of shared maternal ancestry but have little significance in human phenotypic variation or disease predisposition.

More important is the understanding that this accumulation of homoplasmic mutations occurs at a genetic locus that is transmitted only through the female germline and that lacks recombination. In turn, this enables reconstruction of the sequential topology and radiating phylogeny of mutations accumulated through the course of human evolution since the time of the most recent common mtDNA ancestor of all contemporary mtDNA sequences, some 200,000 years ago. The term *haplogroup* is usually used to define major branching points in the human mtDNA phylogeny, nested one within the other, which often demonstrate striking continental geographic ancestral partitioning. At the level of the complete mtDNA sequence, the term *haplotype* is usually used to describe the sum of mutations observed for a given mtDNA sequence and as compared to a reference sequence, such that all haplotypes falling within a given haplogroup share the total sum of mutations that have accumulated since the most recent common ancestor and the bifurcation point they mark. The remaining observed variants are private to each haplotype. Consequentially, the human mtDNA sequence is an almost perfect molecular prototype for a nonrecombining locus, and its variation has been extensively used in phylogenetic studies. Moreover, the mtDNA mutation rate is considerably higher than the rate observed for the nuclear genome, especially in the control region, which contains the displacement loop, or D-loop, in turn comprising two adjacent hypervariable regions (HVR-I and HVR-II). Together with the absence of recombination, this amplifies drift to high frequencies of novel haplotypes. As a result, mtDNA haplotypes are more highly partitioned across geographically defined populations than sequence variants in other parts of the genome. Despite extensive research, it has not been well established that such haplotype-based partitioning has a significant influence on human health conditions. However, mtDNA-based phylogenetic analysis can be used both as a quality assurance tool and as a filter in distinguishing neutral mtDNA variants comprising human mtDNA phylogeny from potentially deleterious mutations.

MITOCHONDRIAL DNA DISEASE

The true prevalence of mtDNA disease is difficult to estimate because of the phenotypic heterogeneity that occurs as a function of heteroplasmy, the challenge of detecting and assessing heteroplasmy in different affected tissues, and the other unique features of mtDNA function and inheritance described above. It is estimated that at least 1 in 200 healthy humans harbors a pathogenic mtDNA mutation with the potential to causes disease but that heteroplasmic germline pathogenic mtDNA mutations actually result in clinical disease in ~1 in 5000 individuals.

The true disease burden relating to mtDNA sequence variation will only be known when the following capabilities become available: (1) ability to distinguish a completely neutral sequence variant from a true phenotype-modifying or pathogenic mutation, (2) accurate assessment of heteroplasmy that can be determined with fidelity, and (3) a

systems biology approach (Chap. 486) to determine the network of epistatic interactions of mtDNA sequence variations with mutations in the nuclear genome.

OVERVIEW OF CLINICAL AND PATHOLOGIC FEATURES OF HUMAN mtDNA DISEASE

Given the vital roles of mitochondria in all nucleated cells, it is not surprising that mtDNA mutations can affect numerous tissues with pleiotropic effects. More than 200 different disease-causing, mostly heteroplasmic mtDNA mutations have been described affecting ETC function. Figure 468-4 provides a partial mtDNA map of some of the better characterized of these disorders. A number of clinical clues can increase the index of suspicion for a heteroplasmic mtDNA mutation as an etiology of a heritable trait or disease, including (1) familial clustering with absence of paternal transmission; (2) adherence to one of the classic syndromes (see below) or paradigmatic combinations of disease phenotypes involving several organ systems that normally do not fit together within a single nuclear genomic mutation category; (3) a complex of laboratory and pathologic abnormalities that reflect disruption in cellular energetics (e.g., lactic acidosis and neurodegenerative and myodegenerative symptoms with the finding of ragged red fibers, reflecting the accumulation of abnormal mitochondria under the muscle sarcolemmal membrane); or (4) a mosaic pattern reflecting a heteroplasmic state. There are no truly sensitive and specific biomarkers of disease, and the presence of a historically quintessential finding of ragged red fibers can be seen in numerous muscle disorders, so laboratory tests must always be interpreted in the context of their limitations and should not be used to define the disease.

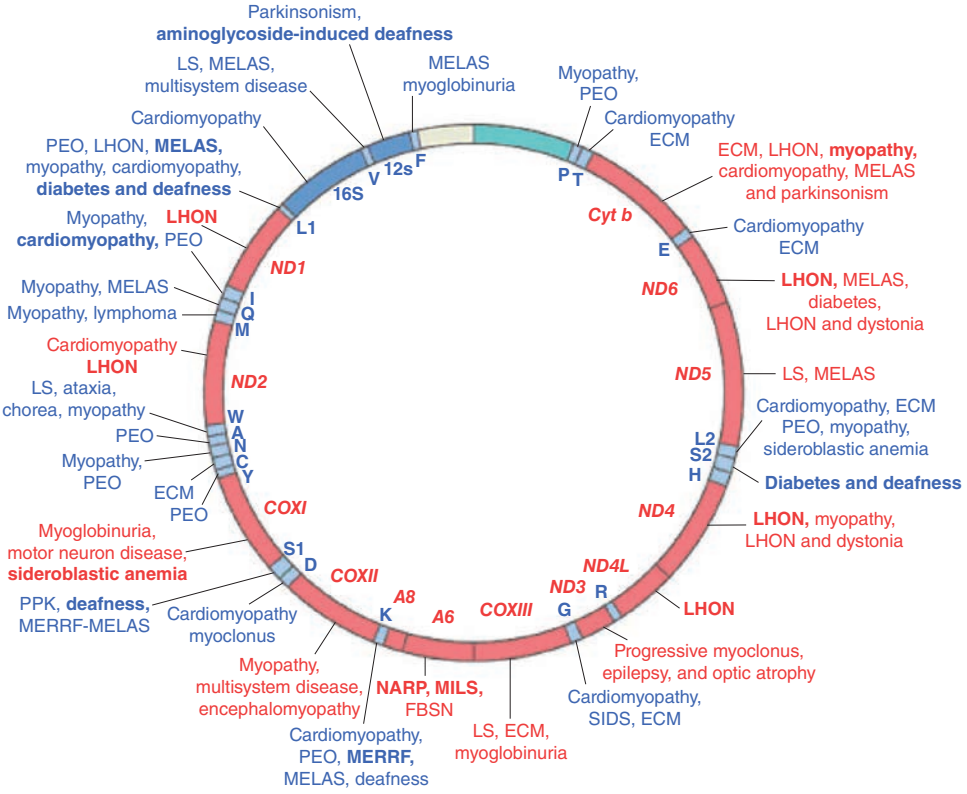

FIGURE 468-4 Mutations in the human mitochondrial genome known to cause disease. Disorders that are frequently or prominently associated with mutations in a particular gene are shown in *boldface*. Diseases due to mutations that impair mitochondrial protein synthesis are shown in *blue*. Diseases due to mutations in protein-coding genes are shown in *red*. ECM, encephalomyopathy; FBSN, familial bilateral striatal necrosis; LHON, Leber's hereditary optic neuropathy; LS, Leigh's syndrome; MELAS, mitochondrial encephalomyopathy, lactic acidosis, and stroke-like episodes; MERRF, myoclonic epilepsy with ragged red fibers; MILS, maternally inherited Leigh's syndrome; NARP, neuropathy, ataxia, and retinitis pigmentosa; PEO, progressive external ophthalmoplegia; PPK, palmoplantar keratoderma; SIDS, sudden infant death syndrome. *(From S DiMauro, E Schon: Mitochondrial respiratory-chain diseases. N Engl J Med 348:2656, 2003. Copyright © 2003, Massachusetts Medical Society. Reprinted with permission from Massachusetts Medical Society.)*

Heteroplasmy can sometimes be elegantly demonstrated at the tissue level using histochemical staining for enzymes in the oxidative phosphorylation pathway, with a mosaic pattern indicating heterogeneity of the genotype for the coding region for the mtDNA-encoded enzyme. Complex II, CoQ, and cytochrome c are exclusively encoded by nuclear DNA. In contrast, complexes I, III, IV, and V contain at least some subunits encoded by mtDNA. Just 3 of the 13 subunits of the ETC complex IV enzyme, cytochrome c oxidase (COX), are encoded by mtDNA, and therefore, this enzyme has the lowest threshold for dysfunction when a threshold level of mutated mtDNA is reached. Histochemical staining for COX activity in tissues of patients affected with heteroplasmic inherited mtDNA mutations (or with the somatic accumulation of mtDNA mutations, see below) can show a mosaic pattern of reduced histochemical staining in comparison with histochemical staining for the complex II enzyme succinate dehydrogenase (SDH) (Fig. 468-5). Heteroplasmy can also be detected at the genetic level through direct Sanger-type mtDNA genotyping under special conditions, although clinically significant low levels of heteroplasmy can escape detection in genomic samples extracted from whole blood using conventional genotyping and sequencing techniques. Next-generation sequencing (NGS) has largely overcome these limitations and enables reliable detection and quantitation of heteroplasmy.

NGS has dramatically improved the clinical genetic diagnostic evaluation of mitochondrial diseases at the level of both the nuclear genome and mtDNA. In the context of the larger nuclear genome, the ability of NGS techniques to dramatically increase the speed at which DNA can be sequenced at a fraction of the cost of conventional Sanger-type sequencing technology is particularly beneficial. Low sequencing costs and short turnaround time expedite "first-tier" screening of panels of hundreds of previously known or suspected mitochondrial disease genes or screening for the entire exome or genome in an attempt to identify novel genes and mutations affecting different patients or families. In the context of the mtDNA, NGS approaches now provide rapid and reliable detection of heteroplasmy in different affected tissues. Although Sanger sequencing allows for complete coverage of the mtDNA, it is limited by the lack of deep coverage and low sensitivity for heteroplasmy detection when levels are <50%. In contrast, NGS technology is an excellent tool for rapidly and accurately obtaining a patient's predominant mtDNA sequence as well as lower frequency heteroplasmic variants and can reliably detect mutant heteroplasmy <10%. Lower levels are often only clinically relevant if in the setting of a striking difference in heteroplasmy in different tissues. This capability to detect heteroplasmy at levels that assist in pointing to an mtDNA-based disease process emanates from deep coverage of the genome through multiple independent sequence reads. Accordingly, recent studies making use of NGS techniques have demonstrated sequence accuracy equivalent to Sanger-type sequencing but also have uncovered heretofore unappreciated heteroplasmy rates ranging between 10% and 50% and detection of single nucleotide heteroplasmy down to levels of <10%.

Clinically, the most striking overall characteristic of mitochondrial genetic disease is the phenotypic heterogeneity associated with mtDNA mutations. This extends to intrafamilial phenotypic heterogeneity for the same mtDNA pathogenic mutation and, conversely, to the overlap of phenotypic disease manifestations with distinct mutations. Thus, although fairly consistent and well-defined "classic" syndromes

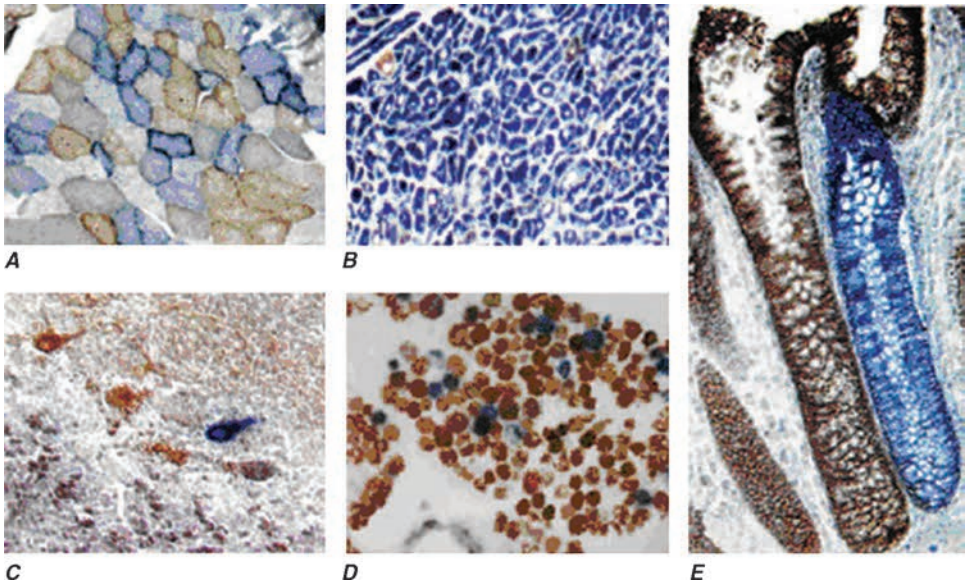

FIGURE 468-5 Cytochrome c oxidase (COX) deficiency in mitochondrial DNA (mtDNA)–associated disease. Transverse tissue sections that have been stained for COX and succinate dehydrogenase (SDH) activities sequentially, with COX-positive cells shown in *brown* and COX-deficient cells shown in *blue*. ***A.*** Skeletal muscle from a patient with a heteroplasmic mitochondrial tRNA point mutation. The section shows a typical "mosaic" pattern of COX activity, with many muscle fibers harboring levels of mutated mtDNA that are above the crucial threshold to produce a functional enzyme complex. ***B.*** Cardiac tissue (left ventricle) from a patient with a homoplasmic tRNA mutation that causes hypertrophic cardiomyopathy, which demonstrates an absence of COX in most cells. ***C.*** A section of cerebellum from a patient with mtDNA rearrangement that highlights the presence of COX-deficient neurons. ***D, E.*** Tissues that show COX deficiency due to clonal expansion of somatic mtDNA mutations within single cells—a phenomenon that is seen in both postmitotic cells (***D***; extraocular muscles) and rapidly dividing cells (***E***; colonic crypt) in aging humans. *(Reproduced with permission from R Taylor, D Turnbull: Mitochondrial DNA mutations in human disease. Nat Rev Genetics 6:389, 2005.)*

have been attributed to specific mutations, frequently "nonclassical" combinations of disease phenotypes ranging from isolated myopathy to extensive multisystem disease are often encountered, rendering genotype-phenotype correlation challenging. In both classical and nonclassical mtDNA disorders, there is often a clustering of some combination of abnormalities affecting the neurologic system (including optic nerve atrophy, pigment retinopathy, and sensorineural hearing loss), cardiac and skeletal muscle (including extraocular muscles), and endocrine and metabolic systems (including diabetes mellitus). Additional organ systems that may be affected include the hematopoietic, renal, hepatic, and gastrointestinal systems, although these are more frequently involved in infants and children. Disease-causing mtDNA coding region mutations can affect either one of the 13 protein-encoding genes or one of the 24 protein synthetic genes. Clinical manifestations do not readily distinguish these two categories, although lactic acidosis and specific muscle pathologic findings (e.g., ragged red and ragged blue fibers, described immunohistochemical staining, paracrystalline inclusions on ultrastructure) tend to be more prominent in the latter. In all cases, either defective ATP production due to disturbances in the ETC or enhanced generation of ROS has been invoked as the mediating biochemical mechanism between mtDNA mutation and disease manifestation.

mtDNA DISEASE PRESENTATIONS

The clinical presentation of adult patients with mtDNA disease can be divided into three categories: (1) clinical features suggestive of mitochondrial disease (Table 468-2) but not a well-defined classic syndrome; (2) classic mtDNA syndromes; and (3) clinical presentation confined to one organ system (e.g., isolated sensorineural deafness, cardiomyopathy, or diabetes mellitus).

Table 468-3 provides a summary of eight illustrative classic mtDNA syndromes or disorders that affect adult patients and highlights some of the most interesting features of mtDNA disease in terms of molecular pathogenesis, inheritance, and clinical presentation. The first five of these syndromes result from heritable point mutations in either protein-encoding or protein synthetic mtDNA genes; the other three result from rearrangements or deletions that usually do not involve the germline.

LHON is a common cause of maternally inherited visual failure. LHON typically presents during young adulthood with subacute painless loss of vision in one eye, with symptoms developing in the other eye 6–12 weeks later. In some instances, cerebellar ataxia, peripheral neuropathy, and cardiac conduction defects are observed. In >95% of cases, LHON is due to one of the three homoplasmic point mutations of mtDNA that affect genes encoding different subunits of complex I of the mitochondrial ETC; however, not all individuals who inherit a primary LHON mtDNA mutation develop optic neuropathy, and the male-to-female ratio is 8.2, indicating that additional environmental (e.g., tobacco exposure) or independent genetic factors are important in the etiology of the disorder. Both the nuclear and mitochondrial genomic backgrounds modify disease penetrance. Indeed, a region of the X chromosome containing a high-risk haplotype for LHON has been identified, supporting the formulation that nuclear genes act as modifiers and affording an explanation for the male prevalence of LHON. This haplotype can be used in predictive genomic testing and prenatal screening for this disease. In contrast to the other classic mtDNA disorders, it is of interest that patients with this syndrome are often homoplasmic for the disease-causing mutation. The somewhat later onset in young adulthood and modifying effect of protective background nuclear genomic haplotypes may have enabled homoplasmic pathogenic mutations to have escaped evolutionary censoring.

Mitochondrial encephalomyopathy, lactic acidosis, and stroke-like episodes (MELAS) is a multisystem disorder with a typical onset between 2 and 10 years of age. Following normal early psychomotor development, the most common initial symptoms are seizures, recurrent headaches, anorexia, and recurrent vomiting. Exercise intolerance or proximal limb weakness can be the initial manifestation, followed by generalized tonic-clonic seizures. Short stature is common. Seizures are often associated with stroke-like episodes of transient hemiparesis or cortical blindness that may produce recurrent encephalopathy with impaired consciousness. It is often not possible to determine if the encephalopathy is due to refractory clinical or subclinical seizures or should be attributed to an independent effect. The cumulative residual effects of the stroke-like episodes gradually impair motor abilities, vision, and cognition, often by adolescence or young adulthood. Sensorineural hearing loss adds to the progressive decline of these

TABLE 468-2 Common Features of Mitochondrial DNA–Associated Diseases in Adults

Neurologic: stroke, epilepsy, migraine headache, peripheral neuropathy, ataxia, dystonia, myoclonus, cranial neuropathy (optic atrophy, sensorineural deafness, dysphagia, dysphasia)
Skeletal myopathy: ophthalmoplegia, exercise intolerance, myalgia, weakness
Cardiac: conduction block, cardiomyopathy
Respiratory: hypoventilation, aspiration pneumonitis
Endocrine: diabetes mellitus, premature ovarian failure, hypothyroidism, hypoparathyroidism
Ophthalmologic: cataracts, pigment retinopathy, neurologic and myopathic (optic atrophy, ophthalmoplegia)

TABLE 468-3 Mitochondrial Diseases Due to Mitochondrial DNA (mtDNA) Point Mutations and Large-Scale Rearrangements

DISEASE	PHENOTYPE	MOST FREQUENT mtDNA MUTATIONS	HETEROPLASMIC/ HOMOPLASMIC	MATERNAL
NARP, Leigh's syndrome	Loss of central vision leading to blindness in young adult life	m.1778G>A, m.14484T>C, m.3460G>A	Heteroplasmic	Maternal
MELAS	*M*itochondrial *e*ncephalomyopathy, *l*actic *a*cidosis, and *s*troke-like episodes; may manifest only as diabetes mellitus	Point mutation in $tRNA^{leu}$	Heteroplasmic	Maternal
MERRF	*M*yoclonic *e*pilepsy, *r*agged *r*ed *f*ibers in muscle, ataxia, increased CSF protein, sensorineural deafness, dementia	Point mutation in $tRNA^{lys}$	Heteroplasmic	Maternal
Deafness	Progressive sensorineural deafness, often induced by aminoglycoside antibiotics	m.1555A>G mutation in 12S rRNA	Homoplasmic	Maternal
	Nonsyndromic sensorineural deafness	m.7445A>G mutation in 12S rRNA	Homoplasmic	Maternal
Chronic progressive external ophthalmoplegia (PEO)	Late-onset bilateral ptosis and ophthalmoplegia, proximal muscle weakness, and exercise intolerance	Single deletions or duplications	Heteroplasmic	Mostly sporadic, somatic mutations
Pearson's syndrome	Pancreatic insufficiency, pancytopenia, lactic acidosis	Large deletion	Heteroplasmic	Sporadic, somatic mutations
Kearns-Sayre syndrome (KSS)	External ophthalmoplegia, heart block, retinal pigmentation, ataxia	The 5-kb "common deletion"	Heteroplasmic	Sporadic, somatic mutations

Abbreviations: CSF, cerebrospinal fluid; NARP, neuropathy, ataxia, and retinitis pigmentosa.

individuals. A plethora of less common symptoms have been described including myoclonus, ataxia, episodic coma, optic atrophy, cardiomyopathy, pigmentary retinopathy, ophthalmoplegia, diabetes mellitus, hirsutism, gastrointestinal dysmotility, and nephropathy. The typical age of death ranges from 10 to 35 years, but some individuals live into their sixth decade. Intercurrent infections or intestinal obstructions are often the terminal events. It is not atypical for some family members to have much less severe or later onset illness, presumably because of a lessor mutation load, and "MELAS" is not used as a diagnosis for these restricted phenotypes. This creates somewhat of a disconnect between the genotype for MELAS (most commonly the m.3243A>G mutation) and a diverse phenotype, which includes the syndrome MELAS, a syndrome of high-frequency hearing loss and diabetes with onset later in life, as well as many other phenotypes between these two extreme syndromes. Certain other mtDNA mutations can also cause such patterns of diverse phenotypic expression. Laboratory investigation commonly demonstrates elevated lactate concentrations at rest with excessive increase after moderate exercise. Brain imaging during stroke-like episodes shows areas of involvement on T2- or fluid-attenuated inversion recovery (FLAIR) sequences, with decreased signal on perfusion-weighted sequences, which typically involve the posterior cerebrum and do not conform to the distribution of major arteries. These magnetic resonance imaging (MRI) abnormalities may be temporary or evolve to subsequent atrophy **(Fig. 468-6)**. Electrocardiography (ECG) may show evidence of cardiomyopathy, preexcitation, or incomplete heart block. Electromyography and nerve conduction studies are consistent with a myopathic process, without or with coexisting axonal and sensory neuropathic findings. Muscle biopsy typically shows ragged red fibers with the modified Gomori trichrome stain or "ragged blue fibers" with the SDH histochemical stain, resulting from the hyperintense reaction. The diagnosis of MELAS is based on a combination of clinical findings and molecular genetic testing. Mutations in the mtDNA gene *MT-TL1* encoding $tRNA^{leu}$ are causative. The most common mutation, present in ~80% of individuals with typical clinical findings, is an A-to-G transition at nucleotide 3243 (m.3243A>G). Mutations can usually be detected in mtDNA from leukocytes in individuals with typical MELAS; however, the occurrence of heteroplasmy can result in varying tissue distribution of mutated mtDNA. In the absence of specific treatment, various manifestations of MELAS are treated according to standard modalities for prevention, surveillance, and treatment. Recent developments in therapy are described below.

Myoclonus epilepsy with ragged red fiber (MERRF) is a multisystem disorder characterized by myoclonus, seizures, ataxia, and myopathy with ragged red fibers. Hearing loss, exercise intolerance, neuropathy, ataxia, cervical lipomas, and short stature are often present. Ataxia and lipomas can be a feature in adults or adult-onset MERRF. Cerebrospinal fluid (CSF) analysis reveals an elevated protein content. Almost all MERRF patients have a mutation in the mtDNA $tRNA^{lys}$ gene, and the m.8344A>G mutation in the mtDNA gene encoding the lysine amino acid tRNA is responsible for 80–90% of MERRF cases.

Neuropathy, ataxia, and retinitis pigmentosa (NARP) is characterized by moderate diffuse cerebral and cerebellar atrophy and symmetric lesions of the basal ganglia on MRI **(Figs. 468-7 and 468-8)**. A heteroplasmic m.8993T>G mutation in the ATPase 6 subunit gene has been identified as causative, which underscores the lack of definitive genotype-phenotype correlation in mitochondrial diseases. Ragged red fibers are not observed in muscle biopsy. When >95% of mtDNA

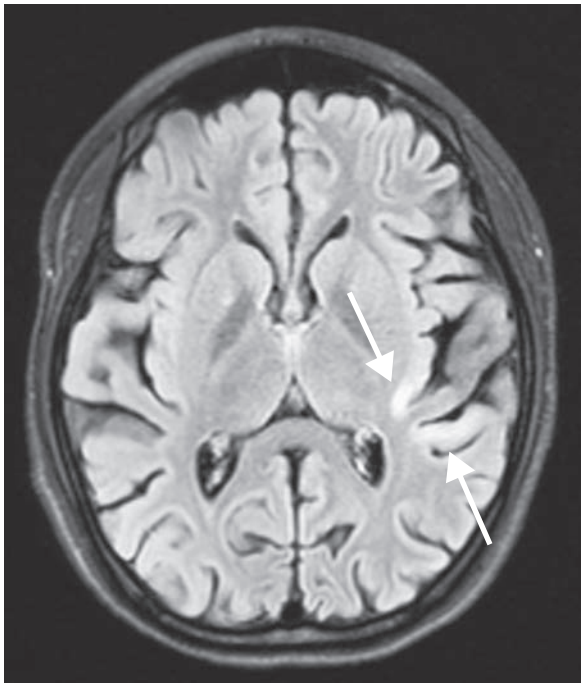

FIGURE 468-6 A 15-year-old girl with MELAS (mitochondrial encephalomyopathy, lactic acidosis, and stroke-like episodes) due to m.A3243G ($tRNA^{Leu(UUR)}$), 85% mutant heteroplasmy, presenting at age 5 with focal motor seizures, ataxia, and short stature, with episodes of acute language and motor dysfunction and progress cognitive impairment. The fluid-attenuated inversion recovery (FLAIR) MRI shows increased signal intensity (*white arrows*) in the left temporal-parietal region in addition to global mild volume loss (increased extra-axial cerebrospinal fluid spaces).

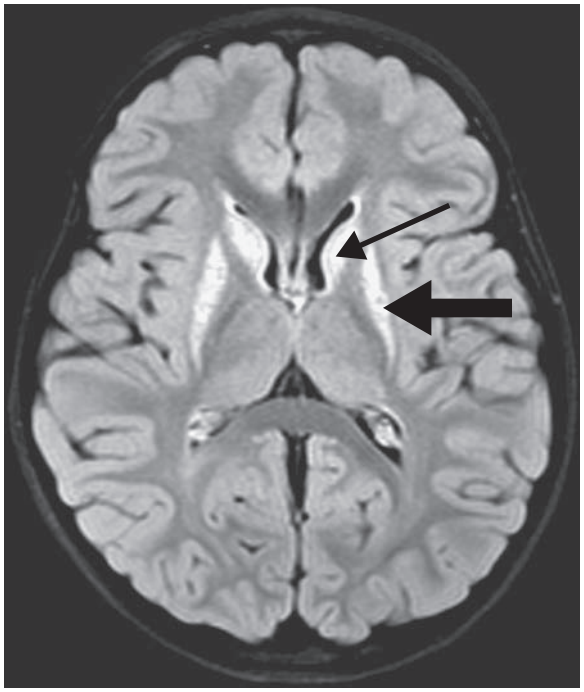

FIGURE 468-7 A 9-year-old girl with Leigh's syndrome due to m.T8993G (ATPase subunit 6), 99% heteroplasmy, presenting at age 14 months with a motor delay and who underwent an MRI at 24 months, at which time she had just begun to walk. She has moderate cognitive impairment, arm chorea, and distal leg dystonia. The fluid-attenuated inversion recover (FLAIR) MRI shows symmetric bilateral increased signal in the caudate nuclei (*thin arrow*) and putamen (*thick arrow*); only left-sided lesions indicated with *arrows*.

molecules are mutant, a more severe clinical, neuroradiologic, and neuropathologic picture (Leigh's syndrome) emerges. Not uncommonly, an infant is diagnosed with Leigh's syndrome due to the m.8993T>G mutation and not until several years later will the mother present with

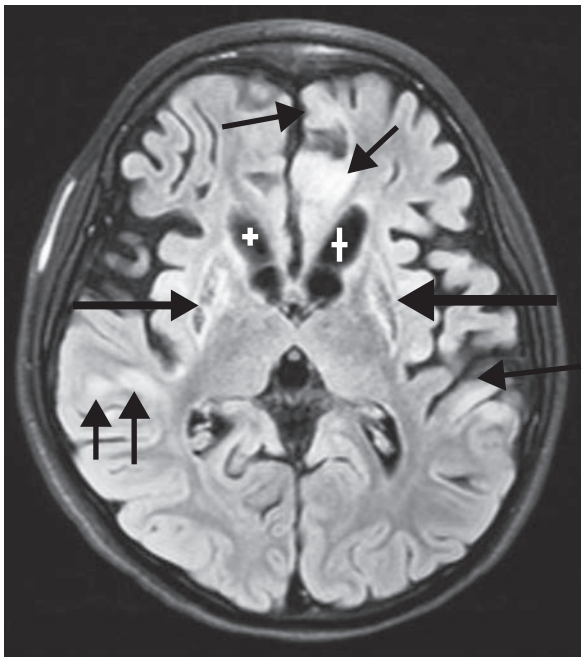

FIGURE 468-8 A 12-year-old boy with Leigh's syndrome due to m.T10191C (ND3 gene, complex I), heteroplasmy percentage not determined, presenting with infantile spasms at 8 months of life. He responded well to adrenocorticotropic hormone (ACTH), and his MRI and development were normal until 30 months when he developed dystonia and progressive medically intractable epilepsy. The fluid-attenuated inversion recover (FLAIR) MRI at 6 years of life shows global atrophy with large extra-axial cerebrospinal fluid spaces, increased signal intensity in the cortex (*thin arrows*), necrotic bilaterally symmetric lesions in the putamina, and enlarged lateral ventricles due to loss of bilateral caudate nuclei volume (*stars*).

symptoms of NARP, a situation that highlights the concept of a higher threshold for lower levels of tissue heteroplasmy.

Point mutations in the mtDNA gene encoding the 12S rRNA (m.A1555G) result in heritable nonsyndromic hearing loss. One such mutation causes heritable ototoxic susceptibility to standard dosing of aminoglycoside antibiotics, which opens a pathway for a simple pharmacogenetic test in the appropriate clinical settings. This is an example of an ecogenetic disorder in that most people with this mutation do not develop any symptoms until exposed to an external agent.

KSS, sporadic progressive external ophthalmoplegia (PEO), and Pearson's syndrome are three disease phenotypes caused by large-scale mtDNA rearrangements including partial deletions or partial duplication. The majority of single large-scale rearrangements of mtDNA are thought to result from clonal amplification of a single sporadic mutational event, occurring in the maternal oocyte during early embryonic development. The typical mtDNA deletion specifically involves 4977 nucleotides, accounting for most KSS and PEO of mtDNA deletion origin. Because germline involvement is rare, most cases are sporadic rather than inherited. KSS is characterized by the triad of onset before age 20, chronic PEO, and pigmentary retinopathy. Cerebellar syndrome, heart block, increased CSF protein content, diabetes mellitus, and short stature are also part of the syndrome. Single deletions/duplication can also result in milder phenotypes such as PEO, characterized by late-onset PEO, proximal myopathy, and exercise intolerance. In both KSS and PEO, diabetes mellitus and hearing loss are frequent accompaniments. Pearson's syndrome is also characterized by infantile onset of a sideroblastic anemia accompanied by lactic acidosis and failure to thrive caused in part by exocrine pancreatic insufficiency. If the child survives, the manifestations appear phenotypically similar to those of severe KSS with myopathy, PEO, encephalopathy, and cardiomyopathy. Pearson's syndrome is generally caused by large-scale sporadic deletion of several mtDNA genes that differ from the common deletion seen in KSS. Typically, the deletion size is larger in Pearson's syndrome, and located with different break points, than in KSS or PEO, but this is not always the case.

Two important dilemmas in classic mtDNA disease have benefited from recent important research insights. The first relates to the greater involvement of neuronal, muscular, renal, hepatic, and pancreatic manifestations in mtDNA disease in these syndromes. This observation has appropriately been mostly attributed to the high energy utilization of the involved tissues and organ systems and, hence, greater dependency on mitochondrial ETC integrity and health. However, because mutations are stochastic events, mitochondrial mutations should occur in any organ during embryogenesis and development. Recently, additional explanations have been suggested based on studies of the common m.3243A>G transition. The proportion of this mutation in peripheral blood cells was shown to decrease exponentially with age. A selective process acting at the stem cell level with a strong bias against the mutated form would have its greatest effect to reduce the mutant mtDNA only in highly proliferating cells, such as those derived from the hematopoietic system. Tissues and organs carrying pathogenic mtDNA mutations and having a lower cell turnover, such as brain, nerve, or retina, would not benefit from this effect and, thus, would accumulate mutational load and be the most affected.

The other dilemma arises from the observation that only a subset of mtDNA mutations accounts for the majority of the familial mtDNA diseases. The random occurrence of mutations in the mtDNA sequence should yield a more uniform distribution of disease-causing mutations. However, recent studies using the introduction of one severe and one mild point mutation into the female germline of experimental animals demonstrated selective elimination during oogenesis of the severe mutation and selective retention of the milder mutation, with the emergence of mitochondrial disease in offspring after multiple generations. Thus, oogenesis itself can act as an "evolutionary" filter for the most harmful mtDNA disease.

THE INVESTIGATION OF SUSPECTED mtDNA DISEASE

The clinical presentations of classic syndromes, groupings of disease manifestations in multiple organ systems, or unexplained isolated

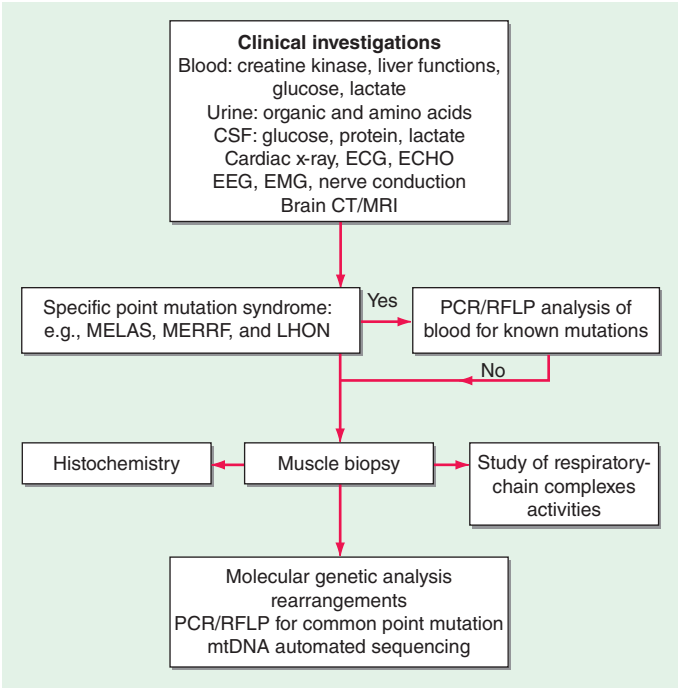

FIGURE 468-9 Clinical and laboratory investigation of a suspected mitochondrial DNA (mtDNA) disorder. CSF, cerebrospinal fluid; CT, computed tomography; ECG, electrocardiogram; ECHO, echocardiography; EEG, electroencephalogram; EMG, electromyogram; LHON, Leber's hereditary optic neuropathy; MELAS, mitochondrial encephalomyopathy, lactic acidosis, and stoke-like episodes; MERRF, myoclonic epilepsy with ragged red fibers; MRI, magnetic resonance imaging; PCR, polymerase chain reaction; RFLP, restriction fragment length polymorphism.

presentations of one of the disease features of a classic mtDNA syndrome should prompt a systematic clinical investigation as outlined in **Fig. 468-9**. Indeed, mitochondrial disease should be considered in the differential diagnosis of any progressive multisystem disorder. Despite the centrality of disruptive oxidative phosphorylation, an elevated blood lactate level is neither specific nor sensitive, because there are many causes of blood lactic acidosis and many patients with mtDNA defects presenting at any age may have normal blood lactate levels. An elevated CSF lactate is a more specific test for mitochondrial disease if there is central nervous system involvement. The serum creatine kinase may be elevated but is often normal, even in the presence of a proximal myopathy. Recently, testing for elevated levels of growth differentiating factor 15 (GDF15) has shown a high degree of sensitivity and specificity in those with a mitochondrial *myopathy*, but the degree of elevation for an individual patient reflects the severity of the illness and does not seem to be a sensitive marker of disease activity. Urinary organic acids (specifically TCA cycle intermediates) and amino acids (alanine, proline) may also be abnormal, reflecting metabolic as well as kidney proximal tubule dysfunction. Every patient with seizures, episodes of confusion or atypical behavioral changes, or cognitive decline should have an electroencephalogram. A brain computed tomography (CT) scan may show calcified basal ganglia or bilateral hypodense regions with cortical atrophy. MRI is indicated in patients with brainstem signs or stroke-like episodes.

For some mitochondrial diseases, it is possible to obtain an accurate diagnosis with a simple molecular genetic screen. For examples, 95% of patients with LHON harbor one of the three mtDNA point mutations (m.11778A>G, m.A3460A>G, or m.14484T>C). These patients have very high levels of mutated mtDNA in peripheral blood cells, and therefore, it is appropriate to send a blood sample for molecular genetic analysis by polymerase chain reaction (PCR) or restriction fragment length polymorphism (RFLP). The same is true for most MERRF patients who harbor a point mutation in the lysine tRNA gene at position 8344. In contrast, patients with the m.3243A>G MELAS mutation often have low levels of mutated mtDNA in blood. If clinical suspicion is strong enough to warrant peripheral blood testing, then patients with a negative result should have testing repeated using a saliva sample or be investigated further by performing a skeletal muscle biopsy to obtain mtDNA from a relatively nonreplicative tissue.

Muscle biopsy histochemical analysis had been the historical cornerstone for investigation of patients with suspected mitochondrial disease. Histochemical analysis may show subsarcolemmal accumulation of mitochondria with the appearance of ragged red fibers, especially in those with mtDNA mutations affecting the tRNA and rRNA genes. Electron microscopy might show abnormal mitochondria with paracrystalline inclusions. Muscle histochemistry may show COX-deficient fibers, which indicate mitochondrial dysfunction (Fig. 468-5). Respiratory chain complex assays may also show reduced enzyme function. If enzymatic or polarographic data are used to aid in the confirmation of diagnosis, a standard method of analysis should be employed. Either of these two abnormalities, within the exact context of established peer-reviewed criteria, may confirm the presence of a mitochondrial disease, to be followed by an in-depth molecular genetic analysis. In most major centers, genetic testing has become the primary means of obtaining a definitive diagnosis, using muscle pathology and biochemistry to assist with interpretation of inconclusive genetic results.

Recent evidence has provided important insights into the importance of nuclear-mtDNA genomic cross-talk and has provided a descriptive framework for classifying and understanding disorders that emanate from perturbations in this cross-talk. Although not strictly considered as mtDNA genetic disorders, manifestations do overlap those highlighted above **(Fig. 468-10)**.

IMPACT OF HOMOPLASMIC SEQUENCE VARIATION ON HERITABLE TRAITS AND DISEASE

The relationship among the degree of heteroplasmy, tissue distribution of the mutant mtDNA, and disease phenotype simplifies inference of a clear causative relationship between heteroplasmic mutation and disease. With the exception of certain mutations (e.g., those causing most cases of LHON), drift to homoplasmy of such mutations would be precluded normally by the severity of impaired oxidative phosphorylation and the consequent reduction in reproductive fitness. Therefore, sequence variants that have reached homoplasmy should be neutral in terms of human evolution and, hence, useful only for tracing human evolution, demography, and migration, as described above. Thus, novel homoplasmic variants are seldom pathogenic. One important exception is in the case of one or more of the homoplasmic population-level variants, which designate the mtDNA haplogroup J, and the interaction with the mtDNA mutations causing LHON. Reduced disease predilection suggests that one or more of the ancient sequence variants designating mtDNA haplogroup J appear to attenuate predisposition to degenerative disease, in the presence of other risk factors. Whether or not additional epistatic interactions between population-level mtDNA haplotypes and common health conditions will be found remains to be determined. If such influences do exist, then they are more likely to be relevant to health conditions in the postreproductive age groups, wherein evolutionary filters would not have had the opportunity to censor deleterious effects and interactions and wherein the effects of oxidative stress during aging or with poor diet or lack of exercise may play a role. Although much has been written about the possible associations between population-level common mtDNA variants and human health and disease phenotypes or adaptation to different environmental influences (e.g., climate), a word of caution is in order.

Many studies that purport to show such associations with phenotypes such as longevity, athletic performance, and metabolic and neurodegenerative disease are limited by small sample sizes, possible genotyping inaccuracies, and the possibility of population stratification or ethnic ancestry bias. Because mtDNA haplogroups are so prominently partitioned along phylogeographic lines, it is difficult to exclude the possibility that a haplogroup for which an association has been reported is simply a marker for otherwise unappreciated population

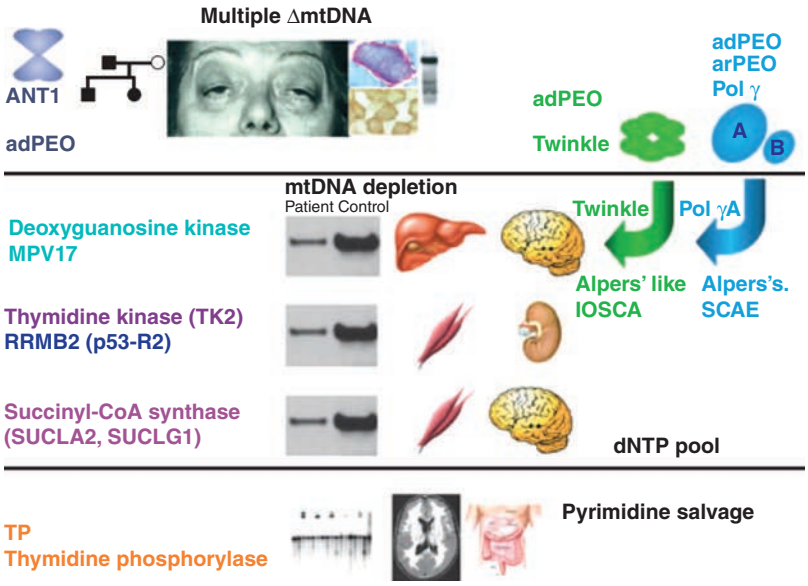

FIGURE 468-10 Disorders associated with perturbations in nuclear-mitochondrial genomic cross-talk. Clinical features and genes associated with multiple mitochondrial DNA (mtDNA) deletions, mtDNA depletion, and mitochondrial neurogastrointestinal encephalomyopathy syndromes. ANT, adenine nucleotide translocators; adPEO, autosomal dominant progressive external ophthalmoplegia; arPEO, autosomal recessive progressive external ophthalmoplegia; IOSCA, infantile-onset spinocerebellar ataxia; SCAE, spinocerebellar ataxia and epilepsy. *(Reproduced with permission from A Spinazzola, M Zeviani: Disorders from perturbations of nuclear-mitochondrial intergenomic cross-talk. J Intern Med 265:174, 2009.)*

heterogeneity, wherein a nongenetic (societal or environmental) difference among the populations marked by the mtDNA haplogroup differences is actually causally related to the disease of interest. The experimental difficulty in generating cellular or animal models to test the functional influence of homoplasmic sequence variants (as a result of mtDNA polyploidy) further compounds the challenge. The most likely formulation is that the risk conferred by different mtDNA haplogroup-defining homoplasmic mutations for common diseases depends on the concomitant nuclear genomic background, together with environmental influences. Progress in minimizing potentially misleading associations in mtDNA heritable trait and disease studies should include ensuring adequate sample size taken from a large sample recruitment base, using carefully matched controls and population structure determination, and performing analysis that takes into account epistatic interactions with other genomic loci and environmental factors.

IMPACT OF ACQUIRED SOMATIC mtDNA MUTATION ON HUMAN HEALTH AND DISEASE

Studies on aging humans and animals have shown a potentially important correlation of age with the accumulation of heterogeneous mtDNA mutations, especially in organ systems that undergo the most prominent age-related degenerative tissue phenotype. Sequencing of PCR-amplified single mtDNA molecules has demonstrated an average of two to three point mutations per molecule in elderly subjects when compared with younger ones. Point mutations observed include those responsible for known heritable heteroplasmic mtDNA disorders, such as the m.3344A>G and m.3243A>G mutations responsible for the MERRF and MELAS syndromes, respectively. However, the cumulative burden of these acquired somatic point mutations with age was observed to remain well below the threshold expected for phenotypic expression (<2%). Point mutations at other sites not normally involved in inherited mtDNA disorders have also been shown to accumulate to much higher levels in some tissues of elderly individuals, with the description of tissue-specific "hot spots" for acquired somatic mtDNA point mutations. Likewise, an age-associated and tissue-specific accumulation of mtDNA deletions has been observed, including deletions involved in known heritable mtDNA disorders, as well as others. The accumulation of functional mtDNA deletions in a given tissue is expected to be associated with mitochondrial dysfunction, as reflected in an age-associated patchy and reduced COX activity on histochemical staining, especially in skeletal and cardiac muscle and brain. A particularly well-studied and potentially important example is the accumulation of mtDNA deletions and COX deficiency observed in neurons of the substantia nigra in Parkinson's disease patients.

The progressive accumulation of ROS has been proposed as the key factor connecting mtDNA mutations with aging and age-related disease pathogenesis **(Fig. 468-11)**. As noted above, ROS are a by-product of normal oxidative phosphorylation and are removed by detoxifying antioxidants into less harmful moieties; however, environmental factors or mutations that result in exaggerated production of ROS or impaired removal result in ROS accumulation and subsequent cellular injury. One of the main targets for ROS-mediated injury is DNA, and mtDNA is particularly vulnerable because of its proximity to the origin of free radical production, the lack of protective histones, and less efficient injury repair systems compared with nuclear DNA. In turn, accumulation of mtDNA mutations results in inefficient oxidative phosphorylation, with the potential for excessive production of ROS, generating a "vicious cycle" of cumulative mtDNA damage. Indeed, measurement of the oxidative stress biomarker 8-hydroxy-2-deoxyguanosine has been used to measure age-dependent increases in mtDNA oxidative damage at a rate exceeding that of nuclear DNA. It should be noted that mtDNA mutations can potentially occur in postmitotic cells as well, because mtDNA replication is not synchronized with the cell cycle. Two other proposed links between mtDNA mutation and aging, besides ROS-mediated tissue injury, are the perturbations in efficiency of oxidative phosphorylation with disturbed cellular aerobic function and perturbations in apoptotic pathways, whose execution steps involve mitochondrial activity.

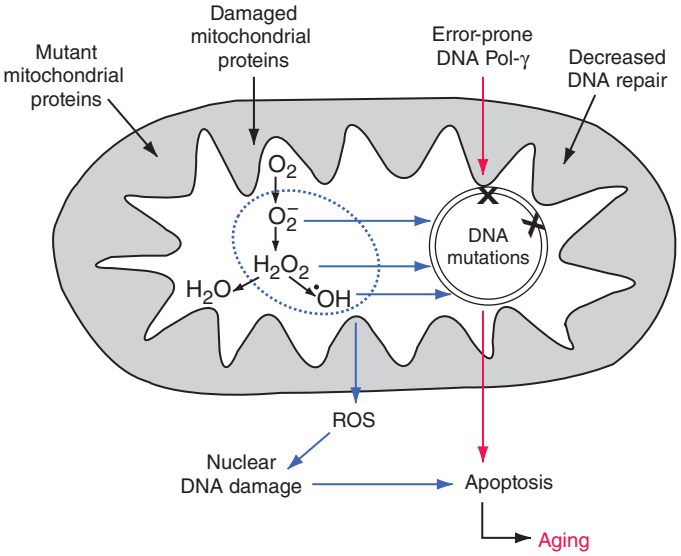

FIGURE 468-11 Multiple pathways of mitochondrial DNA (mtDNA) damage and aging. Multiple factors may impinge on the integrity of mitochondria that lead to loss of cell function, apoptosis, and aging. The classic pathway is indicated with *blue arrows*; the generation of reactive oxygen species (ROS; superoxide anion, hydrogen peroxide, and hydroxyl radicals), as a by-product of mitochondrial oxidative phosphorylation, results in damage to mitochondrial macromolecules, including the mtDNA, with the latter leading to deleterious mutations. When these factors damage the mitochondrial energy-generating apparatus beyond a functional threshold, proteins are released from the mitochondria that activate the caspase pathway, leading to apoptosis, cell death, and aging. *(Reproduced with permission from L Loeb et al: The mitochondrial theory of aging and its relationship to reactive oxygen species damage and somatic mtDNA mutations. Proc Natl Acad Sci USA 102:18769, 2005. Copyright (2005) National Academy of Sciences, U.S.A.)*

Genetic intervention studies in animal models have sought to clarify the potential causative relationship between acquired somatic mtDNA mutation and the aging phenotype and the role of ROS in particular. Replication of the mitochondrial genome is mediated by the activity of the nuclear-encoded *POLG*. A transgenic homozygous mouse knock-in mutation of this gene renders the polymerase enzyme deficient in proofreading and results in a threefold to fivefold increase in mtDNA mutation rate. Such mice develop a premature aging phenotype, which includes subcutaneous lipoatrophy, alopecia, kyphonia, and weight loss with premature death. Although the finding of increased mtDNA mutation and mitochondrial dysfunction with age has been solidly established, the causative role and specific contribution of mitochondrial ROS to aging and age-related disease in humans have yet to be proved. Similarly, although many tumors display higher levels of heterogeneous mtDNA mutations, a causal relationship to tumorigenesis has not been proved.

Besides the age-dependent acquired accumulation in somatic cells of heterogeneous point mutations and deletions, a quite different effect of nonheritable and acquired mtDNA mutations has been described affecting tissue stem cells. In particular, disease phenotypes attributed to acquired mtDNA mutation have been observed in sporadic and apparently nonfamilial cases involving a single individual or even tissue, usually skeletal muscle. The presentation consists of decreased exercise tolerance and myalgias, sometimes progressing to rhabdomyolysis. As in the case of the sporadic, heteroplasmic, large-scale deletion, classic syndromes of chronic PEO, Pearson's syndrome, and KSS, the absence of a maternal inheritance pattern and the finding of limited tissue distribution suggest a molecular pathogenic mechanism emanating from mutations arising de novo in muscle stem cells after germline differentiation (somatic mutations that are not sporadic and occur in tissue-specific stem cells during fetal development or in the postnatal maintenance or postinjury repair stage). Such mutations would be expected to be propagated only within the progeny of that stem cell and affect a singular tissue within a given individual, without evidence of heritability.

PROSPECTS FOR CLINICAL MANAGEMENT OF mtDNA DISEASE

TREATMENT OF mtDNA DISORDERS

No specific curative treatment for mtDNA disorders is currently available; therefore, the management of mitochondrial disease is largely supportive. Management issues may include early diagnosis and medical management of epilepsy, gastrointestinal dysfunction, weakness, diabetes mellitus, cardiac dysrhythmia, hearing loss, endocrinopathy, ptosis, and cataracts. The value of aggressive symptom management cannot be understated. Less specific interventions in the case of other disorders involve combined treatment strategies including dietary intervention and removal of toxic metabolites. Cofactors and vitamin supplements are widely used in the treatment of diseases of mitochondrial oxidative phosphorylation, although there is little evidence, apart from anecdotal reports, to support their use. This includes administration of artificial electron acceptors, including vitamin K_3, vitamin C, and ubiquinone (CoQ_{10}); administration of cofactors (coenzymes) including riboflavin, carnitine, and creatine; and use of oxygen radical scavengers, such as vitamin E, copper, selenium, ubiquinone, and idebenone. Drugs that could interfere with mitochondrial function, such as the anesthetic agent propofol, barbiturates, and high doses of valproate, should be avoided. The use of valproate in patients with pathogenic mutations in *POLG* and possibly other mutations affecting mtDNA stability and replication is especially contraindicated. Supplementation with the nitric oxide synthase substrate L-arginine and, more recently, L-citrulline has been advocated as a vasodilator treatment during stroke-like episodes as well as for chronic management in patients with MELAS. Open-label studies demonstrate that levoarginine and levocitrulline may be helpful in reducing the stroke-like symptoms in MELAS but may have serious side effects. As CSF folate deficiency has been reported in some cases of mitochondrial disease, this can be treated with folinic acid.

The physician should also be familiar with environmental interactions, such as the strong and consistent association between visual loss in LHON and smoking or ethanol consumption. A clinical penetrance of 93% was found in men who smoked. Asymptomatic carriers of an LHON mtDNA mutation should, therefore, be strongly advised not to smoke and to moderate their alcohol intake. Although not a cure, these interventions might stave off the devastating clinical manifestations of the LHON mutation. Another example is strict avoidance of aminoglycosides in the familial syndrome of ototoxic susceptibility to aminoglycosides in the presence of the mtDNA m.1555A>G mutation of the 12SrRNA encoding gene.

Clinical trials using novel agents have been initiated and launched. These agents include α-tocotrienol (PTC-743 previously termed EPI-743, PTC Therapeutics), REN-001 (Reneo Pharmaceuticals), ASP0367 (Astellas Pharmaceuticals), and elamipretide (Stealth Biotherapeutics). In an open-label study of α-tocotrienol used to treat 10 children with Leigh's syndrome, there were improvements in the primary endpoints, including the Newcastle Pediatric Mitochondrial Diseases Scale, the Gross Motor Function Measure, and the PedsQL Neuromuscular Module. Ongoing studies continue for α-tocotrienol in children with epilepsy, along with REN001, ASP0367, and elamipretide in adults with primary mitochondrial myopathy. Conclusive progress has experienced some delay due to the COVID-19 pandemic.

GENETIC COUNSELING, PRENATAL DIAGNOSIS, AND PGD IN mtDNA DISORDERS

The provision of accurate genetic counseling and reproductive options to families with mtDNA mutations is challenging due to the unique genetic features of mtDNA inheritance that distinguish it from Mendelian genetics. mtDNA defects are transmitted by maternal inheritance. mtDNA de novo mutations are often large deletions, affect one family member, and usually represent no significant risk to other members of the family. In contrast, mtDNA point mutations or duplications can be transmitted maternally. Accordingly, the father of an affected individual has no risk of harboring the disease-causing mutation, and a male cannot transmit the mtDNA mutation to his offspring. In contrast, the mother of an affected individual usually harbors the same mutation but may be completely asymptomatic. This wide phenotypic variability is primarily related to the phenomena of heteroplasmy and the mutation load carried by different members of the same family. Consequently, a symptomatic or asymptomatic female harboring a disease-causing mutation in a heteroplasmic state will transmit to her offspring variable amounts of the mutant mtDNA molecules. The offspring will be symptomatic or asymptomatic primarily according to the mutant load transmitted via the oocyte and, to some extent, subsequent mitotic segregation during development. Interactions with the mtDNA haplotype background or nuclear human genome (as in the case of LHON) serve as an additional important determinant of disease penetrance. Because the severity of the disease phenotype associated with the heteroplasmic mutation load is a function of the stochastic differential segregation and copy number of mutant mtDNA during the oogenesis bottleneck and, subsequently, following tissue and organ development in the offspring, it is rarely predictable with any degree of accuracy. For this reason, prenatal diagnosis (PND) and PGD techniques that have evolved into integral and well-accepted standards of practice are severely hampered in the case of mtDNA-related diseases.

The value of PND and PGD is limited, partly due to the absence of data on the rules that govern the segregation of wild-type and mutant mtDNA species (heteroplasmy) among tissue in the developing embryo. Three factors are required to ensure the reliability of PND and PGD: (1) a close correlation between the mutant load and the disease severity, (2) a uniform distribution of mutant load among tissues, and (3) no major change in mutant load with time. These criteria are suggested to be fulfilled for the NARP m.8993T>G mutation but do not seem to apply to other mtDNA disorders. In fact, the level of mutant mtDNA in a chorionic villous or amniotic fluid sample may be very different from the level in the fetus, and it would be difficult to deduce whether the mutational load in the prenatal samples provides clinically useful information regarding the postnatal and adult state.

PREVENTION OF MITOCHONDRIAL DISEASE INHERITANCE BY ASSISTED REPRODUCTIVE TECHNOLOGIES

Because the treatment options for patients with mitochondrial disease are rather limited, with no current U.S. Food and Drug Administration (FDA)–approved therapies for established mitochondrial DNA disease, preventive interventions that eliminate the likelihood of transmission of affected mtDNA into offspring are desirable. The poor reliability of prenatal and preimplantation approaches in predicting mitochondrial DNA disease has resulted in the search for alternative preventive approaches. The common purpose underlying various emerging approaches is to reduce mutant heteroplasmy levels to a level below a pathogenic threshold. This is based on the observed relationship between heteroplasmy and disease inheritance patterns, which indicates that even a small increase in copy number of nonmutant mtDNA molecules in the fertilized egg can exceed the threshold required to ameliorate serious clinical disease. Use of gene editing, with clustered regularly interspaced short palindromic repeats (CRISPR) or mitochondrial-targeted TALEN (transcription activator-like effector nucleases) technology, for example, to shift the heteroplasmy load in affected tissues will require future development of corrective gene delivery techniques. Likewise, induced pluripotent cell technology has not yet met with widespread success in the preclinical research setting. This has prompted the application of mitochondrial replacement therapy (MRT) approaches **(Fig. 468-12)**. These approaches substitute in vitro the entire oocyte or zygote complement of mitochondria, together

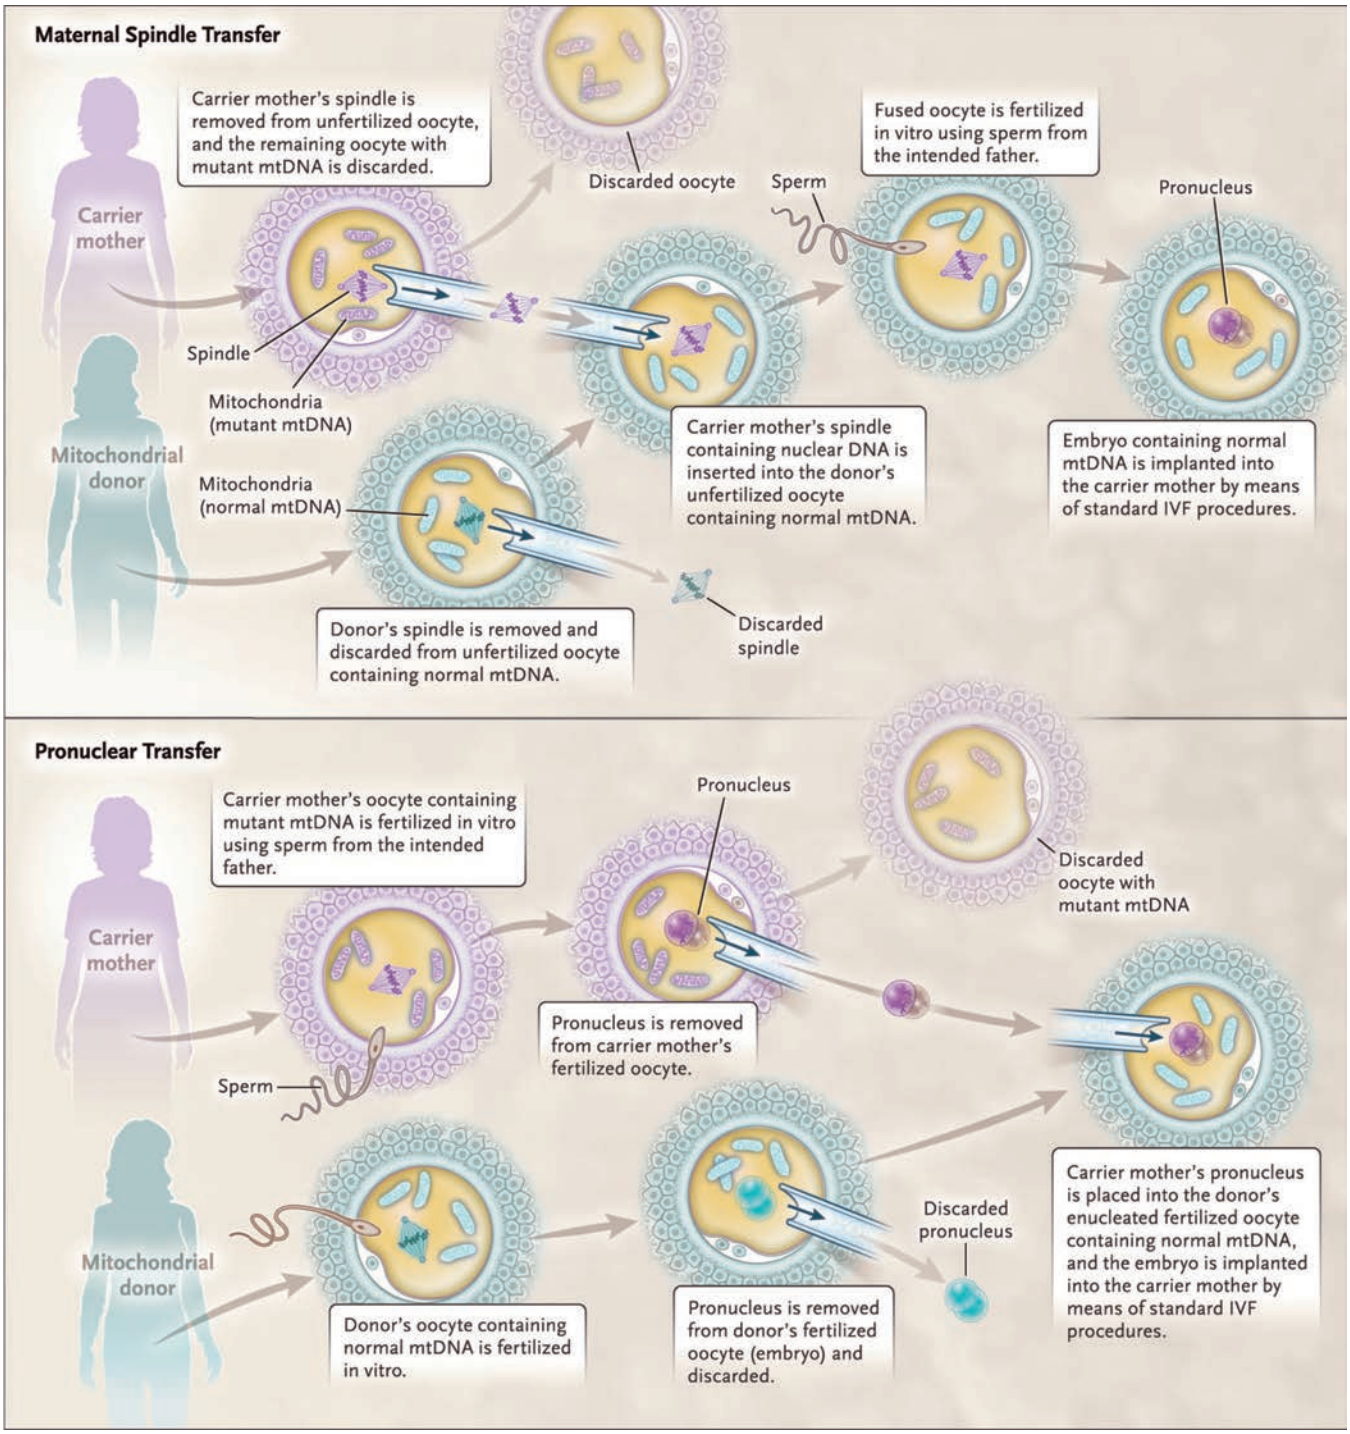

FIGURE 468-12 Mitochondrial replacement techniques—maternal spindle transfer and pronuclear transfer. In both procedures, some mutant mtDNA, estimated at 1–2%, might be carried over together with the spindle or pronucleus, but the levels are low enough to avoid disease risk. IVF, in vitro fertilization. *(From MJ Falk et al: Mitochondrial replacement techniques—Implications for the clinical community. N Engl J Med 374:1103, 2016. Copyright © 2016, Massachusetts Medical Society. Reprinted with permission from Massachusetts Medical Society.)*

with their mtDNA from the carrier mother, with the unaffected complement of mitochondria and their unaffected mtDNA from a donor woman. This can be accomplished either by removing and transferring the carrier mother's spindle with her nuclear DNA into the unfertilized oocyte of the donor or, alternatively, by transferring the pronucleus from the fertilized oocyte of the carrier mother to the unfertilized donor oocyte from which the pronucleus has been removed. These approaches provide a "bulk" substitution and hence do not target the specific mtDNA mutation, and they are potentially applicable to a wide variety of mtDNA disorders. This is a form of germline genetic therapy, and therefore, it projects onto future generations in the case of a female offspring. Accordingly, ethical and regulatory bodies have appropriately weighed in on the societal implications of such approaches and have been tentatively supportive of human clinical investigation for situations that would prevent great suffering and when the clinical need is clear and unambiguous, subject to specified conditions and principles and subject to ethical scrutiny. Several such studies have been initiated, and careful examination and follow-up are needed to determine developmental and longer-term health and fertility of children who have undergone genetic manipulation at the earliest stages of human development and whose genomes comprise separate maternal origins of nuclear and mtDNA genomes. It has been recommended that such studies be limited to male offspring, who cannot then transmit the donor mtDNA to future generations, until such time as the health, ethical, and societal issues are well understood and live up to the exciting promise of reducing the burden of clinical mtDNA disease in the future.

469 Telomere Disease

Rodrigo T. Calado, Neal S. Young

DEFINITION

In telomere diseases (also called *telomeropathies* or *telomere spectrum disorders*), organ dysfunction is caused by loss of the ends of chromosomes, a process termed *accelerated telomere attrition*. Inadequate repair or insufficient protection of telomeres and their resulting erosion induces cell death, deficient cell proliferation, and chromosome instability; affected tissues show defective organ regeneration, fibrosis or replacement by fat, and a proclivity for cancer. A variety of regenerative disorders affecting especially the bone marrow, lungs, liver, and skin share telomere dysfunction and accelerated loss as their common molecular mechanism. Cross-sectional data of average telomere length in cohorts of different ages and longitudinal studies in individuals indicate that telomeres shorten with aging at an average of 50 base pairs/year in peripheral blood leukocytes. Despite shortening of telomeres over time, normal aging is not associated with the development of a telomere disease from short telomeres. In normal aging, sufficient stem cell number and function are maintained to sustain vital processes. For example, in stem cell transplant, even a limited number of donor hematopoietic cells maintains normal hematopoiesis for many years, at least in part related to normal telomerase function and telomere repair. Telomere length associates with life span in the general population. While shorter leukocyte telomeres correlate with increased mortality risk, especially from nonmalignant causes, telomere loss is not established as the cause of physiologic aging.

DISEASE MECHANISM

Telomeres, the physical termini of linear chromosomes, are repeated hexanucleotide sequences physically associated with specific proteins. Telomeres function to protect the chromosome ends against recognition as damaged or infectious DNA by the DNA repair machinery **(Fig. 469-1)**. During mitosis, the DNA polymerase employs an RNA oligonucleotide with a 3′ hydroxyl group to prime replication. The primer dissociates as the DNA polymerase advances along the template strand, and a gap is left at the ends of linear DNA molecules: the newly synthesized DNA strand is necessarily shorter than the original template—the "end-replication problem." Chromosome erosion is thus inevitable with mitotic cell division, but the noncoding telomeric long, repetitive structure buffers loss of genetic information. In human cells, telomeres are composed of hundreds to thousands of TTAGGG tandem repeats in the leading and CCCTAA in the lagging DNA strand. At birth, telomeres are relatively long, but they inexorably shorten with chronological aging (Fig. 469-1). In an individual cell, critically short telomere length triggers the p53 pathway, usually leading to proliferative arrest, senescence, and apoptosis. Telomere loss is the molecular basis for the "Hayflick phenomenon," the limit to cell division and thus to cell proliferation in tissue culture. If a cell overcomes proliferation arrest, extremely short telomeres engage the DNA damage repair machinery, and chromosome end-to-end fusions, chromosome breaks, aneuploidy, and chromosome instability may occur. In addition to the telomere repeated sequences, a group of specialized proteins, collectively termed *shelterins*, directly bind to or indirectly associate with telomeres, assisting in the organization of the telomere tertiary structure and inhibiting activity of DNA damage response proteins (Fig. 469-1).

To escape telomere attrition, cells with high proliferative demand, including embryonic and adult stem cells, lymphocytes, and the majority of cancer cells have at least two mechanisms to preserve telomere length: homologous recombination (important in malignant cell transformation) and the synthesis of telomeric repeats (in physiologic telomere maintenance). The telomerase machinery adds GTTAGG hexanucleotides to the 5′ end of the leading DNA strand using telomerase, a reverse transcriptase enzyme (TERT), and TERC, its RNA template (Fig. 469-1). The telomerase holoenzyme complex is composed of two copies of TERT, TERC, and dyskerin, and associated proteins. TERC binds to TERT and serves as the RNA template for its function as a reverse transcriptase. Dyskerin, encoded by *DKC1*, stabilizes the complex, and TCAB1, encoded by the *WRAP53* gene, aids telomerase trafficking to the Cajal bodies, nuclear structures for ribonucleoprotein processing where telomerase associates with telomeres for elongation. Telomerase expression is tightly regulated. MYC, sex hormones, and many additional factors stimulate *TERT* transcription. In mature cells, the *TERT* gene is repressed. In addition, shelterin proteins can also regulate telomerase function and processivity, modulating its catalytic activity on telomeres. Other proteins also are important for telomere length maintenance. RTEL1, an essential DNA helicase, dismantles T-loops and resolves G-quadruplexes, ensuring adequate telomere elongation.

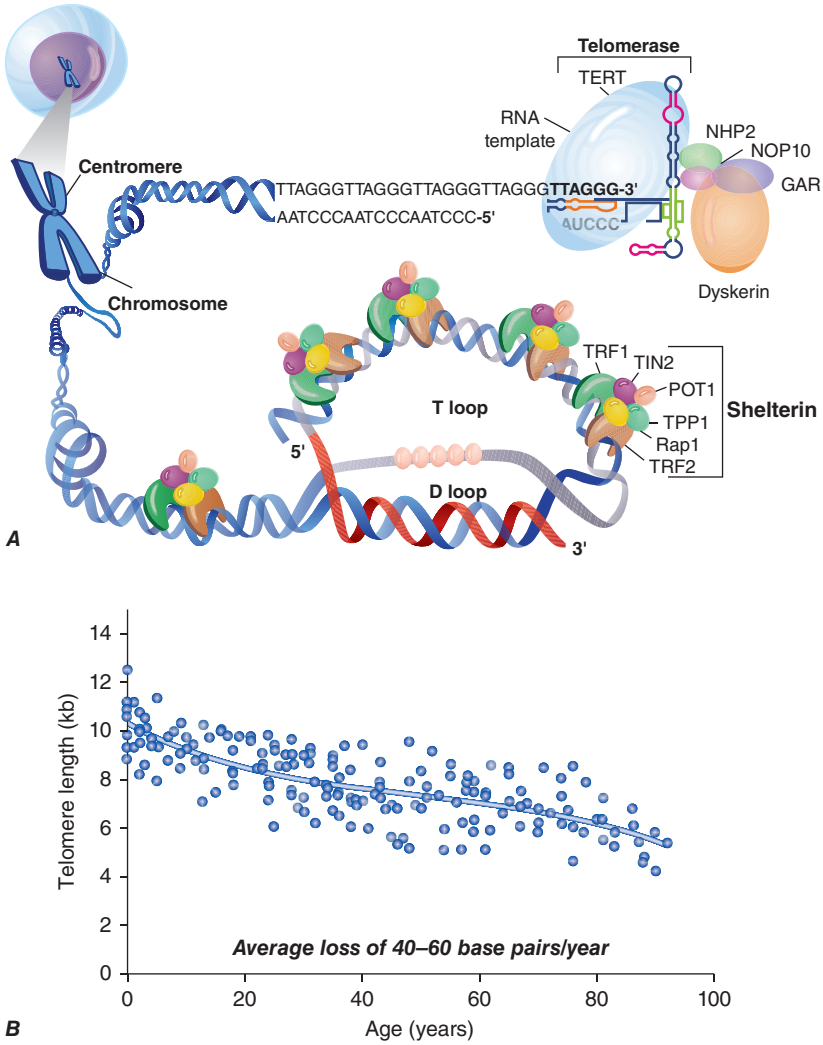

FIGURE 469-1 Telomeres and telomerase. ***A.*** Telomeres are ribonucleoprotein structures located at the termini of linear chromosomes inside the cell nucleus composed of hundreds of tandem hexameric DNA repeats. A group of proteins bind directly or indirectly to telomere sequences in order to provide protection to the structure and are collectively termed *shelterin* or *telosome* (TRF1, TRF2, TIN2, POT1, TPP1, and RAP1). As the 3′ end of the leading strand forms a single-stranded overhang, it folds back and invades the telomeric double helix, forming a lariat termed *T-loop*. The telomerase complex is composed of the enzyme telomerase reverse transcriptase (TERT), its RNA component (TERC), the protein dyskerin, and associated proteins (NHP2, NOP10, and GAR). This enzymatic complex elongates telomeres by adding GTTAGG hexameric repeats to the 3′ end of the telomeric leading strand, using a sequence in TERC as the template. ***B.*** The average telomere length in human leukocytes varies: it is longer at birth (10–11 kb) and progressively shortens with aging (5–7 kb at age 90 years) at an average loss of 40–60 base pairs/year. However, there is significant variability in telomere length in each given age.

When telomeres are critically short, the DNA damage response machinery may be recruited, mistaking telomeres for damaged or infectious DNA and forcing inappropriate repair. Activation of this pathway may cause chromosome instability due to end-to-end fusion of chromosomes or translocations; these alterations generate genomic instability and potentially malignant clones of cells. That telomere dysfunction increases the risk of cancer development has been demonstrated in murine models of telomerase deficiency, and patients with telomere diseases are prone to develop acute myeloid leukemia and head and neck squamous cell carcinomas.

GENETICS

The pattern of inheritance is variable: X-linked, autosomal recessive, and autosomal dominant. Complex genetic architecture also occurs, and affected patients may inherit pathogenic loss-of-function variants in more than one gene involved in the same telomere biology pathway. At least 15 genes have been implicated in the etiology of telomeropathies **(Table 469-1)**.

CLINICAL MANIFESTATIONS

Presentation of telomere disease in the clinic is highly variable—in the tissues affected, in the severity of organ dysfunction, and in patterns of disease within families and between families with similar mutations. In a same family, one individual may be severely affected, but close relatives carrying the same mutation may be asymptomatic and with normal laboratory results. Asymptomatic carriers, however, may have subclinical organ dysfunction, which may be detected by directed or specialized testing (reduced forced vital capacity on pulmonary function test, hypocellular bone marrow at biopsy, hepatic steatosis on ultrasound). Somatic genetic rescue may occur in telomere diseases and modulate the clinical phenotype. Rescue is a rare spontaneous genetic event in a somatic cell, conferring a selective advantage and annulling the effect of the original pathogenic germline mutation. In telomeropathies, somatic genetic rescue has been detected in hematopoietic cells, so that one clonal population adequately produces blood cells and mitigates the marrow failure phenotype. Generally, relatives sharing the same mutation and short telomeres may have different organs affected: for instance, while one individual may have aplastic anemia, another within the pedigree may suffer from pulmonary fibrosis. Environmental regenerative stresses, factors such as smoking and alcohol consumption, and viral infection may increase susceptibility to organ damage in these patients and contribute to disease heterogeneity.

Disease anticipation, in which clinical phenotype manifests at an earlier age in successive generations, is observed in some families with telomeropathies, due to the direct inheritance of short telomeres present in sperm and oocytes.

The diagnosis of a telomere disease is suggested by personal and family history, strengthened by simple measurement of leukocyte telomere length, and usually definitively established by next-generation sequencing for genes encoding telomere repair enzyme complex and shelterin components.

Pathologic accelerated telomere attrition has a genetic origin. Germline loss-of-function mutations in genes involved in telomere maintenance and function impair telomere length repair, thus increasing the rate of telomere erosion in highly proliferative cells. Telomeres reach critically short lengths faster than with normal aging; the consequences are limited cell proliferation and impaired tissue regeneration. Some organs appear to be particularly susceptible to telomere erosion. Billions of blood cells are produced daily **(Chap. 96)**, and telomere attrition curtails cell proliferation, producing a hypocellular marrow and often low blood counts. The liver also is an organ with high proliferative capacity, and telomere dysfunction impairs hepatic regeneration after injury, with a variety of pathologic consequences. The lung alveolar epithelium is in contact with exogenous toxins that stimulate regeneration, and telomere loss may hinder these physiologic responses. However, it remains unclear why other regenerative tissues, such as the intestine, are less affected by telomere dysfunction; the mechanism by which telomere loss provokes a fibrotic response in the lungs (pulmonary fibrosis), an adipose response in the marrow (aplastic anemia), and both in the liver (hepatic steatosis and cirrhosis) is also unclear.

Dyskeratosis Congenita Dyskeratosis congenita is the classic telomere disease, a mainly pediatric syndrome diagnosed in the first two decades of life. Affected children often have at least two features of the mucocutaneous triad of ungual dystrophy, reticular skin pigmentation, and oral leukoplakia **(Fig. 469-2)**. In severe syndromes, affected newborns have cerebellar hypoplasia (Hoyeraal-Hreidarsson

syndrome) or exudative retinopathy (Revesz syndrome) (Fig. 469-3). Telomeres are usually extremely short, below the first percentile expected for age (Fig. 469-4). Most patients with dyskeratosis congenita develop bone marrow failure, often requiring transfusions and ultimately bone marrow transplant. Pulmonary fibrosis appears in as many as 20% of cases and liver disease in 10%, often after bone marrow transplant for hematopoietic failure. Other tissues and organs also may be affected (Fig. 469-3). The most common mutations in dyskeratosis congenita patients are in the *DKC1*, *TINF2*, *TERT*, *TERC*, and *RTEL1* genes, and triallelic inheritance (involving two genes in the same pathway) also may occur (Table 469-1).

FIGURE 469-2 Skin manifestations of dyskeratosis congenita. The pediatric syndrome dyskeratosis congenita is characterized by the mucocutaneous triad of ***(A)*** reticular skin pigmentation, ***(B)*** oral leukoplakia, and ***(C, D)*** nail dystrophy.

Bone Marrow Failure Aplastic anemia (Chap. 102) is the most common major clinical manifestation of dyskeratosis congenita. However, young or older patients carrying a telomere defect, without typical physical stigmata of dyskeratosis, also may also develop marrow failure. Genetic variants usually are monoallelic (one mutated allele and one wild-type allele), and *TERT*, *TERC*, and *RTEL1* are the genes usually affected. Telomere loss in these cases is often less intense than in classic dyskeratosis congenita. As a result of inadequate telomerase function, the stem cell pool is limited in size and in its ability to regenerate. There is insufficient production of erythrocytes, platelets, and granulocytes with anemia, thrombocytopenia, and leukopenia of peripheral blood and low marrow cellularity (Fig. 469-5). The most typical presentation is moderate aplastic anemia after a long history of macrocytic mild to moderate anemia and/or thrombocytopenia, with preservation of leukocyte numbers. A comprehensive personal and family history is important, querying especially for blood count abnormalities and cytopenia as well as lung and liver disease; early hair graying, while not specific to telomeropathies, strongly suggests telomere disease in the appropriate context.

Immunosuppressive therapy is generally ineffective in these patients, and they may be more susceptible to pulmonary or hepatic complications after hematopoietic stem cell transplant.

Myeloid Neoplasms Some patients diagnosed with myelodysplastic syndrome (Chap. 102) or acute myeloid leukemia (Chap. 104) have a family history of bone marrow failure or of other myeloid neoplasms. One of the genetic causes for myeloid neoplasia predisposition is a telomere defect, and these disorders are now classified together by the World Health Organization as "myeloid neoplasms associated with telomere biology disorders." Telomere length measurement may be confounded by the presence of circulating immature cells, which may have very short telomeres, precluding appropriate test interpretation.

Pulmonary Fibrosis Pulmonary fibrosis appears in ~20% of children with dyskeratosis congenita, and conversely, ~10–15% of patients with idiopathic pulmonary fibrosis (Chap. 293) or familial pulmonary fibrosis have an etiologic telomerase gene mutation. Most pulmonary fibrosis patients, regardless of mutation status, have short telomeres for their age but not as short as in dyskeratosis congenita. How telomere erosion causes pulmonary fibrosis is unclear, but it might prevent adequate proliferation and regeneration of pneumocytes type II. Idiopathic pulmonary fibrosis due to a telomere disease usually manifests after the fourth decade of life, with a restrictive pattern on pulmonary function testing associated with decreased diffusion capacity for carbon monoxide (DL_{CO}) and a diffuse "honeycomb" appearance on high-resolution CT

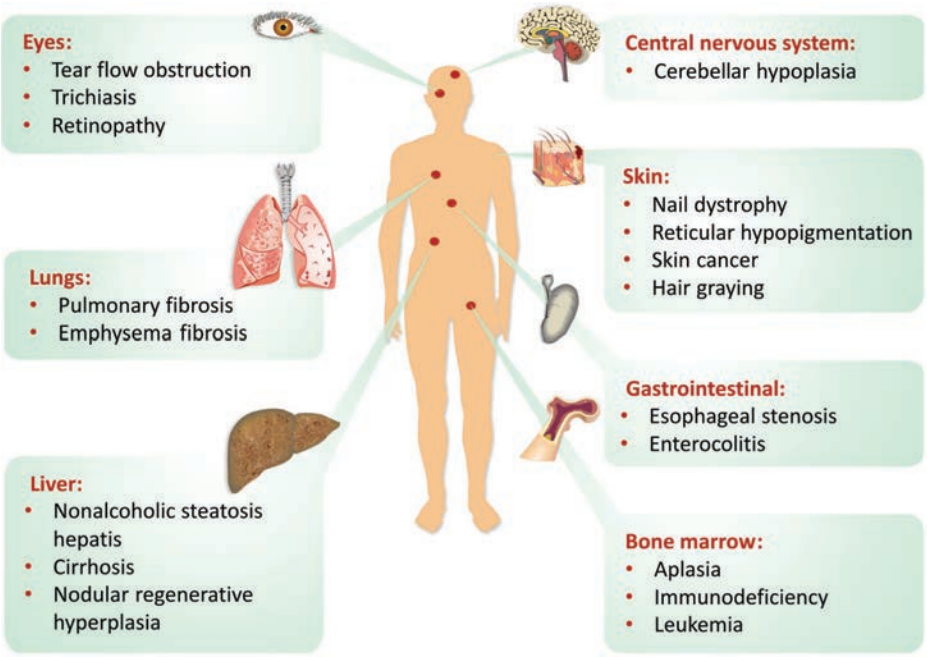

FIGURE 469-3 Clinical consequences of telomere diseases. Telomere dysfunction affects a variety of organs: cerebellum, eyes, lungs, liver, skin, gastrointestinal tract, and the bone marrow.

Liver Disease Genetic telomere defects may cause hepatic cirrhosis (Chap. 344), nodular regenerative hyperplasia of the liver, nonalcoholic fatty liver disease (Chap. 343), and hepatocellular carcinoma (Chap. 82). Hepatocytes of most patients with cirrhosis have very short telomeres. Eroded telomeres limit hepatocyte proliferation, especially upon chronic injury. Additionally, hepatocytes with short telomeres display abnormal metabolic pattern and defective mitochondrial function. Abnormal liver pathology may be uncovered incidentally during the evaluation of telomeropathy patients with aplastic anemia or pulmonary fibrosis, but cirrhosis also may be the sole or most prominent clinical presentation of a telomere defect. A minority of individuals with cirrhosis associated with virus B or C infection or alcohol-associated liver disease may carry a telomere-associated gene mutation. Liver histopathology is variable, but cirrhosis is usually associated with inflammation and inflammatory cells (Fig. 469-5), increased iron deposit, positivity for CD34 in sinusoid endothelial cells, and widening of hepatocyte plates. Defective telomere maintenance may increase susceptibility of the liver to environmental challenges, such as alcohol and viruses, increasing the risk for developing severe hepatic disease in mutation carriers.

(Fig. 469-5). Histopathology of biopsied lung most commonly shows usual interstitial pneumonia. The pulmonary clinical presentation in telomere disease is indistinguishable from idiopathic pulmonary fibrosis, except that those with an underlying telomere defect may have cryptic hepatic cirrhosis, macrocytosis, cytopenias, and a family history of lung, liver, or bone marrow disease. Pulmonary arteriovenous malformation leading to right-to-left shunting is observed in patients with pulmonary fibrosis due to telomere disease. Patients with idiopathic pulmonary fibrosis or familial pulmonary fibrosis should have leukocyte telomere length assayed and, if telomeres are short, undergo screening for mutations in telomere-associated genes and telomeres; however, telomere length may be normal in some cases despite the presence of pathogenic mutations. *TERT*, *TERC*, *RTEL1*, and *PARN* are the most commonly mutated genes.

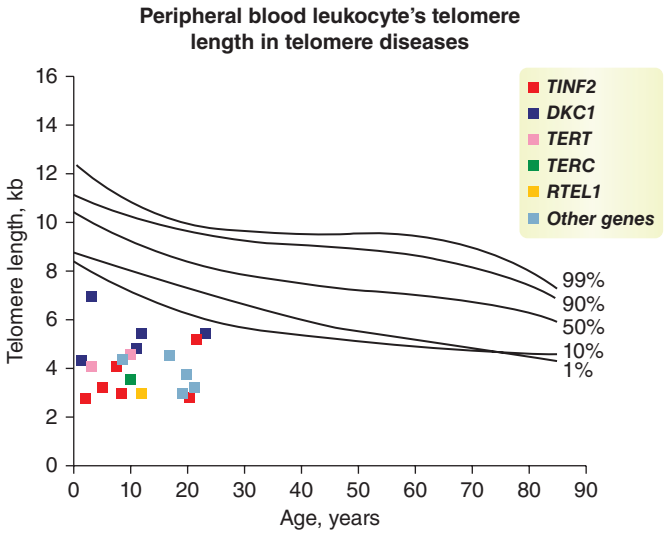

FIGURE 469-4 Telomere length measurement in dyskeratosis congenita. Telomeres shorten with aging, and solid curves represent the percentiles for age in healthy subjects. Telomeres are considered "short" when below the tenth percentile and very short when below the first percentile. In patients with dyskeratosis congenita, telomeres are usually below the first percentile, regardless of the gene lesion.

TELOMERE LENGTH MEASUREMENT

Length of telomeres can be accurately measured in peripheral blood leukocytes by commercial laboratories. Of several methods available, flow–fluorescent in situ hybridization (FISH) and quantitative real-time polymerase chain reaction (qPCR) are most widely utilized. Both methods have advantages and limitations and require high-quality samples, usually fresh or freshly processed, as cell death and DNA degradation impact the accuracy of testing. Results are usually expressed as leukocyte telomere length in kilobases. However, the interpretation of length must account for patient age due to physiologic telomere loss. A normal range for telomeres is available for each year of age, with length longest at birth and shortening at 40–60 base pairs per year (Fig. 469-1). For each age bracket, the percentile curves are calculated, and a given patient's test result is interpreted in the context of normal age variation: telomeres below the tenth percentile for age are defined as "short," and telomeres below the first percentile are considered "very short" (Fig. 469-4).

Telomeres may also be short in groups of patients with some chronic conditions, such as cardiovascular disease or diabetes. However, in these settings, telomere erosion is not assumed to be etiologic, but rather a consequence of chronic inflammation; telomere testing is not known to have clinical utility and is not recommended. Likewise, telomere length tests have no known clinical utility in the assessment of aging and longevity or as a basis for therapeutic interventions absent a diagnosis of telomere disease.

Flow-FISH uses a fluorescent-labeled nucleotide probe specific for telomere repeats in order to estimate telomere content in an individual cell by flow cytometry. It has the advantage of determining telomere length in individual cells and in leukocyte subpopulations (neutrophils, lymphocytes, monocytes); lymphocyte telomere shortening is more specific for telomere diseases than in other cells. However, flow-FISH requires intact cells for analysis, which are not always available, and neutrophils are susceptible to damage during processing, freezing, and thawing.

qPCR utilizes telomere-binding modified primers to measure telomere content in comparison to a housekeeping gene in the whole leukocyte population and thus does not require intact cells. qPCR

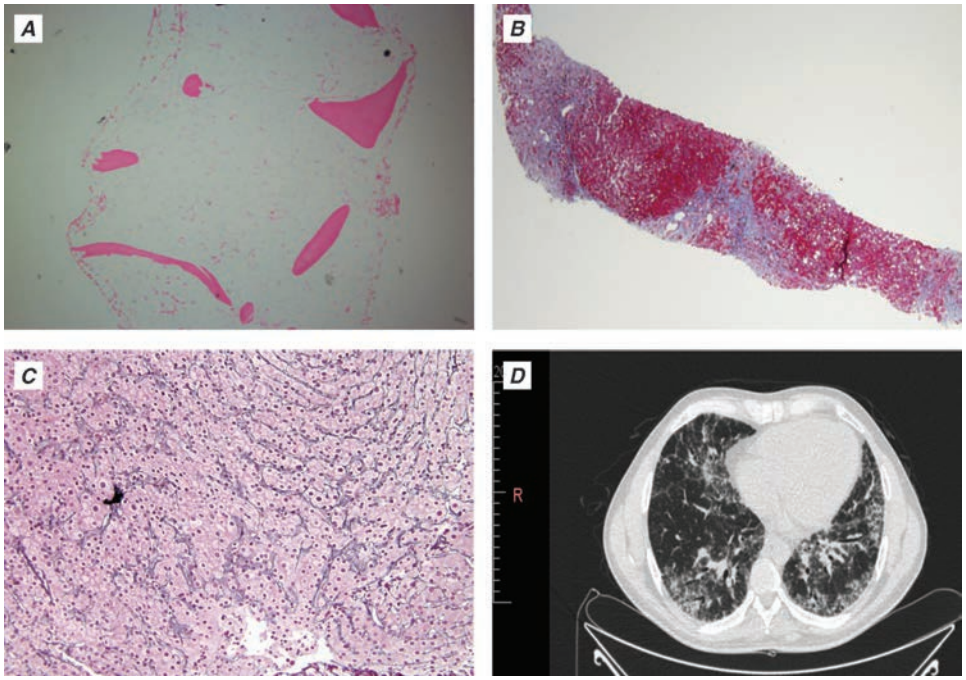

FIGURE 469-5 Pathologic manifestations of telomere diseases. ***A.*** In the bone marrow, telomere erosion predisposes to aplastic anemia, characterized by an empty hematopoietic marrow replaced by fat (hematoxylin and eosin). ***B.*** In the liver, telomere attrition predisposes to cirrhosis (hematoxylin and eosin). ***C.*** Telomere shortening may also result in nodular regenerative hyperplasia of the liver (reticulin stain). ***D.*** In the lungs, telomere dysfunction predisposes to pulmonary fibrosis mainly in the subpleural regions, which may be detected by high-resolution CT scan.

provides an estimate of the average telomere length of a given sample without determining telomere length in individual cells. Good DNA quality is essential for adequate qPCR testing and automation or semi-automation required for clinical purposes, as variability in conditions among batches may result in interassay variation.

GENETIC TESTING

When a patient with a suspected telomeropathy has short or very short telomeres, genetic screening for mutations in genes involved in telomere maintenance and biology is indicated (Table 469-1). Genetic testing should be restricted to patients with suspected telomere disorders. Sanger sequencing has been used for screening purposes but has been replaced by next-generation sequencing, and for telomerase complex and shelterin genes, commercial panels are available. Mutations may be biallelic or triallelic, involving two genes (especially in dyskeratosis congenita), but in most cases of aplastic anemia, myelodysplastic syndrome, acute myeloid leukemia, idiopathic pulmonary fibrosis, and hepatic cirrhosis, only one allele is mutated. Thus, it is crucial to appropriately interpret genetic screening results, as several rare singleton polymorphisms of unknown significance have been identified in large cohorts of healthy individuals. In silico analysis, mutation location, and functional studies are utilized before declaring a mutation pathogenic.

Genetic counseling is necessary after screening, as the inheritance pattern may be autosomal dominant, mutation penetrance is highly variable, and phenotypes may be diverse even within a pedigree. Potential family stem cell donors must be screened before transplantation to ensure that they do not have mutations.

TREATMENT

Telomere Disease

Patients with severe aplastic anemia due to telomere disease may undergo allogeneic hematopoietic stem cell transplant when a suitable donor is available. Treatment-related mortality may be increased due to pulmonary and hepatic complications, for which reduced-intensity conditioning regimens may be advantageous. Lung transplant for pulmonary fibrosis is feasible but often not performed due to coexisting cytopenias, especially thrombocytopenia, and other comorbidities. Additionally, patients with pulmonary fibrosis associated with telomere disease have a poorer outcome after lung transplant and with nontransplant therapies. Similarly, there is no specific treatment for the liver in telomere disease; liver transplant has been attempted in rare cases. Telomeropathy patients should be advised to avoid toxins (metal dust, busulfan, amiodarone), ionizing radiation, cigarette smoke, and alcohol as possibly harmful.

Long-term therapy with androgens may mitigate telomere attrition and even elongate leukocyte telomere length in humans. In research trials, danazol improved blood counts in marrow failure patients and reduced transfusion requirement.

470 Gene- and Cell-Based Therapy in Clinical Medicine

Katherine A. High, Marcela V. Maus

Gene therapy is a novel area of therapeutics in which the active agent is a nucleic acid sequence rather than a protein or small molecule. One of the most powerful concepts in modern molecular medicine, gene therapy has the potential to address a host of diseases for which there are currently no available treatments. Because delivery of naked DNA or RNA to a cell is an inefficient process, most gene therapy is carried out using a vector, or gene delivery vehicle. These vehicles have generally been engineered from viruses by deleting some or all of the viral genome and replacing it with the therapeutic gene of interest under the control of a suitable promoter, but nonviral delivery vehicles such as lipid nanoparticles have also been used **(Table 470-1)**. Gene therapy strategies can thus be described in terms of three essential elements: (1) a gene delivery vehicle; (2) a gene to be delivered, sometimes called the transgene; and (3) a physiologically relevant target cell to which the DNA or RNA is delivered. The series of steps in which the vector and donated DNA or RNA enter the target cell and express the transgene is referred to as *transduction*. Gene delivery can take place in vivo, in which the vector is directly injected into the patient, or, in the case of hematopoietic, immune, and some other target cells, ex vivo, with removal of the target cells from the patient, followed by return of the gene-modified autologous cells to the patient after manipulation in the laboratory. The latter approach effectively combines gene transfer techniques with cellular therapies **(Chap. 484)**.

Currently approved gene therapies rely on transfer of DNA, but investigational RNA-based therapies have gained ground rapidly, partly as a key component of CRISPR-based gene editing (guide RNAs) and, more recently, as the active agent in two SARS-CoV-2 vaccines. This chapter will focus primarily on approved therapies **(Table 470-2)**, with some discussion of investigational therapies in late-phase development and earlier trials of historical interest.

Clinical trials of gene therapy have been under way since 1990; the first gene therapy product to be licensed in the United States or Europe was approved in 2012 (see below). Given that vector-mediated gene therapy is arguably one of the most complex therapeutics yet developed, typically consisting of both a nucleic acid and a protein component, this time course from first clinical trial to licensed product is noteworthy for being similar to those seen with other novel classes of therapeutics, i.e., monoclonal antibodies. Thousands of subjects have been enrolled in gene transfer studies or have received approved products, and serious adverse events have been rare. Some of the initial trials were characterized by an overabundance of optimism and a failure to be appropriately critical of preclinical studies in animals; in addition, it was in some contexts not fully appreciated that animal studies are only a partial guide to safety profiles of products in humans (e.g., insertional mutagenesis and human immune responses to the vector). Clinical experience and laboratory research led to a more nuanced understanding of the risks and benefits of these new therapies and more sophisticated selection of disease targets. Currently, gene therapies are being developed for a variety of disease entities **(Table 470-3)**.

GENE TRANSFER FOR GENETIC DISEASE

Gene transfer strategies for genetic disease generally involve gene addition therapy, an approach characterized by transfer of the missing gene to a physiologically relevant target cell. However, other strategies are possible, including supplying a truncated form of the gene with comparable biologic activity (e.g., a gene encoding B domain-deleted factor VIII for hemophilia A); supplying a gene that achieves a similar biologic effect through an alternative pathway (e.g., utrophin in place of dystrophin for Duchenne's muscular dystrophy); supplying an antisense oligonucleotide to alter splicing of a transcript to generate a functional protein (e.g., nusinersen in the treatment of spinal muscular atrophy); or downregulating a harmful effect through a small interfering or short hairpin RNA. From a therapeutic standpoint, gene therapies for genetic disease fall into two distinct categories: first, they may provide treatment for diseases that have hitherto lacked any pharmacologic therapies; or second, they may provide an alternative to complex medical regimens that are frequently characterized by significant nonadherence due to the burden of treatment (e.g., monthly red blood cell transfusions and iron chelation in transfusion-dependent β thalassemia).

Gene therapy for genetic disease requires long-term expression of the transgene. Two distinct strategies are available to achieve this goal: one is to transduce stem cells with an integrating vector, so that all progeny cells will carry the donated gene; and the other is to transduce long-lived, postmitotic cells, such as skeletal muscle or neurons. In the case of long-lived cells, integration into the target cell genome is unnecessary. Instead, because the cells are nondividing, the donated DNA, even if stabilized predominantly in an episomal form, will give rise to expression for the life of the cell. This latter approach mitigates risks related to integration and insertional mutagenesis.

TABLE 470-1 Characteristics of Commonly Used Gene Delivery Vehicles

	VIRAL				NONVIRAL
FEATURES	RETROVIRAL	LENTIVIRAL	ADENOVIRAL	AAV	LIPID NANOPARTICLES
Viral genome	RNA	RNA	DNA	DNA	N/A
Cell division requirement	Yes	G_1 phase	No	No	No
Packaging limitation	8 kb	8 kb	8–30 kb	5 kb	10 kb or more
Immune responses to vector	Few	Few	Extensive	Few	Few
Genome integration	Yes	Yes	Poor	Poor	May be used to package either RNA or DNA
Long-term expression	Yes	Yes	No	Yes	Transient for RNA
Main advantages	Persistent gene transfer in dividing cells	Persistent gene transfer in transduced tissues; no history of insertional oncogenesis; can add desired promoter	Highly effective in transducing various tissues	Elicits few inflammatory responses, nonpathogenic	Limited immune responses against the vector
Main disadvantages	History of insertional oncogenesis (occurred in multiple cases); only used ex vivo; gene silencing	Might induce oncogenesis in some cases (not yet observed); only used ex vivo	Viral capsid elicits strong immune responses	Limited packaging capacity	Currently available reagents predominantly target the liver

Abbreviations: AAV, adeno-associated virus; N/A, not applicable.

TABLE 470-2 Currently Approved Gene and Cell Therapy Products in the United States and/or Europe

PRODUCT	INDICATION	AGE GROUP	YEAR FIRST APPROVED	WHERE APPROVED	VECTOR	TRANSGENE	TARGET TISSUE
Strimvelis®[a]	ADA-SCID	Pediatric	2016	Europe	Retroviral	*ADA* (adenosine deaminase)	Autologous hematopoietic stem cells (HSCs)
Kymriah® Tisagenlecleucel	Relapsed or refractory (R/R) B-cell acute lymphoblastic leukemia (pediatric); R/R large B-cell lymphoma (adult)	Pediatric and adult, different disease indications	2017	U.S. and Europe	Lentiviral	Chimeric antigen receptor with 4-1BB signaling domain	Autologous T cells
Yescarta® Axicabtagene ciloleucel	R/R large B-cell lymphomas	Adult	2017	U.S. and Europe	Retroviral	Chimeric antigen receptor with CD28 signaling domain	Autologous T cells
Luxturna® Voretigene neparvovec	Confirmed biallelic *RPE65* mutation-associated retinal dystrophy	Pediatric and adult	2017	U.S. and Europe	AAV	*RPE65* (retinal pigment epithelial 65-kDa protein)	Retinal pigment epithelial cells
Zolgensma® Onasemnogene abeparvovec	Spinal muscular atrophy type 1 due to biallelic mutations in the *SMN1* gene	Pediatric <2 years of age	2019	U.S. and Europe	AAV	*SMN1* (survival motor neuron 1)	Spinal motor neurons
Zynteglo® Betibeglogene autotemcel	Transfusion-dependent β thalassemia	Adult and pediatric ≥12 years of age	2019	Europe	Lentiviral	$b^{A\text{-}T87Q}$-globin gene	Autologous HSCs
Libmeldy®[b]	Metachromatic leukodystrophy due to biallelic mutations in the arylsulfatase A gene	Pediatric	2020	Europe	Lentiviral	*ARSA* (arylsulfatase A)	Autologous HSCs
Tecartus® Brexucabtagene autoleucel	R/R mantle cell lymphoma	Adult	2020	U.S.	Retroviral	Chimeric antigen receptor with CD28 signaling	Autologous T cells

[a]Autologous CD34+-enriched cell fraction that contains CD34+ cells transduced with retroviral vector that encodes for the human ADA cDNA sequence. [b]Autologous CD34+ cells encoding arylsulfatase A.

Abbreviations: AAV, adeno-associated virus; ADA-SCID, adenosine deaminase severe combined immunodeficiency.

IMMUNODEFICIENCY DISORDERS: PROOF OF PRINCIPLE FOR EX VIVO GENE TRANSFER

Early attempts to effect gene replacement into hematopoietic stem cells (HSCs) were stymied by the relatively low transduction efficiency of retroviral vectors, which require dividing target cells for integration. Because HSCs are normally quiescent, they are a formidable transduction target. However, identification of cytokines that induced cell division without promoting differentiation of stem cells, along with technical improvements in the isolation and transduction of HSCs, led to modest but real gains in transduction efficiency.

The first convincing therapeutic effect from gene transfer occurred with X-linked severe combined immunodeficiency disease (SCID), which results from mutations in the gene (*IL2RG*) encoding the γc subunit of cytokine receptors required for normal development of T and natural killer (NK) cells **(Chap. 351)**. Affected infants present in the first few months of life with overwhelming infections and/or failure to thrive. In this disorder, it was recognized that successfully transduced cells, even if few in number, would have a proliferative advantage compared to nontransduced cells, which lack receptors for the cytokines required for lymphocyte development and maturation. Isolation of autologous CD34+ cells, followed by transduction with a retroviral vector encoding the γc subunit and transplantation of the gene-modified autologous cells, led to complete reconstitution of the immune system, including documented responses to standard childhood vaccinations, clearing of infections, and remarkable gains in growth in most of the treated children. However, among 20 children treated in the initial trials, five eventually developed a syndrome similar to T-cell acute lymphocytic leukemia, with splenomegaly, rising white blood cell counts, and the emergence of a single clone of T cells. Molecular studies revealed that, in most of these children, the retroviral vector had integrated within a gene, *LMO-2* (LIM only-2), that encodes a component of a transcription factor complex involved in hematopoietic development. The retroviral long terminal repeat acted as a promoter to increase the expression of *LMO-2*, resulting in T-cell leukemia.

The X-linked SCID studies were a watershed event in the evolution of gene therapy. They demonstrated conclusively that gene therapy could cure disease, with dramatic and durable clinical results. However, they also demonstrated that insertional mutagenesis leading to cancer was more than a theoretical possibility **(Table 470-4)**. As a result of the experience in these trials, all protocols using integrating vectors in hematopoietic cells must include a plan for monitoring sites of insertion and clonal proliferation for 15 years after infusion (although to date, insertional mutagenesis has never been reported in over several thousand patient-years of experience where the transduced cell is a mature T cell rather than an HSC). Strategies to overcome this complication have included using a "suicide" gene cassette in the vector, so that errant clones can be quickly ablated, or using "insulator" elements in the cassette, which can limit the activation of genes surrounding the insertion site. The occurrence of malignancy in the X-linked SCID trials has fueled a transition to lentiviral vectors. These efficiently

TABLE 470-3 Most Common Indications in Gene Therapy Trials

INDICATION	NUMBER
Cancer	1688
Monogenic diseases	287
Infectious diseases	182

TABLE 470-4 Potential Complications of Gene Therapy

Gene silencing—repression of promoter
Genotoxicity—complications arising from insertional mutagenesis
Phenotoxicity—complications arising from overexpression or ectopic expression of the transgene
Immunotoxicity—harmful immune response to either the vector or transgene; or a harmful immune response of the vector (e.g., CAR T cells)
Risks of horizontal transmission—shedding of infectious vector into environment
Risks of vertical transmission—germline transmission of donated DNA

Abbreviation: CAR, chimeric antigen receptor.

transduce nondividing target cells and are characterized by a different pattern of integration into the genome that appears to be safer than retroviral vectors. To date, there have been no reports of tumorigenesis due to insertional events with lentiviral vectors; the field is thus gradually moving toward these to replace retroviral vectors for transduction of cells other than T cells.

Gene therapy also produced clear success for another form of SCID, that due to adenosine deaminase (ADA) deficiency **(Chap. 351)**. ADA-SCID is clinically similar to X-linked SCID, although it can be treated by enzyme replacement therapy with a pegylated form of the enzyme (PEG-ADA), which leads to immune reconstitution but not always to normal T-cell counts. Enzyme replacement therapy is expensive (annual cost: $200,000–$300,000 [U.S. dollars]), and some patients develop antibodies to PEG-ADA, reducing therapeutic efficacy. The initial trials of gene therapy for ADA-SCID were unsuccessful, but modifications of this protocol to include the use of HSCs rather than T cells as the target for transduction; discontinuation of PEG-ADA at the time of vector infusion, so that the transduced cells have a proliferative advantage over the nontransduced cells; and the use of a mild conditioning regimen to facilitate engraftment of the transduced autologous cells led to success without the complications seen in the X-linked SCID trials. This therapy (Strimvelis®) was approved in 2016 by the European Medicines Agency (Table 470-2). Recently, however, a patient who received the treatment in 2016 has been diagnosed with T-cell leukemia, and preliminary findings suggest an insertional event related to the gene therapy as the cause. Thus, although the risk of insertional mutagenesis appears to be much lower in the setting of ADA-SCID (1 patient out of 36 treated in the clinical trials or with the approved product), it is not absent. Despite this, ADA-SCID is an example where gene therapy has changed therapeutic options for patients. For those with a human leukocyte antigen (HLA)-identical sibling, bone marrow transplantation is still the best treatment option, but this includes only a minority of those affected. For those without an HLA-identical match, gene therapy has comparable efficacy to PEG-ADA, does not require repetitive injections, and does not present the risk of development of neutralizing antibodies to the bovine enzyme. Continued observation of previously treated patients may change the risk/benefit assessment and perhaps promote development of lentivirus-based vectors for the disease.

TRANSFUSION-DEPENDENT THALASSEMIA: EXTENSION OF PRINCIPLE

A goal of gene therapy is to provide therapeutic options for more prevalent diseases such as thalassemia and sickle cell disease. These red cell disorders are more challenging targets for gene therapy than the immunodeficiencies for several reasons: first, in immunodeficiency disorders, the transduced cells have a survival advantage over nontransduced cells, which is not the case in red cell disorders. Second, in order to achieve transfusion independence or freedom from vaso-occlusive crises, one must achieve higher transduction efficiency and engraftment of higher numbers of stem cells. Promising clinical data exist now for both of these conditions, and the first product for transfusion-dependent β thalassemia has been conditionally approved in Europe (Table 470-2). Standard of care for transfusion-dependent β thalassemia (TDT) consists of lifelong regular red blood cell transfusions, typically monthly, to support hemoglobin levels >9 g/dL, coupled with an intensive regimen of iron chelation to minimize iron overload to the liver, heart, and endocrine system **(Chap. 98)**. Allogeneic stem cell transplantation addresses the underlying cause of the disease but carries risks of myeloablation, graft-versus-host disease (GVHD), and graft rejection and thus is reserved primarily for those with an HLA-matched sibling donor (<25% of patients). The first approved gene therapy for β thalassemia consists of a lentiviral vector driving expression of an antisickling variant of β-globin (the same product is being developed for sickle cell disease), introduced into autologous HSCs, which are then transplanted back into the patient after myeloablation. Results of clinical trials showed that 15 of 19 patients with TDT due to genotypes other than β^0/β^0 (the most severe genotype of the disease) achieved durable transfusion independence that was maintained through follow-up ranging up to 5 years. The remaining four patients had substantial reduction in the transfusion requirement. Gene therapy with lentiviral transduction of autologous cells thus dramatically simplifies the medical regimen for these patients, since it eliminates the need for transfusion and iron chelation and carries no risk of GVHD or graft rejection because it is generated from the patient's own cells. Similarly, since the transduced cells are autologous, there is no requirement for an HLA-matched donor, expanding the numbers of patients who can be treated. Safety in the initial trials has been excellent, with most adverse events related to the known risks of the myeloablative conditioning regimen. Studies currently underway aim to achieve the higher levels of transduction, expression, and engraftment needed for patients with β^0/β^0 thalassemia and those with sickle cell disease.

Encouraging results using a gene-editing approach provide another therapeutic option for these patients. In recent trials, a CRISPR/Cas9 vector targeting the *BCL11A* gene, which normally represses γ-globin (the fetal β-like globin), was introduced into autologous CD34+ cells of patients with TDT or sickle cell disease. Results with up to 18 months of follow-up show a gradual rise in fetal hemoglobin in the circulation to levels that obviate the need for transfusion and, in sickle cell disease, the cessation of vaso-occlusive crises. The gene-editing approach still requires myeloablation to ensure engraftment of the gene-edited autologous cells. Studies designed to support licensing are underway; currently, there are no approved gene-editing products.

NEURODEGENERATIVE DISEASES: BROADENING OF PRINCIPLE

The SCID trials gave support to the hypothesis that gene transfer into HSCs could be used to treat any disease for which allogeneic bone marrow transplantation was therapeutic. Moreover, the use of genetically modified autologous cells carried the advantages noted above, i.e., no risk of GVHD, guaranteed availability of a "donor" (unless the disease itself damages the stem cell population of the patient), and low likelihood of failure of engraftment. Investigators in Paris capitalized on this realization to conduct the first trial of lentiviral vector transduction of HSCs for a neurodegenerative disorder, X-linked adrenoleukodystrophy (ALD). The key to the mechanism of action is that a subpopulation of the gene-modified cells give rise to myeloid cells that cross the blood-brain barrier and engraft as central nervous system (CNS)–resident microglia and perivascular CNS macrophages. The transduced cells carry the gene encoding the missing protein, in this case an adenosine triphosphate–binding cassette transporter. Following lentiviral transduction of autologous HSCs in young boys with the disease, dramatic stabilization of disease occurred, demonstrating that stem cell transduction could work for neurodegenerative as well as immunologic disorders.

Investigators in Milan carried this observation one step further to develop a treatment for another neurodegenerative disorder that had previously responded poorly to bone marrow transplantation. Metachromatic leukodystrophy is a lysosomal storage disorder caused by mutations in the gene encoding arylsulfatase A (ARSA). The late infantile form of the disease is characterized by progressive motor and cognitive impairment and death within a few years of onset, due to accumulation of the ARSA substrate sulfatide in oligodendrocytes, microglia, and some neurons. Recognizing that endogenous levels of production of ARSA were too low to provide cross-correction by allogeneic transplant, a lentiviral vector was engineered to direct supraphysiologic levels of ARSA expression in transduced cells. Transduction of autologous HSCs from children born with the disease, at a point when they were still presymptomatic, has led to preservation and continued acquisition of motor and cognitive milestones at time periods as long as 8 years after treatment, with observation ongoing. This product is approved in Europe for those with late infantile or early juvenile forms of the disease (Table 470-2). These results illustrate that the ability to engineer levels of expression can allow gene therapy approaches to succeed where allogeneic bone marrow transplantation cannot. It is likely that a similar approach will be used in other neurodegenerative conditions.

LONG-TERM EXPRESSION IN GENETIC DISEASE: IN VIVO GENE TRANSFER WITH RECOMBINANT ADENO-ASSOCIATED VIRAL VECTORS

Recombinant adeno-associated viral (AAV) vectors have emerged as attractive gene delivery vehicles for genetic disease. Engineered from a small replication-defective DNA virus, they are devoid of viral coding sequences and trigger very little immune response in experimental animals. They are capable of transducing nondividing target cells, and the donated DNA is stabilized primarily in an episomal form, thus minimizing risks arising from insertional mutagenesis. Because the vector has a tropism for certain long-lived cell types, such as skeletal muscle, the CNS, and hepatocytes, long-term expression can be achieved even in the absence of integration. Of note, because the donated DNA is predominantly nonintegrated, long-term expression requires targeting of nondividing or slowly dividing cells; otherwise, expression is lost as cells divide.

FIRST LICENSED PRODUCT

These features of AAV were used to develop the first approved gene therapy product in the Western world, an AAV vector conditionally approved in Europe in 2012 for treatment of the autosomal recessive disorder lipoprotein lipase (LPL) deficiency. This rare disorder (1–2 cases/million) is due to loss-of-function mutations in the gene encoding LPL, an enzyme normally produced in skeletal muscle and required for the catabolism of triglyceride-rich lipoproteins and chylomicrons. Affected individuals have lipemic serum and may have eruptive xanthomas, hepatosplenomegaly, and in some cases, recurrent bouts of acute pancreatitis, and do not respond to treatment with statins. Clinical trials demonstrated the safety of intramuscular injection of AAV-LPL and provided preliminary evidence supporting a reduction in frequency of episodes of pancreatitis. The sponsor allowed the approval to expire in 2017, without completing the postmarketing requirements, but the initial approval, demonstrating a regulatory pathway for this class of therapeutics, was a crucial catalyst for the current robust activity in gene therapy, with ongoing trials in a range of diseases including muscular dystrophies, Parkinson's disease, Huntington's disease, Pompe disease, hemophilia B and A, several forms of congenital blindness, and a variety of other inherited conditions. Currently there are two approved AAV gene therapies for genetic disease, one for a rare form of congenital blindness and the other for the fatal pediatric neurodegenerative disease spinal muscular atrophy type 1 (Table 470-2).

RETINAL GENE THERAPY

The retina is an attractive target for AAV-mediated gene transfer: It is a relatively immuneprivileged space, obviating problems related to immune responses, and the photoreceptors, retinal ganglion cells, and retinal pigment epithelial cells are long-lived postmitotic cells. Routes of administration for these cell types—either intravitreal or by subretinal injection—involve standard procedures in ophthalmology. Given the small space, doses required are relatively low, lessening the manufacturing burden. Finally, canine models of a number of inherited retinal dystrophies have been well characterized and faithfully reflect the human disease. Work carried out in the 1990s had demonstrated that the canine disease could be reversed, with durable restoration of vision, by subretinal injection of an AAV vector in dogs with a mutation in the gene encoding RPE65 (retinal pigment epithelial-associated 65-kDa protein), an enzyme key to the visual cycle. Like the canine disease, the human disease is characterized by early-onset visual impairment, with most patients progressing to blindness over time. Phase 1 clinical trials by multiple groups established the safety of subretinal injections of an AAV vector expressing *RPE65*. A phase 3 trial, the first randomized controlled trial in human gene therapy, demonstrated improvement in multiple measures of retinal and visual function. Of note, and likely to be a recurring theme as gene therapies address diseases for which there are no existing treatments, successful clinical development required the development and validation of a novel clinical endpoint, a mobility test conducted at varying levels of environmental illumination, that could measure improvements in functional vision. This product, the first licensed AAV gene therapy product in the United States, is now approved in both the United States and Europe (Table 470-2). Trials for other inherited retinal degenerative disorders such as choroideremia are underway, as are studies for certain complex acquired disorders such as age-related macular degeneration, which affects several million people worldwide. The neovascularization that occurs in age-related macular degeneration can be inhibited by expression of vascular endothelial growth factor (VEGF) inhibitors such as angiostatin or through the use of RNA interference (RNAi)–mediated knockdown of VEGF. Early-phase trials of an AAV vector designed to achieve long-term inhibition of the biologic effects of VEGF through a soluble VEGF receptor, however, failed to provide convincing evidence of efficacy, illustrating the challenges of developing genetic approaches for complex acquired disorders.

SPINAL MUSCULAR ATROPHY TYPE 1

Spinal muscular atrophy type 1 is the most common genetic cause of death in infancy and affects ~1 in 11,000 births. The disease is caused by autosomal recessive mutations in the *SMN1* gene, encoding survival motor neuron 1; affected infants undergo degeneration and loss of lower motor neurons, presenting as hypotonia, severe weakness, and failure to sit without support. In a large natural history study of untreated infants with the disease, by age 20 months, only 8% of patients with the disease were alive and free of ventilator support. In a phase 1 gene therapy study, intravenous infusion of an AAV vector (one with tropism for the nervous system [AAV9]) expressing *SMN1* showed survival without ventilator support in 100% of participants (n = 15) at 20 months of age. A phase 3 trial was initiated, but the treatment was approved in the United States based on the efficacy data from the first 21 participants enrolled in that study, coupled with the safety data from the ongoing phase 3 study and the completed phase 1 study (Table 470-2). The major safety concern was the risk of acute serious liver injury; because the vector is infused intravenously, there is considerable biodistribution to the liver (and to the spinal motor neurons, the therapeutic target). The approved dose of 1.1×10^{14} vg/kg is quite high and results in marked elevation of liver transaminases if untreated. The phase 1 study showed that this could be controlled using a course of corticosteroids begun 1 day before the vector infusion and continued for 30 days, with tapering at that point and carried out with monitoring of liver transaminases. Patients receiving the approved treatment are followed in a registry designed to assess effectiveness, long-term safety, and overall survival of patients with spinal muscular atrophy. An alternative treatment, intrathecal administration of an antisense oligonucleotide designed to increase expression of functional SMN from a mostly nonfunctional *SMN2* gene, was approved during the course of the gene therapy studies, but the efficacy data in the clinical trial were less robust, and the drug requires intrathecal administration every 4 months. Clearly, the gene therapy approach is a disease-modifying one, for a disease that previously lacked treatment. Additional follow-up in this population should address questions of long-term safety and efficacy.

GENE THERAPY FOR CANCER

The majority of clinical gene transfer experience has been in subjects with cancer. The intent has been to increase the precision of cancer therapies and thereby make them less toxic and more effective. Most approaches have either modified the tumor directly or altered the host's response to the malignancy to produce immune effector cells that are precisely targeted to the tumor phenotype.

MODIFYING THE CANCER

Since cancer is an (acquired) genetic disorder, initial efforts were directed at correcting the genetic deficits of the tumor or introducing lethal genes. Two major and persisting obstacles, however, are the poor biodistribution and transduction efficiency of all currently available vectors and the heterogeneity and genetic instability of the tumor targets themselves, so that correction of single driver mutations does not preclude the evolution of a resistant population.

Tumor Correction One widely used direct intratumoral approach was adenoviral-mediated expression of the tumor suppressor p53,

which is mutated in many different cancers. Initial studies showed some complete and partial responses in squamous cell carcinoma of the head and neck, esophageal cancer, and non-small-cell lung cancer, but as yet, there have been no successful product licensing studies for this approach except in China.

Prodrug Metabolizing Genes Efforts to overcome the above limitations have included the introduction of a prodrug or a suicide gene that would increase sensitivity of tumor cells to cytotoxic drugs. An early strategy was intratumoral injection of an adenoviral vector expressing the thymidine kinase (*TK*) gene. Cells that take up and express the *TK* gene can be killed after the administration of ganciclovir, which is phosphorylated to a toxic nucleoside by *TK*. The advantage of this approach is that the effects of transducing even a limited number of tumor cells are amplified by the spread of active drug to adjacent tumor cells. Although the approach continues to be examined in aggressive brain tumors and locally recurrent prostate, breast, and colon tumors, progress remains slow, and systemic benefits against metastatic disease have not been established.

MODIFYING THE HOST

Recruiting the Immune System The successful use of monoclonal antibodies that produce antitumor activity by activating the immune response has demonstrated the feasibility of manipulating the immune system to recognize the abnormal pattern of antigen expression on tumor cells. Immune cells are capable of almost unlimited expansion and persistence and can provide long-term tumor control. They can also traffic to tumor sites irrespective of location and, in principle, have the potential to evolve with the changing pattern of tumor cell phenotype and function. Antibodies targeting "checkpoint" molecules, particularly CTLA-4 and the PD-1/PD-L1 axis, which naturally limit T-cell responses and maintain tolerance, have been particularly successful **(Chap. 73)**.

Vaccination This strategy promotes more efficient recognition of tumor cells by the immune system, but the development of a therapeutic vaccine, as opposed to the preventative vaccines required to combat infectious diseases, has proved to be a considerable challenge. Approaches have included direct injection of tumor- or tumor antigen–derived RNA or DNA; transduction of tumor cells with immune-enhancing genes encoding cytokines, chemokines, or costimulatory molecules; and the ex vivo manipulation of dendritic cells to enhance the presentation of tumor antigens. A dendritic cell vaccine for treatment of recurrent prostate cancer has received approval in the United States, but its limited potency and high cost have constrained commercial success.

Adoptive Cell Transfer Host immune cells such as T cells, NK cells, and others can be modified to express new transgenic receptors intended to recognize tumor cells and their microenvironment **(Fig. 470-1)**. Retargeting may use a modification of the cells' own receptor or a molecularly synthesized chimeric antigen receptor (CAR) that is usually composed of the antigen recognition portion of an antibody and the signaling components of the cell's native antigen receptor along with one or more additional signaling domains that boost T-cell activation. Both approaches have been successful, with significant responses reported with native receptors targeted to melanoma and synovial cell sarcoma and—most dramatically—with CARs targeted to CD19, an antigen expressed at high levels on normal and many malignant B cells, or B-cell maturation antigen (BCMA), an antigen expressed at high levels in normal and multiple myeloma plasma cells. Infused CAR T cells can expand many thousand fold in vivo, persist long term, and have produced >80% complete response rates when targeting intractable B-cell acute lymphoblastic leukemia; approximately half of treated patients have remained in remission for many years afterward without further cancer therapies. This approach has also been successful in adult patients with relapsed or chemotherapy-refractory B cell–derived large-cell lymphoma, mantle cell lymphoma, and multiple myeloma. Many responses are sustained long term, and several of these

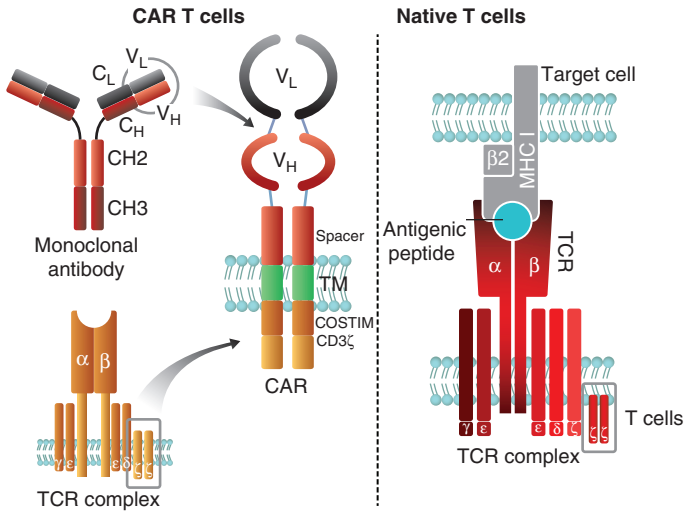

FIGURE 470-1 T-cell receptors. A native T-cell receptor (TCR) recognizes processed peptide antigens bound to major histocompatibility (MHC) molecules through its αβ chains. Signaling then occurs through a multichain intracellular CD3 complex. A chimeric antigen receptor (CAR) usually contains an extracellular receptor component derived from the antigen binding portion (V_H and V_L) of a monoclonal antibody. This produces a receptor that can recognize either protein or nonprotein antigens independent of the MHC. A transmembrane (TM) domain then connects this receptor to the ζ chain of the CD3 complex derived from the native TCR. A costimulation domain (COSTIM), such as CD28 or 4-1BB, is also present.

CAR T-cell products have been approved by the U.S. Food and Drug Administration (FDA), as well as be international regulatory agencies, and adopted as standard of care. The general approach of CAR T cells is under rapid development, including trials with CAR T cells targeting different antigens for solid tumors and other hematologic malignancies and CAR T cells with different molecular structures and different gene transfer vectors. Remaining challenges in the field and application of adoptive T-cell approaches include (1) the immune inhibitory microenvironment associated with most solid tumors; recent studies further modify the T cells with countermeasures to tumor inhibitory signals; (2) acute and severe (though rarely fatal) systemic inflammatory and neurologic toxicities during the phase of T-cell expansion and tumor killing, which typically require access to intensive care for clinical management; (3) the off-target or on-target but off-tumor effects that may damage normal host tissues (e.g., normal B cells following CD19 CAR therapy); and (4) the cost, time, and complexity of manufacture, which is a particular problem when antigens unique to each tumor's individual mutations are targeted (neoantigens), rather than widely shared tumor-associated antigens.

Nonimmunologic Modifications to Host Gene transfer can be used to protect normal cells from the toxicities of chemotherapy and thereby increase the therapeutic index of these drugs. The most extensively studied approach has been to transduce hematopoietic cells with genes encoding resistance to chemotherapeutic agents, including the multidrug resistance gene *MDRI* or the gene encoding O^6-methylguanine DNA methyltransferase (*MGMT*). Although such approaches reduce hematologic toxicity, cytotoxic dose escalation quickly reveals dose-limiting toxicities to other organ systems. Chemotherapy resistance can also be engineered into immune cells redirected to target cancer to enable combination treatments with cells and chemotherapy.

Finally, gene transfer can be used to inhibit the host angiogenesis required for tumor support, for example, by constitutive expression of inhibitors such as angiostatin and endostatin or the transfer of T cells genetically modified to recognize antigens specific to newly forming vasculature. These studies are in the early phase.

COMBINATION APPROACHES—MODIFICATION OF HOST AND TUMOR BY VIROTHERAPY

Immuno-oncolytic Viruses These viruses are genetically modified to replicate in malignant but not normal cells. The replicating

vectors thus proliferate and spread within the tumor, facilitating eventual tumor clearance. However, physical limitations to viral spread, including fibrosis, intermixed normal cells, basement membranes, and necrotic areas within the tumor, may reduce clinical efficacy, and their activity against metastatic disease has proved limited. Recently, the FDA granted licensing approval to talimogene laherparepvec, an oncolytic herpes virus containing the human granulocyte-macrophage colony-stimulating factor gene, for treatment of melanoma. This success has led to resurgent interest in combining the local tumor destruction and tumor antigen release mediated directly by oncolytic viruses with the recruitment of a systemic immune response mediated by immunostimulatory genes contained within the oncolytic virus. In principle, such immune-oncolytic viruses should produce responses in both local and metastatic disease. Numerous novel viral agents are now entering early-phase clinical testing.

OTHER APPROACHES

This chapter has focused on gene addition therapy, in which a normal gene is transferred to a target tissue to drive expression of a gene product with therapeutic effects. Another powerful technique beginning to yield dramatic clinical results is genome editing, which has the potential to correct a mutation in situ, generating a wild-type copy under the control of the endogenous regulatory signals. This approach makes use of novel reagents including zinc finger nucleases, TALENs, and CRISPR, which introduce breaks into the DNA near the site of the mutation and then rely on a donated repair sequence and cellular mechanisms for repair to reconstitute a functioning gene. Another strategy recently introduced into clinical trials is the use of small interfering RNAs or short hairpin RNAs as transgenes to knock down expression of deleterious genes (e.g., mutant huntingtin in Huntington's disease).

SUMMARY

The power and versatility of gene therapy approaches are such that there are few serious disease entities for which gene therapies are *not* under development. The development of new classes of therapeutics typically takes two to three decades; monoclonal antibodies and recombinant proteins are recent examples. Gene therapeutics, which entered clinical testing in the early 1990s, traversed the same time course. Examples of clinical success are now abundant, and gene therapy approaches are likely to become increasingly important as a therapeutic modality in the twenty-first century. A central question to be addressed is the long-term safety of gene transfer, and regulatory agencies have mandated a 15-year follow-up for subjects enrolled in gene therapy trials **(Table 470-5)**. Realization of the therapeutic benefits of modern molecular medicine will depend on continued progress in gene transfer technology.

TABLE 470-5 Taking History from Subjects Enrolled in Gene Transfer Studies

Elements of History for Subjects Enrolled in Gene Transfer Trials
1. What vector was administered? Is it predominantly integrating (retroviral, lentiviral, herpesvirus [latency and reactivation]) or nonintegrating (plasmid, adenoviral, adeno-associated viral)?
2. What was the route of administration of the vector?
3. What was the target tissue?
4. What gene was transferred in? A disease-related gene? A marker?
5. Were there any adverse events noted after gene transfer?
Screening Questions for Long-Term Follow-Up in Gene Transfer Subjects[a]
1. Has a new malignancy been diagnosed?
2. Has a new neurologic/ophthalmologic disorder, or exacerbation of a preexisting disorder, been diagnosed?
3. Has a new autoimmune or rheumatologic disorder been diagnosed?
4. Has a new hematologic disorder been diagnosed?

[a]Factors influencing long-term risk include integration of the vector into the genome, vector persistence without integration, and transgene-specific effects.

471 The Human Microbiome

Neeraj K. Surana, Dennis L. Kasper

"All disease begins in the gut."

—Hippocrates

Nearly two and a half millennia after Hippocrates made this statement, we are just coming to truly appreciate its profundity. Since the beginning of humankind, scholars have been investigating the underpinnings of disease with an almost singular focus on the human side of the equation. Microbes were not recognized as an important cause of disease until the inception of the "germ theory" in the late nineteenth century. During the first century of medical microbiology, research largely centered on the role of microbes as pathogens. Only recently has there been a resurgence of interest in understanding how commensal organisms—the bacteria, viruses, fungi, and Archaea that make up the *microbiota*—impact human physiology. The idea that these microorganisms are vital to the well-being of humans has challenged our traditional notions of "self." Indeed, a human being can most accurately be described as a *holobiont*: a complex assemblage of human cells and microorganisms interacting in an elaborate *pas de deux* that drives normal physiologic processes.

Aimed at a better understanding of this relationship, myriad studies during the past decade have begun to catalogue the microbiota at various body sites and in a multitude of disease conditions. Diseases in virtually every organ system have been associated with changes in the microbiota. Indeed, the microbiota has been linked to intestinal disorders, disturbances in metabolic function, autoimmune diseases, and psychiatric conditions and has been shown to influence susceptibility to infection and the efficacy of pharmaceutical therapies. Knowledge of the specific mechanism(s) underlying most of these microbe–disease associations is lacking; it remains unclear whether the disease-associated alterations in the microbiota represent mere biomarkers of disease, a

causal relationship, or a combination of the two. Although cause-and-effect relationships are still being elucidated for many diseases, it is clear that humans coexist in an intricate relationship with commensal organisms. This chapter explores in detail the nature of these host–commensal interactions, focusing on how this information might be translated into clinically meaningful interventions.

HISTORICAL PERSPECTIVE

Massive undertakings, such as the Human Microbiome Project (HMP) sponsored by the National Institutes of Health and MetaHIT sponsored by the European Commission, have catalogued all the bacteria present at multiple body sites in people with and without disease. Coupled with the confluence of advances in sequencing technologies **(Chap. 121)**, gnotobiotic animal availability, and microbial culture, significant progress has been made toward an understanding of the interplay between the microbiota and human health. However, recent findings were foreshadowed by work done centuries ago.

The human microbiota was first explored in 1683 when Antony van Leeuwenhoek described in a letter to the Royal Society of London the "very little living animalcules, very prettily a-moving" that he had observed in the plaque between his teeth. Leeuwenhoek went on to perform the first comparative "microbiota" studies by assessing how fecal and oral bacteria differ, how oral microbes change in the setting of disease (e.g., alcoholism and tobacco use), and how microbial composition changes across the age spectrum (e.g., in young children vs old men). He attempted—unsuccessfully—to eliminate these bacteria. Although Leeuwenhoek was not taken seriously when he first reported his findings, his studies laid the groundwork for what is now the field of microbiome research, and investigators are still trying to answer many of the same overarching questions that he raised more than three centuries ago.

Although Leeuwenhoek first reported the existence of bacteria and their association with humans at the end of the seventeenth century, the significance of commensal bacteria was not realized until late in the nineteenth century. In 1885, Pasteur suggested that animals could not survive if they were "artificially and completely deprived of the common microbes." Although Pasteur's preconceived ideas were proven incorrect in 1912 by the advent of germ-free animals (animals raised without exposure to any microorganisms), the underlying concept that commensal organisms are critical to health has held up. Élie Metchnikoff made another conceptual advance in this field by suggesting at the beginning of the twentieth century that clinical outcomes could be altered by the administration of specific beneficial organisms (*probiotics*). In particular, Metchnikoff believed that aging was caused by toxic bacteria in the gut and that lactic acid–producing bacteria (e.g., *Lactobacillus* species) present in sour milk and yogurt could mitigate against this process. The data behind this specific claim are still lacking, but recent discoveries offer continued hope that the microbiome can be effectively harnessed to protect against and treat a variety of diseases. Thus, although the field of microbiome research is sometimes considered to have emerged over the last one or two decades, the basic tenets—that the microbiota varies according to body site and clinical characteristics, that microbes are critical for human health, and that specific modulation of the microbiota may lead to improved clinical outcomes—are far from new.

A PRIMER ON TAXONOMY

Given that microbiome-based studies have identified and compared microbes at different levels of taxonomic resolution **(Fig. 471-1)**, some understanding of taxonomy is essential for better comprehension of the implications of these studies. Of the ~100 bacterial phyla that exist in nature, only five (Actinobacteria, Bacteroidetes, Firmicutes, Fusobacteria, and Proteobacteria) are dominant members of the human microbiome. Each of these phyla can be further categorized into multiple classes, orders, families, genera, and species. Early studies on the microbiota focused on changes in the relative abundance at the phylum level between different groups (e.g., obese vs normal-weight patients); however, these comparisons are at such a broad taxonomic level that they often provide little or no biologic insight. As illustrated in Fig. 471-1, drawing comparisons between organisms in two different bacterial phyla is analogous to comparing humans to sea stars: the evolutionary distance between the two is tremendous. The limitations of current bioinformatic tools require lumping together of taxonomically related strains and thus cloud the richness of microbial ecology. Examining microbial profiles at the phylum, family, or even genus level—as is often done at present—ignores the great heterogeneity within different strains of the same bacterial species. The analytical pipelines are just now beginning to enable strain-level comparisons, and these improvements will likely facilitate our ongoing investigation of host–commensal interactions.

THE MICROBIOTA AND HUMAN HEALTH

OVERVIEW OF THE HUMAN MICROBIOTA

The overwhelming majority of microbiota studies have focused on stool, given that this sample type represents the most ecologically rich anatomic site, is easy to obtain, and can readily be followed longitudinally in the same individual. A landmark study by the HMP sought to define the "normal" microbiota throughout the entire body in healthy Western adults. To this end, the microbial populations at 15–18 body sites were characterized in 242 people. One striking finding was that all samples from a given body region (e.g., skin) were more similar to each other than they were to samples from a different body region (e.g., stool), even in the same individual individual **(Fig. 471-2*A*)**. In essence, the effect of the anatomic site on microbial composition is far greater than the effect of heterogeneity between individuals. That said, there was a remarkable amount of interindividual variation at any given body site **(Fig. 471-2*B*)**. In stool, for example, the abundance of the phylum

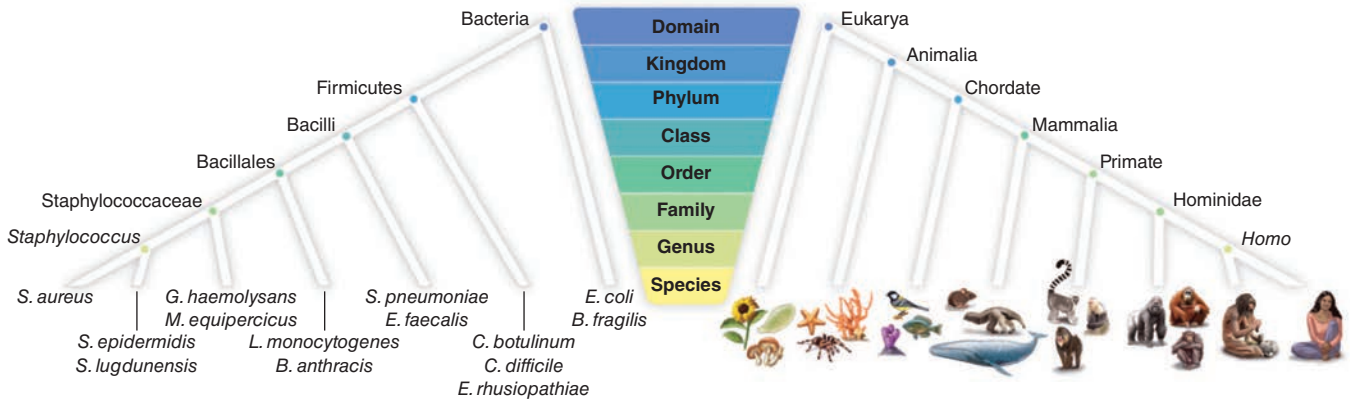

FIGURE 471-1 Juxtaposition of bacterial and human taxonomy highlights the evolutionary distance between different taxonomic levels. The listed species represent exemplars that are members of the taxon to which they are connected but that are not contained within the next-lower-level taxon listed. For example, *Clostridium botulinum*, *Clostridium difficile*, and *Erysipelothrix rhusiopathiae* are members of the phylum Firmicutes, but are in classes other than Bacilli. Similarly, starfish and humans are both members of the kingdom Animalia, but they are in different phyla.

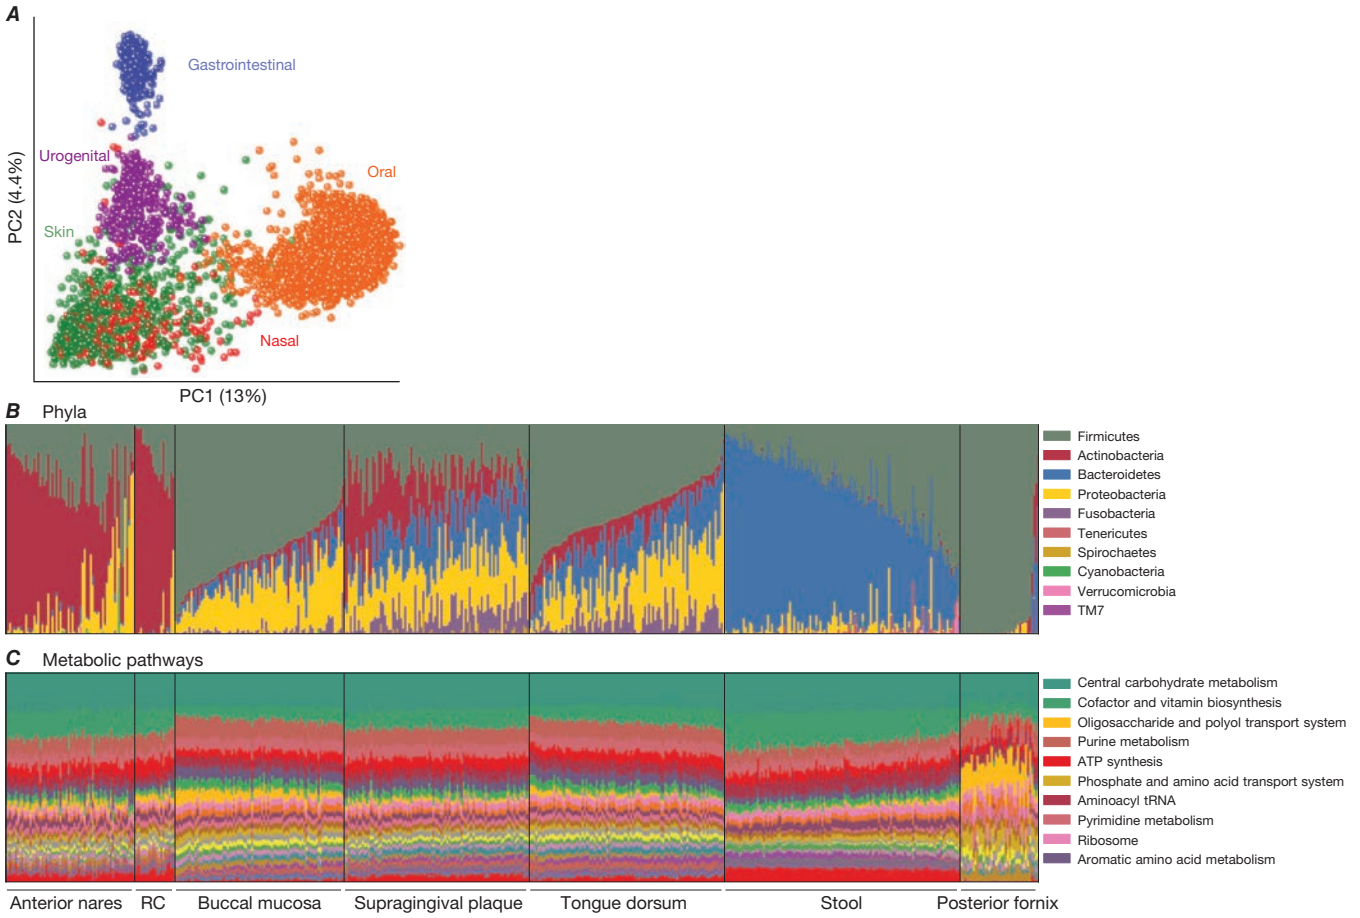

FIGURE 471-2 The human microbiome exhibits significant taxonomic variability among body sites and between individuals while maintaining core metabolic pathways. ***A.*** Principal coordinates (PC) plot showing variation among samples demonstrates that primary clustering is by body area, with the oral, gastrointestinal, skin, and urogenital habitats separate; the nares habitat bridges oral and skin habitats. Each circle represents an individual sample. ***B, C.*** Vertical bars represent microbiome samples by body habitat, with each bar within a given body site representing a different individual. Bars indicate relative abundances colored by microbial phyla (***B***) and metabolic pathways (***C***). The legend on the right indicates the most abundant phyla/pathways. RC, retroauricular crease. *(Reproduced with permission from Human Microbiome Project Consortium: Structure, function and diversity of the healthy human microbiome. Nature 486:207, 2012.)*

Bacteroidetes ranged from ~10% in some individuals to >90% in others. Remarkably, even with person-to-person variability and differences among body sites, the functional capacity of the microbiota—assessed using metagenomic data to identify gene pathways—was quite similar across different people and different body sites (Fig. 471-2*C*). This discrepancy between the substantial differences in microbial composition and the little or no resulting change in the functional properties of the microbiota reflects an important ecologic property of the microbiota: the microbial communities at different body sites and in different people assemble in such a way that all the core metabolic functions are maintained. This finding also hints at the likely possibility of significant functional redundancy within the microbiota, with different species executing the same biologic functions in different people and/or at different anatomic sites.

While the HMP provided the first large-scale catalogue of the microbiome in multiple people and at many different body sites, the amount of data generated by what, at the time, was by far the largest microbiome study has been dwarfed by subsequent studies. These more recent studies have confirmed the HMP's major tenets: the composition of the microbiota differs by body site, there is tremendous interindividual variation, and the microbial gene content is relatively conserved irrespective of the body site or individual. No microbial species are ubiquitous in all individuals and at all body sites, but some species are highly prevalent at a given body site: in the HMP study, *Staphylococcus epidermidis* was present in 93% of nares samples and *Escherichia coli* in 61% of stool samples. These findings highlight the remarkable personalization of the human microbiome. While the human genome is typically >99.5% identical in different people, the microbiotas of two individuals may not overlap at all. Although the "precision medicine" approach currently focuses on teasing out how differences in the human genome relate to different clinical end points, the human microbiome clearly represents a critical component for consideration.

THE MICROBIOTA BY THE NUMBERS

It has long been known that the human-associated microbiota is numerically dense. Leeuwenhoek estimated that there were more "animals living in the scrum on the teeth in man's mouth than there are men in a kingdom." Specific enumeration of the components of the microbiota has been challenging, in part because of its variability across time, space (body region), and clinical conditions. Moreover, the majority of human-associated microbes are not readily cultivable—a situation that raises questions about the best methodology for such quantitation. Initial back-of-the-envelope calculations performed in the 1970s suggested that there were roughly tenfold more bacteria in the body than there were human cells. This rather astounding estimate suggested that humans are really only ~10% "human" and that by far the greatest part of the holobiont is represented by microbes. This stark numerical discrepancy has prompted some to question "who parasitizes whom." However, a more recent estimate has suggested that there are "only" ~1.3 times more bacteria in the body than there are human cells and thus that humans are ~56% "bacterial." Of note, this more recent study does not include the numbers of viruses (known to generally be approximately tenfold more abundant than other microbes), fungi, or Archaea. Given these additional microorganisms, the notion that microbes constitute >90% of the cells present in a human body is likely correct. These ratios are even starker when one considers the genetic potential of human cells versus that of commensal organisms. In contrast to the ~20,000 genes in the human genome, the estimated

total number of genes in the microbiota (which together constitute the *microbiome*)—i.e., >2,000,000—indicates that the human genome contributes <1% to the total genetic potential of the overall holobiont. Most microbiome studies to date have focused almost exclusively on the bacterial component; much remains to be learned about the functional interplay of bacteria, viruses, fungi, and Archaea and how these other classes of microorganisms impact human health.

In terms of overall diversity, >10,000 different bacterial species are present in the human microbiota; the intestines alone contain >1000 species. At any given time, the body of any given individual harbors 500–1000 bacterial species, with 100–200 bacterial species in the gut alone. If one considers different strains of the same bacterial species, which may be functionally different from one another, the diversity of the microbiota is probably at least a magnitude greater. Although marked diversity exists at the strain and species level, only limited bacterial phyla are generally found in the human microbiota at any given body site **(Fig. 471-3)**.

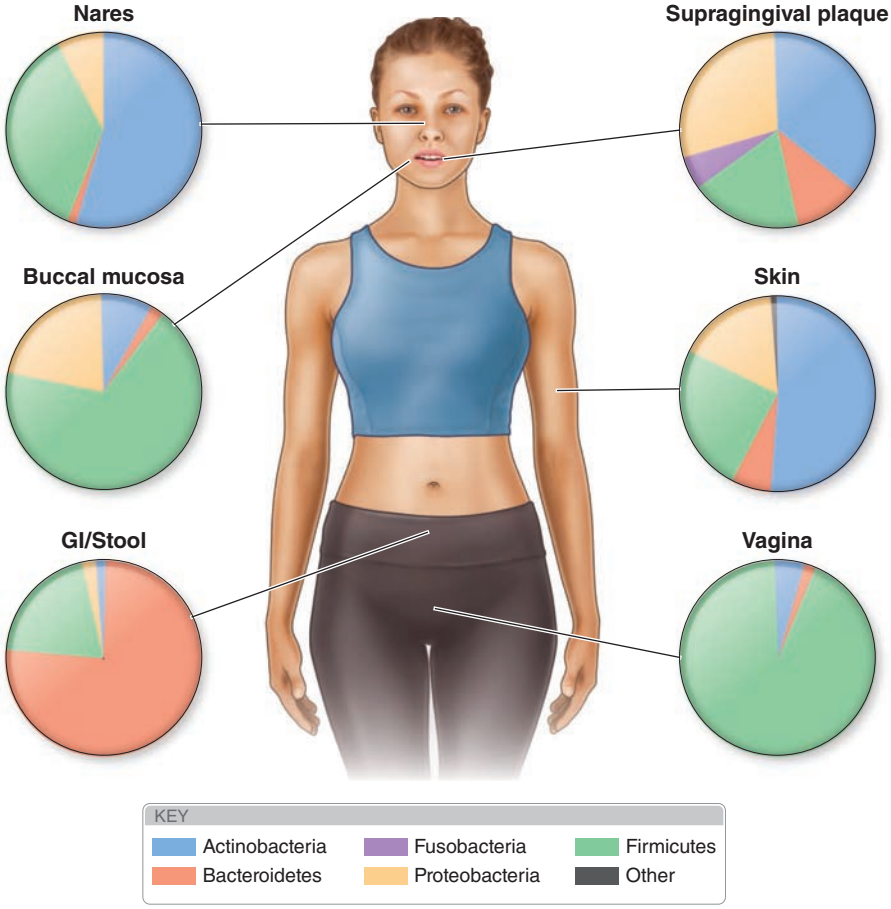

FIGURE 471-3 Different anatomic sites harbor very different microbiomes. The figure indicates the relative proportion of sequences determined at the taxonomic phylum level at six anatomic sites. *(Data for stool, vagina, nares, buccal mucosa, and supragingival plaque are from the Human Microbiome Project; data for the skin are from EA Grice et al: Topographical and temporal diversity of the human skin microbiome. Science 324:1190, 2009.)*

INFLUENCES ON THE MICROBIOTA

An individual's specific microbial configuration is dynamic and is quickly altered in response to subtle changes in the microenvironments in which the bacteria reside. On a day-to-day basis, these changes usually reflect alterations in the relative abundance of the various microbes. However, some exposures have a greater effect on the microbiota and can shift the microbial population to a new equilibrium via the loss of specific species and/or the acquisition of others; this new microbial equilibrium can be associated with either health or a disease state **(Fig. 471-4)**. Identification of the factors that influence the microbiota's composition is critical to an understanding of what leads to and controls intra- and interindividual variation. Moreover, an understanding of the influences on the microbiota will facilitate the design and proper interpretation of microbiota studies. While it is clear that the microbiota can be altered through these various mechanisms, it is not yet clear whether these changes are biologically significant.

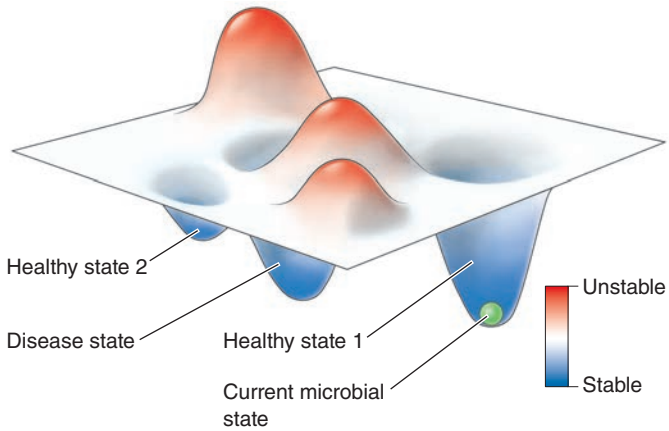

FIGURE 471-4 A stability landscape of the human microbial ecosystem. A stable state, illustrated as a depression in the landscape, can be associated with either a healthy state or a disease state. The topology of an individual's landscape reflects that person's genetics, age, diet, medications, medical history, and lifestyle. The position of the green ball represents the current microbial state. Clinical changes (e.g., administration of antibiotics, development of disease) can influence both the current state and the overall topology.

Genetics Studies of monozygotic and dizygotic twins have revealed that host genetics have a small but statistically significant effect on the microbiota's composition. Notably, some taxa, such as *Christensenella* species, are more heritable than others. A cross-sectional study of >1000 healthy individuals who have distinct ancestral origins and a relatively shared common environment confirmed a weak association between host genetics and the microbiome but highlighted that environmental factors are more prominent modulators of the microbiome. That said, the host's genetic contribution to the microbiota, albeit small, may be meaningful. Studies in mice have demonstrated that genetic variation in the major histocompatibility complex, a specific set of immune-related genes, leads to changes in the microbiota that alter susceptibility to an autoimmune disease. These studies offer a proof of concept for the notion that the genetic predisposition observed for certain diseases may actually be mediated by indirect alterations in the microbiota.

Age Burgeoning evidence now indicates that microbial exposure may begin in utero: bacterial DNA from bacteria typically associated with the oral microbiota has been identified in otherwise healthy placentas, in amniotic fluid obtained at early stages of gestation, and in meconium of term newborns. Although some controversy persists about whether these results reflect contamination and/or the presence of nonviable bacteria, they raise the possibility that human exposure to the microbial world begins before birth. The delivery mode (vaginal vs cesarean section) and the method of feeding (breast milk vs formula, timing of solid food introduction) are major determinants of an infant's

early microbiota. After birth, the infant's microbiota goes through a stereotyped succession process; with increases in bacterial diversity and functional capacity, the child's microbiota resembles that of an adult by the age of 2–3 years. Cross-sectional studies that have examined the microbiota across the entire age spectrum have revealed a general stability of the fecal microbiota after 2–3 years of age; however, the microbiota of the elderly (persons >80 years of age) demonstrates notable differences from those of their younger counterparts, with increases in *Bacteroides* and *Eubacterium* species and decreases in the bacterial family Lachnospiraceae.

Diet Diet is a strong determinant of human health. The impact of diet is mediated, in part, by its effects on the composition of the gut microbiota. This makes intuitive sense, as the human diet provides nutrients needed not only by our own cells but also by the microbes living in the alimentary tract. In young children, this dietary influence is marked by major shifts (e.g., a decrease in *Bifidobacterium* species) in the intestinal microbiota that occur at weaning and with the introduction of solid food. In adults, long-term dietary patterns are associated with relatively stable microbial compositions. However, drastic changes in short-term macronutrient availability cause rapid (within 1 day) and reproducible fluctuations in the fecal microbiota that reflect the biologic processes needed to degrade and metabolize the nutrients in the new diet. For example, vegetarian diets are associated with a microbiota that has an increased ability to metabolize plant polysaccharides (e.g., *Roseburia* species, *Eubacterium rectale*, *Ruminococcus bromii*), while animal-based diets result in an increased abundance of bile-tolerant organisms (e.g., *Alistipes*, *Bilophila*, and *Bacteroides* species). At the completion of dietary interventions and the resumption of the individual's normal dietary pattern, the microbial communities revert back to their previous states, probably because the individual resumes his or her typical diet. Taken together, dietary studies confirm that the microbiota is highly adaptable and varies in relation to changes in the diet. Of note, virtually all of these studies have focused on how the diet influences the fecal microbiota. It will be interesting to determine whether dietary changes similarly influence the microbiota at nonintestinal sites.

Drugs Virtually all drugs have the capacity to change the microbiota by altering the chemical landscape in which the microorganisms live (e.g., statins, bile acid sequestrants), modulating the host's ability to recognize and react to microbes (e.g., immunosuppressants) and/or directly interfering with the microbiota's constituents (e.g., antibiotics). These potential effects have made critical interpretation of microbiota studies much more difficult. A prominent study that claimed to identify a fecal microbiota signature associated with type 2 diabetes was later found actually to have identified a signature for patients taking metformin instead; the effects of this drug on the microbiota were far greater than the effects of the disease itself. These results highlight the importance of controlling for clinical variables in microbiota studies.

Antibiotics are the most obvious and best-studied class of drugs that modulate the microbiota. Multiple groups have demonstrated that antibiotics exert a considerable effect on the gut microbiota by depleting antibiotic-sensitive strains. What is more surprising is that many strains resistant to the antibiotic tested are also eliminated. This observation highlights the intricate microbe–microbe interactions that are fundamental to maintenance of the overall microbial community. For example, treatment with ciprofloxacin, which has little to no activity against clinically relevant anaerobes, leads to a loss of roughly one-third of the bacterial taxa in the gut. This broad effect is likely mediated by the depletion of certain "keystone" species that are required for the persistence of other, unrelated species. While many of the observed antibiotic effects (e.g., loss of specific taxa) are shared across many different individuals, some effects vary greatly among people. For example, studies found that microbiota recovery following antibiotic treatment differed significantly in terms of timing and degree. The microbiota of most healthy people who received ciprofloxacin for 5 days had completely recovered within 4 weeks, whereas microbiologic changes lasted up to 6 months in other individuals. Moreover, the degree of variation was compounded by repeated antibiotic administration, with fewer individuals reverting to their baseline microbiota after a second course of ciprofloxacin given 6 months after the first. These findings are consistent with those of microbial ecology experiments, which also showed that this type of repeated disturbance leads to less predictable results.

Lifestyle Many seemingly innocuous lifestyle decisions can impact the human microbiota. For example, a person's skin and fecal microbiotas are more similar to those of their household members, regardless of genetic relatedness, than to those of residents of different households. The degree of similarity in skin microbiotas is even greater if a dog also lives in the home; in contrast, the presence of a young child does not accentuate this microbial relatedness. The presumption is that the dog serves as a more effective "vector" for transmitting microbes during its frequent direct contact with adults in the household. The type of setting in which a person lives also impacts the microbiota. Living in a rural or farm setting leads to a different fecal microbiota than living in an urban environment. Similarly, the individual's country of residence affects the microbiota. An analysis of daily fecal samples from an individual who temporarily (i.e., for a couple of months) moved from the United States to Thailand demonstrated a large shift in the fecal microbiota that coincided with arrival in Thailand and a reversion in most respects to the "American" microbial configuration upon return to the United States. Similarly, immigration to the United States "westernizes" the microbiome of individuals coming from non-Western countries. These geography-driven changes probably reflect a combination of environmental and dietary differences between locations.

Circadian Rhythms Many human biologic processes follow a circadian clock; aspects of physiology are tuned by external cues, including the degree and timing of ambient light, temperature, and availability of nutrients. This endogenous biologic clock enables animals to efficiently adapt to changing environmental conditions. Similarly, the microbiota maintains a circadian rhythm that is linked to—and helps entrain—the host's circadian clock. If circadian oscillations are disrupted in the host, they are similarly disrupted in the microbiota, and vice versa. These bacterial vacillations occur at the level of spatial localization within the intestine, relative species abundance, and bacterial metabolite secretion. Work in the 1960s showed that mice exhibited daily periodicity of susceptibility to infection with either *Streptococcus pneumoniae* or *E. coli* lipopolysaccharide. Although the fundamental basis for this difference was not known at the time, it is likely to be related, in part, to the microbial circadian clock. Derangements of these microbial oscillations have also been linked to the development of metabolic diseases and may underlie some of the health hazards associated with shift work and jet lag.

THE MICROBIOTA AND DISEASE

THE HYGIENE HYPOTHESIS

Over the past few decades, abundant epidemiologic data have revealed an inverse correlation between exposure to microbes and the incidence of autoimmune and/or atopic diseases **(Fig. 471-5)**. This type of epidemiologic correlation led to the proposal of the "hygiene hypothesis" in 1989. Initially, this hypothesis focused on the development of atopic diseases in young children, with the idea that these epidemiologic observations could "be explained if allergic diseases were prevented by infection in early childhood, transmitted by unhygienic contact with older siblings, or acquired prenatally from a mother infected by contact with her older children."[1] In fact, this notion that differences in living conditions and environmental exposures contribute to susceptibility to hay fever (*summer catarrh*) dates back to at least the early nineteenth century. The hygiene hypothesis has continued to evolve over the past three decades and now posits that inadequacies in microbial exposure—in combination with genetic susceptibilities—lead to a collapse of the normally highly coordinated, homeostatic immune response. At its core, the hygiene hypothesis holds that specific early-life microbial

[1]D Strachan: BMJ 299:1259, 1989.

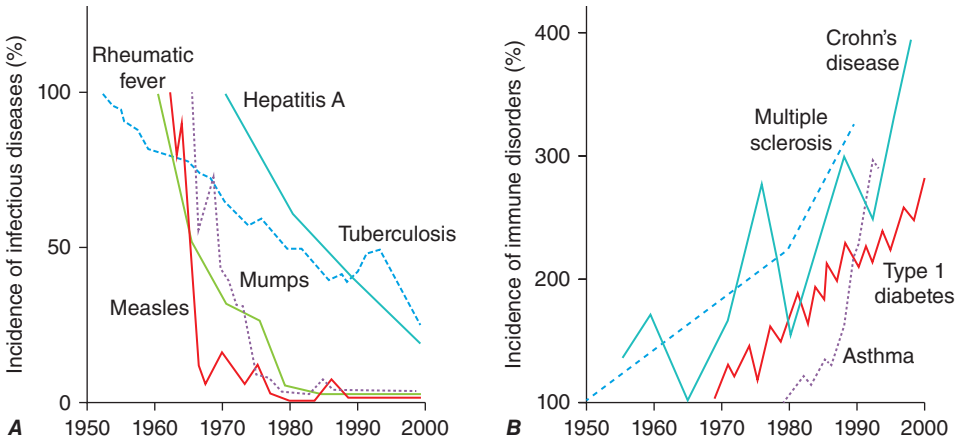

FIGURE 471-5 There was an inverse relationship between the incidence of select infectious diseases and the incidence of autoimmune disorders during the latter half of the twentieth century. *A*. Relative incidence of prototypical infectious diseases from 1950 to 2000. ***B***. Relative incidence of select autoimmune disorders from 1950 to 2000. *(From JF Bach: The effect of infections on susceptibility to autoimmune and allergic diseases. N Engl J Med 347:911, 2002. Copyright © 2002, Massachusetts Medical Society. Reprinted with permission from Massachusetts Medical Society.)*

exposures are required to prevent subsequent disease and that the "westernization" of society has led to a decrease in such exposures. This concept is now being applied beyond atopic diseases to other inflammatory and autoimmune diseases and is thought to reflect processes that occur in later life as well.

RELATIONSHIP BETWEEN THE MICROBIOTA AND SPECIFIC DISEASE STATES

The ideas inherent in the hygiene hypothesis—in sum, that microbial exposure can affect long-term health outcomes—laid the theoretical foundation for translational microbiome studies. While most of the studies described earlier sought to describe how the microbiota responds to specific and often transient influences (e.g., a course of antibiotics, dietary interventions, travel), a multitude of studies have characterized the microbiota in patients with various diseases in the hope that a better understanding of the nature of disease-specific microbial communities will provide insight into disease pathogenesis and potentially uncover novel treatment modalities. Remarkably, virtually all of these studies have demonstrated differences between the microbiotas of healthy controls and patients, irrespective of the specific disease process examined. Although it is difficult to generalize across all studies, a couple of general themes have emerged. First, disease states are typically associated with microbiotas that are less diverse than those of healthy individuals. This loss of diversity can be measured either as a decrease in the number of species (*alpha diversity*; often measured as the number of operational taxonomic units or amplicon sequence variants, which are the bioinformatic equivalent of species) or as a reduction in the microbial relatedness of the species present (*beta diversity*). Often, both alpha and beta diversity decrease in the setting of disease. Second, states of inflammation—regardless of site or underlying disease process—are often associated with a relative increase in the abundance of the bacterial family Enterobacteriaceae and a decrease in the abundance of Lachnospiraceae.

Dissecting Correlation and Causality Given that most of these investigations have been designed as case-control studies, it is difficult to determine whether microbiologic findings are the cause or the effect of the disease. Even studies that examine treatment-naïve patients at the time of initial diagnosis are still confounded by this "chicken or egg" issue. Moreover, prospective, longitudinal clinical studies—still rare in the microbiome field—may simply yield correlations between the microbiome and subclinical disease rather than necessarily proving causality. Experiments in animals—specifically, studies using gnotobiotic mice (germ-free mice that have been colonized with specified microbial communities)—have been critical in this regard as they allow investigation of specific differences in microbial components while controlling for the host's genetics, diet, and housing conditions. Moreover, human microbes can be transplanted into gnotobiotic mice to permit in-depth mechanistic studies of how these microbial communities affect disease pathogenesis. This marriage of human samples and animal experiments has facilitated the identification of causal roles played by some microbes in disease pathogenesis; these findings provide a critical proof of concept for the interplay of the microbiota with human health. However, the vast majority of microbiome studies are still at the level of correlation. The next several sections describe the clinical and animal data for many different disease processes. Given the voluminous and rapidly changing nature of this field, it is impossible to cover all of the disease associations known to date; rather, the following discussion represents a combination of the leading exemplars of microbiome data and nascent areas of significant clinical interest. In all cases, the hope is that further study of the role of the microbiota will provide novel diagnostics, new therapeutic modalities, and/or additional insight into disease pathogenesis.

Gastrointestinal Diseases Given that the intestines harbor the largest number and greatest diversity of organisms in the body, much work has focused on how the microbiota impacts gastrointestinal diseases. Even though the luminal surface area of the gastrointestinal tract is 30–40 square meters (~90% of which is contained within the small intestine) and features marked anatomic and functional differences that result in many discrete macro- and micro-ecosystems, stool is often used as a surrogate for the intestinal microbiota given the relative ease of collecting samples. A few studies that have compared the microbial profile in stool with the mucosa-adherent organisms present in biopsy samples have demonstrated that stool is, in fact, a reasonable proxy for biopsy samples; however, the relative microbial "noise" present in stool can sometimes overwhelm the "signal," making biopsy samples more informative for some scientific questions. The key issue is to ensure that the biopsy samples evaluated represent relatively similar intestinal regions, as there are significant differences between the organisms present in the crypt and the tip of the villus and between microbes found in the ascending versus the descending colon.

OBESITY Obesity is a worsening epidemic throughout the world, and multiple studies have linked the composition of the intestinal microbiota to the development of obesity in animal models and in humans. Indeed, many of the initial translational microbiome studies performed in mice at the beginning of the twenty-first century focused on obesity. These early studies suggested that the ratio of the relative abundance of Bacteroidetes to Firmicutes was lower in obese mice than in control animals. Moreover, a causal relationship between the microbiota and obesity was established by the finding that gnotobiotic mice colonized with the microbiota from obese individuals had more rapid and more extensive weight gain than gnotobiotic mice colonized with the microbiota from lean individuals. Biologically, it is posited on the basis of metagenomic surveys that the obesity-associated microbiome has an increased capacity to harvest energy from the diet. Notably, the relationship between the Bacteroidetes/Firmicutes ratio and obesity did not hold in initial human studies; however, the finding that this ratio increased in obese patients who lost weight while on a fat- or carbohydrate-restricted diet suggested some generalizability between mice and humans. Beyond this ratio of major bacterial phyla, obesity was linked to a microbiome with a lower alpha diversity. Over the past ~15 years, numerous human studies examining the relationship between the microbiome and obesity have been completed, all with mixed results. A recent meta-analysis of 10 studies including nearly 3000 individuals revealed an apparent lack of relationship between the Bacteroidetes/Firmicutes ratio and obesity,

though there is ~2% lower diversity associated with obesity that is statistically significant but of unclear biologic significance. This finding highlights a problem common to microbiome studies: i.e., there is no sense as to what magnitude of change is biologically meaningful. Ultimately, although murine studies have indicated a causal link between the microbiota and obesity, the human data are less convincing, and their significance may be limited because the studies primarily examined only high-level taxonomic information rather than also assessing transcriptional or metabolic differences.

The rise in obesity has elicited a plethora of ideas about the type of diet that might be most successful in leading to sustained weight loss. It has become clear that the same dietary ingredient can have highly diverse effects on blood glucose measurements in different people and that this effect is mediated largely by the microbiome. These observations suggest that the "optimal" diet needs to be individualized in the context of the person's microbiome, which itself may continue to change over the course of the diet. An intriguing parallel question is whether the microbiota may also influence dietary preferences; such an influence would suggest important feedback loops between the microbiome and diet.

MALNUTRITION Representing the other end of the metabolic spectrum from obesity, malnutrition is also linked to an altered microbiome. Analysis of Malawian twin pairs (≤3 years of age) who were discordant for kwashiorkor—a severe form of malnutrition—revealed that kwashiorkor is associated with a microbiologically "immature" fecal microbiota that resembles that of a chronologically younger child. Transplantation of the fecal microbiota from these discordant twins into gnotobiotic mice that were fed a diet similar in composition to a typical Malawian diet established that the kwashiorkor-associated microbiome is causally related to poor weight gain. Subsequent studies demonstrated these same general trends in malnourished Bangladeshi children. Investigators were able to identify five bacterial species (*Faecalibacterium prausnitzii*, *Ruminococcus gnavus*, *Clostridium nexile*, *Clostridium symbiosum*, and *Dorea formicigenerans*) that—when administered together as a "cocktail" to mice colonized with a kwashiorkor-associated microbiome—were able to prevent growth impairments. Moreover, children with moderate acute malnutrition fed therapeutic food purposefully designed for its ability to alter the microbiota in defined manners have altered serum biomarkers consistent with improved growth. These results demonstrate that rationally designed modulation of the microbiota may lead to improved health outcomes.

INFLAMMATORY BOWEL DISEASE Ulcerative colitis and Crohn's disease, the two predominant forms of inflammatory bowel disease (IBD), are chronic gastrointestinal inflammatory conditions that differ in their locations and patterns of inflammation **(Chap. 326)**. The following observations have led to the suggestion that IBD is the result of an immune response to a dysbiotic microbiota in a genetically susceptible individual: genes account for only ~20% of susceptibility to IBD (and many of the relevant genes are related to host–microbe interactions), antibiotic treatment reduces the clinical severity of disease, and relapses of Crohn's disease are prevented by diversion of the fecal stream. While the microbiota clearly is not the only driver of disease, it is considered to be an important element. Accordingly, numerous animal and clinical studies have been designed to tease out the nature of the relationship between the microbiota and IBD.

Most of these studies have focused on comparing the microbiome's composition in IBD patients with that in healthy controls, concentrating on microbial diversity and specific bacterial taxa that are associated with health or disease. Unfortunately, few, if any, results have been universally obtained, probably because of differences in study design, inclusion criteria, and methodology (e.g., the use of stool, rectal swabs, or biopsy samples; the choice of sequencing primers; the analysis pipeline). Even with these differences among studies, patients with IBD have been shown typically to have reduced alpha and beta diversity in their fecal microbiotas. Moreover, *Clostridium* clusters IV and XIVa, which are polyphyletic and encompass several different bacterial families, are generally reduced in patients with IBD. *F. prausnitzii* is a notable example from *Clostridium* cluster IV that is often underrepresented in the stool of patients who have Crohn's disease, with more mixed results in biopsy samples. The bacterial family Lachnospiraceae, which is largely contained in *Clostridium* cluster XIVa, and other butyrate-producing organisms are also reduced in the stool of patients with IBD. Some of these species produce butyrate by using acetate generated by other members of the microbiome, and some of these acetate-producing species are similarly reduced (e.g., *Ruminococcus albus*). These complex interactions and dependencies among bacterial species pose unique challenges to definitive ascertainment of the cause–effect relationships between microbes and disease. Even before researchers were able to assess the entire microbiome at once, they often noted that patients with Crohn's disease had a higher representation of adherent invasive *E. coli* in the ileal mucosa, an observation consistent with the increased abundance of Enterobacteriaceae seen in more recent microbiome studies. Beyond bacteria, burgeoning evidence supports a role for Caudovirales bacteriophages in IBD pathogenesis, though these findings may merely reflect the underlying dysbiosis related to the loss of bacterial diversity in IBD. Moreover, some data suggest that IBD is also associated with fungal dysbiosis; several studies have demonstrated an increased ratio of Basidiomycota to Ascomycota. It is still unclear whether any of these microbial associations reflect the cause of IBD or merely serve as biomarkers of disease.

Studies of antibiotic-treated mice and gnotobiotic mice colonized with IBD-associated microbiotas have been useful in confirming that the microbiota affects colitis severity. Several bacterial species have been identified as either promoting colitis in mice (e.g., *Klebsiella pneumoniae*, *Prevotella copri*) or protecting against it (e.g., *Bacteroides fragilis*, *Clostridium* species); however, these organisms do not always correlate with the taxa identified as differentially abundant across multiple clinical studies. In contrast, IgA-coated commensal organisms isolated from patients with IBD promote more severe colitis in mice than either IgA-uncoated bacteria from patients with IBD or IgA-coated bacteria from healthy controls. These data suggest that functional categorization of the microbiota based on immune recognition (e.g., IgA coating) may be a useful approach for identifying pathogenic organisms.

Cardiovascular Disease Inflammation helps drive the pathogenesis of atherosclerosis, and it has long been postulated that microbes are involved in the atherosclerotic process. Early work demonstrated that patients with cardiovascular disease have higher titers of antibody to *Chlamydia pneumoniae* than control patients, that *C. pneumoniae* is present within atherosclerotic lesions, and that *C. pneumoniae* can both initiate and exacerbate atherosclerotic lesions in animal models. This type of analysis has been extended to other bacteria, such as *Porphyromonas gingivalis*, with the idea that multiple different bacteria may play some role in the pathogenesis of atherosclerosis.

More recent studies have demonstrated clinical correlations between serum levels of trimethylamine *N*-oxide (TMAO) and atherosclerotic heart disease. Given that red meat, eggs, and dairy products are important sources of carnitine and choline (both precursors of TMAO), it is not surprising that levels of TMAO are higher in omnivores than in vegans. Animal studies have confirmed that transfer of the gut microbiota from atherosclerosis-susceptible strains of mice to atherosclerosis-resistant animals leads to increased serum levels of TMAO and a dietary choline-dependent increase in atherosclerotic plaques; this observation confirms the role of the gut microbiota in the generation of TMAO and atherosclerosis. Moreover, treatment of atherosclerosis-susceptible strains of mice with a structural analogue of choline that inhibits the first enzymatic step in TMAO formation leads to decreased circulating TMAO levels and, more importantly, restrains macrophage foam-cell formation and atherosclerotic lesion development. In a study of >4000 patients, plasma TMAO levels were also predictive of incident thrombosis risk (myocardial infarction, stroke). Gnotobiotic animals were used to demonstrate that this risk was dependent on the microbiota; although eight bacterial taxa were identified as being associated with both plasma TMAO levels and thrombotic risk, organisms with choline-utilization genes that represent the first step

of TMAO production were not more abundant in animals at greater risk for thrombosis. This discrepancy highlights the complexity of the microbiota and suggests that other aspects of the overall dynamics of the microbial community may be in play.

Oncology Recent studies exploring the link between the microbiota and cancer have demonstrated that specific members of the microbiota can affect treatment efficacy in both a positive and a negative manner. For example, therapy with antibody to programmed cell death ligand 1 (anti-PD-L1) has proven highly effective for a number of different cancers **(Chap. 73)**; however, a significant proportion of patients do not respond even when their tumors have high PD-L1 expression levels, a prerequisite for this type of checkpoint blockade inhibition. Three groups have independently performed clinical studies—sometimes coupled with gnotobiotic mouse experiments to verify causal relationships—to demonstrate that specific bacteria can potentiate checkpoint blockade inhibition in melanoma, non-small-cell lung cancer, and renal cell carcinoma. Intriguingly, these groups identified different bacteria (*Bifidobacterium*, *Faecalibacterium*, and *Akkermansia* species) as being associated with the anticancer effects, even when the same oncologic process was being studied. The biologic factors driving these differences are not yet clear but may relate to differences in adjunctive therapies, geography, and/or other as-of-yet unidentified factors. Although these seemingly disparate findings raise concern about the generalizability of microbiome studies, it may be that identifying relevant bacterial species—as opposed to their bioactive molecules—does not offer sufficient granularity for comparison across studies.

In a separate set of studies, the efficacy of therapy with antibody to cytotoxic T lymphocyte–associated antigen 4 (anti-CTLA-4) was associated with T-cell responses specific for either *Bacteroides thetaiotaomicron* or *B. fragilis*. In particular, administration of *B. fragilis* to germ-free or antibiotic-treated mice restored the normally absent anticancer response to anti-CTLA-4 therapy. While these examples demonstrate potentiation of anticancer therapies by the microbiota, other therapies can be antagonized. Some cancers, such as pancreatic ductal adenocarcinoma, contain intratumoral bacteria, particularly Gammaproteobacteria, that can metabolize the chemotherapeutic agent gemcitabine and thereby contribute to the drug resistance of these tumors. Overall, these examples highlight the microbiota's critical impact—both direct and indirect—on the efficacy of drugs. Many other notable examples have been described (e.g., involving cyclophosphamide, digoxin, levodopa, and sulfasalazine), and many more likely remain to be discovered.

The application of microbiome science to hematopoietic stem cell transplantation (HSCT) is an area of expanding interest, particularly given the significant morbidity and mortality related to graft-versus-host disease (GVHD). In light of studies in the 1970s showing that germ-free mice developed less frequent and less severe gut GVHD than wild-type mice, clinicians began to use antibiotics to decontaminate the gut of patients undergoing HSCT. This decontamination approach yielded mixed results, probably because of differences in the antibiotic regimens used. The natural history of patients undergoing allogeneic HSCT includes a substantial loss of diversity in the fecal microbiota, intestinal domination (≥30% abundance in the fecal microbiota) by *Enterococcus* species and other pathogens, and increased mortality. Moreover, a retrospective analysis of ~850 patients undergoing allogeneic HSCT revealed that receipt of imipenem-cilastatin or piperacillin-tazobactam for neutropenic fever was associated with increased GVHD-related mortality at 5 years; this observation suggested that specific bacteria may help protect against GVHD-related mortality. More detailed analyses revealed an association between the abundance of *Blautia* species and protection against GVHD and mortality, though this correlation is still being examined with regard to its causal relationship. Despite significant interest in examining these microbial relationships with HSCT, little has yet been studied in the context of solid organ transplantation, which likely represents the next frontier of transplantation-related microbiome investigation.

Autoimmune Diseases The dramatic rise in the incidence of many autoimmune diseases over the past few decades has been far more rapid than can be explained simply by genetic factors (Fig. 471-5). It is increasingly thought that environmental triggers, including the microbiome, are partially responsible for the development of these autoimmune diseases.

TYPE 1 DIABETES Type 1 diabetes (T1D) is an autoimmune disorder characterized by T cell–mediated destruction of insulin-producing pancreatic islets **(Chap. 403)**. There is a clear genetic predisposition for the disease: ~70% of patients with T1D have human leukocyte antigen (HLA) risk alleles. However, only 3–7% of children with these risk alleles actually develop disease, an observation that suggests a role for other environmental factors. Studying a prospective, densely sampled, longitudinal cohort of at-risk, HLA-matched children from Finland and Estonia, investigators detailed changes in the microbiota prior to development of disease. Although only 4 of the 33 children studied developed T1D within the time frame of the study, a marked decrease of ~25% in alpha diversity occurred after seroconversion but before disease diagnosis. The low number of cases in this study unfortunately precluded identification of any specific disease-associated taxa. A follow-up study compared the microbiomes of a larger cohort of these high-risk northern European children with those of low-risk Russian children who lived in geographic proximity. *Bacteroides* species were more abundant in the high-risk group than in the low-risk group, particularly at early ages. This difference was postulated to be associated with an altered structure of the bacterial lipopolysaccharide to which children were exposed at a young age. It was further suggested that *Bacteroides*-derived lipopolysaccharide was not able to provide the immunogenic stimulus necessary to prevent T1D. These two studies offer attractive—though logistically complicated—options for future clinical investigations aimed at exploring the role of the microbiome. The first approach—longitudinally following individuals who are at high risk for a given disease—may provide insight into host–microbe relationships by mapping temporal changes in the microbiome with disease onset. An important caveat with this type of study, though, is that the associations identified may reflect preclinical disease rather than specifically indicating causality for any observed changes. The second approach illustrates how careful selection of study participants may offer an opportunity to uncover more meaningful associations that can subsequently be experimentally verified.

RHEUMATOID ARTHRITIS Similar to many other autoimmune diseases, rheumatoid arthritis (RA) is a multifactorial disease that comes to clinical attention after an environmental factor triggers symptoms in an individual with preexisting autoantibodies. Multiple lines of evidence support the notion that RA pathogenesis is reliant on the microbiota, including the findings that germ-free mice do not develop symptoms in several RA models and that antibiotic treatment of mice mitigates against RA development. Several taxa (e.g., *Bacteroides* species, *Lactobacillus bifidus*, and segmented filamentous bacteria) have been implicated in promoting RA in murine models, and analysis of the fecal microbiota of patients with newly diagnosed RA has indicated that *P. copri* is a biomarker of disease. That this association with *P. copri* does not exist for chronic, treated RA or for psoriatic arthritis suggests some specificity for new-onset RA. A major limitation of this approach is that the identified association is shown to be a biomarker of disease (and, in this case, potentially of response to treatment), but no added insight is gained into a possible causal relationship between *P. copri* and RA. In fact, many of the patients with new-onset RA had no *Prevotella* detected, and several of the healthy controls had significant levels of *Prevotella*. The lack of a strict concordance between the presence (or absence) of a specific taxon and a given disease state argues against a possible causal role.

MULTIPLE SCLEROSIS Epidemiologic studies of twin pairs and at-risk individuals moving between high- and low-risk geographic areas indicate that genetics plays a minor component in multiple sclerosis (MS) susceptibility relative to environmental factors. For example, in monozygotic twin pairs in which one sibling has MS, the other sibling also develops MS in only ~30% of cases. Although MS is a disease of the central nervous system (CNS), there is growing evidence of a link between MS and the microbiota, specifically that of the gut. Germ-free

animals and antibiotic-treated animals display reduced disease incidence and severity in an MS model. Similarly, some clinical studies suggest improved disease outcomes in patients with MS who have been treated with minocycline, while patients treated with long-term penicillin appear to have an increased disease risk. Although several studies have compared the fecal microbiotas of healthy controls to those of patients with MS, these studies have all been relatively small and have yielded few results (if any) that are common throughout. Although work relating the microbiome to MS is ongoing, it has opened the door to exploring this link with other neurologic diseases. Already, there are animal data demonstrating links between the microbiota and both Parkinson's disease and autism, and there are clinical data assessing fecal microbiomes in relation to a variety of neurologic conditions. It is not quite clear how the gut microbiota is communicating with the CNS—i.e., whether communication takes place via bacterial metabolites that travel in the bloodstream and cross the blood-brain barrier, via migration of whole organisms into the CNS, or via feedback through the vagus nerve. Emerging data suggest that a subset of enteroendocrine cells in the intestinal epithelium is synaptically connected to the CNS, which may provide another means for the gut microbiota to impact neurologic function. Although our understanding of this brain-gut axis is still in its infancy, research in this area has elicited tremendous excitement as a tractable approach to potential treatments for these challenging diseases.

Atopic Diseases The incidence and prevalence of allergic diseases continue to steadily increase, as do more severe clinical presentations. Life-threatening food allergies are now such a public health issue that nut-free classrooms are the norm in many cities. The development of allergic diseases often follows a stereotyped progression that begins with atopic dermatitis (AD) and continues, in order, with food allergy, asthma, and allergic rhinitis. The microbiome has been linked to all of these conditions and has the potential to modulate effects anywhere along this spectrum.

ATOPIC DERMATITIS The skin is the largest organ in the body, and its different anatomic sites (e.g., antecubital fossa, volar forearm, alar crease) represent distinct ecologic niches and harbor unique microbial communities. Moreover, given that the skin serves as a critical interface between the body and the external environment (e.g., microbes), it must be able to respond to unwanted microbes with an adequate immune response. AD is an inflammatory skin disorder involving immune dysfunction and a dysbiotic skin microbiota that is typically marked by greater abundances of *Staphylococcus aureus* and a lesser degree of bacterial diversity. Effective treatment of AD does not require complete elimination of *S. aureus* but is associated with restoration of the normal level of diversity. It is likely that this increase in bacterial diversity reestablishes normal immune homeostasis in the skin; specific members of the skin microbiota have been shown to induce protective skin-restricted immune responses. Coagulase-negative staphylococci (CoNS; primarily *S. epidermidis* and *S. hominis*) obtained from lesional and nonlesional skin of patients with AD were functionally screened and compared to CoNS from healthy controls; AD-lesional CoNS were much less often able to produce antimicrobial peptides (lantibiotics) directed against *S. aureus*. To demonstrate that these lantibiotic-producing CoNS were biologically relevant, they were incorporated into a lotion and applied to the arms of patients with AD. Surprisingly, a single application of the probiotic-laced lotion led to a decrease in the abundance of *S. aureus* recovered; no such decrease was observed when lantibiotic-negative strains were used. The authors of this study did not specifically comment on the clinical improvement of the AD lesions. Nevertheless, this is one of a limited number of studies that is beginning to extend microbiome-related findings into clinical trials.

ASTHMA Asthma is characterized by the clinical triad of airflow obstruction, bronchial hyperresponsiveness, and inflammation in the lower respiratory tract. Although the long-standing dogma was that the lungs are sterile, there is now convincing evidence for a constant ebb and flow of bacteria within the lower airways. In healthy states, the mucociliary escalator continually eliminates these bacteria soon after they land in the airways; in disease states (e.g., cystic fibrosis, chronic obstructive pulmonary disease), these bacteria establish long-term colonization of the airways and influence disease pathogenesis. In asthma specifically, both fecal and airway microbes have been linked to clinical outcomes.

Early studies of the microbiome's influence on asthma used culture-based methods to assess the hypopharyngeal microbiota of asymptomatic 1-month-old infants. Intriguingly, in one study, early-life colonization with *S. pneumoniae*, *Haemophilus influenzae*, *Moraxella catarrhalis*, or a combination of these organisms—but not *S. aureus*—was significantly associated with persistent wheeze and asthma at 5 years of age. Eosinophilia and total IgE levels at 4 years of age were also increased in children who were neonatally colonized with these organisms. Although this study examined a fairly focused set of bacteria, it laid the experimental groundwork indicating that early-life microbial exposures influence subsequent development of asthma. A later longitudinal investigation of the fecal microbiota in a general-population birth cohort of >300 children demonstrated that lower abundances of the genera *Lachnospira*, *Veillonella*, *Faecalibacterium*, and *Rothia* at 3 months of age were associated with an increased risk for development of asthma. The fact that these bacterial changes were no longer apparent when the children were 1 year of age is consistent with the notion that microbial exposures early in life are important to disease pathogenesis later in life. Transplantation of stool samples from 3-month-old children at risk for asthma into gnotobiotic mice resulted in significant airway inflammation in a murine model of asthma; pre- and postnatal exposure of mice to a four-species cocktail (*F. prausnitzii*, *Veillonella parvula*, *Rothia mucilaginosa*, and *Lachnospira multipara*) inhibited airway inflammation, with a marked reduction in neutrophil numbers in bronchoalveolar lavage fluid. These data suggest that early-life modulation of the microbiome may be an effective strategy to help prevent asthma, though the specific logistics (e.g., strains, dose, timing of exposure, patient selection) remain to be clarified.

Infectious Diseases The increased susceptibility of antibiotic-treated mice to infection with a wide range of enteric pathogens was initially observed in the 1950s and led soon thereafter to the concept of *colonization resistance*, which holds that the normal intestinal microbiota plays a critical role in preventing colonization—and therefore disease production—by invading pathogens. Seminal work in the 1970s demonstrated that this protection is largely reliant on anaerobic gram-positive organisms, and the subsequent half-century has been spent trying to identify the specific microbes involved. Although much of the work relating the microbiota to infection has focused on enteric pathogens, the intestinal microbiota has also been clearly linked to bacterial pneumonia in mouse models, and changes in the microbial composition of the gut have been causally related to changes in the severity of disease. Although this gut-lung axis clearly exists in animals, its relevance in humans is still unclear. Several groups are beginning to study the human lung microbiome in the context of pneumonia and tuberculosis. Moreover, the relationships between the microbiota and both systemic infections (e.g., HIV infection, sepsis) and the response to vaccination are starting to be explored.

ENTERIC INFECTIONS *Clostridium difficile* infection (CDI) represents a growing worldwide epidemic and is the leading cause of antibiotic-associated diarrhea **(Chap. 134)**. Roughly 15–30% of patients who are successfully treated for CDI end up with recurrent disease. The strong association between antibiotic exposure and CDI initially raised the idea that the microbiota is inextricably linked to acquisition of disease, presumably because of the loss of colonization resistance. Consistent with the epidemiologic data, characterization of the fecal microbiota of patients with CDI revealed that it is a markedly less diverse, dysbiotic community. Fecal microbiota transplantation (FMT)—the "transplantation" of stool from a healthy individual into patients with disease—was successfully used in the 1950s to treat four patients with severe CDI and has recently been demonstrated in numerous studies to be an effective therapy for recurrent CDI, with clinical cure in 85–90% of patients (as detailed below). Thus, FMT for recurrent CDI has become the "poster child" for the idea that microbiome-based

therapies may transform the management of many diseases previously considered to be refractory to medical therapy. Although FMT is agnostic as to the underlying mechanism of protection, work is ongoing to identify specific microbes and host pathways that can protect against CDI. Studying mice with differential susceptibilities to CDI due to antibiotic-induced changes in their microbiota, investigators identified a cocktail of four bacteria (*Clostridium scindens*, *Barnesiella intestihominis*, *Pseudoflavonifractor capillosus*, and *Blautia hansenii*) that conferred protection against CDI in a mouse model. Intriguingly, treatment of mice with just *C. scindens* offered significant, though not complete, protection in a bile acid–dependent manner. Clinical data from patients who underwent HSCT also associated *C. scindens* with protection from CDI, an observation that suggests the possibility of translating these findings from mice to humans. This study provides another example of the identification of relevant bacterial factors through examination of microbial differences in populations that differ in disease risk.

Microbiome-related changes associated with *Vibrio cholerae* infection include a striking loss of diversity (largely due to *V. cholerae* becoming the dominant member of the microbiota) and an altered composition that rapidly follows the onset of disease. These changes, which occur in a reproducible and stereotypical manner, are reversible with treatment of the disease. This recovery phase involves a microbial succession that is similar to the assembly and maturation of the microbiota of healthy infants. In addition to *V. cholerae*, streptococcal and fusobacterial species bloom during the early phases of diarrhea, and the relative abundances of *Bacteroides*, *Prevotella*, *Ruminococcus/Blautia*, and *Faecalibacterium* species increase during the resolution phase and mark the return to a healthy adult microbiota. Analysis of these microbial changes occurring in patients with cholera and in healthy children led to the selection of 14 bacteria that were transplanted into gnotobiotic mice, which were then challenged with *V. cholerae*. Bioinformatic analysis of specific taxa changing during cholera determined that *Ruminococcus obeum* restrained *V. cholerae* growth. Subsequently, this relationship was experimentally confirmed, and the *R. obeum* quorum-sensing molecule AI-2 (autoinducer 2) was found to be responsible for restricting *V. cholerae* colonization via an unclear mechanism. These studies highlight the potential for use of microbiome-based therapies to prevent and/or treat infectious diseases. Moreover, they suggest that temporal analysis of longitudinal microbiome data may be an effective strategy for identifying microbes with causal relationships to disease.

HIV INFECTION The augmentation of HIV pathogenesis by some viral, bacterial, and parasitic co-infections suggests that a patient's underlying microbial environment can influence the severity of HIV disease. Moreover, it has been hypothesized that the intestinal immune system plays a significant role in regulating HIV-induced immune activation; this seems particularly likely since the intestines are an early site for viral replication and exhibit immune defects before peripheral CD4+ T-cell counts decrease. Several studies have examined the intestinal microbiotas of HIV-infected individuals. Initial studies performed in nonhuman primates infected with simian immunodeficiency virus found no alteration in the bacterial components of the fecal microbiota; however, there were profound changes in the enteric virome. In contrast, many recent studies exploring this issue in patients have identified substantial differences in the HIV-associated fecal microbiota that correlate with systemic markers of inflammation. Curiously, these microbial changes do not necessarily normalize with antiretroviral therapy; this finding suggests that the microbiota may have some "memory" of the previously high HIV loads and/or that HIV infection helps reset the "normal" microbiota. This memory-like capacity of the microbiota has been demonstrated in animal models in the context of other infections and in response to dieting.

Given that the majority of new HIV transmission events follow heterosexual intercourse, there has been significant interest in examining the relationship between the vaginal microbiota and HIV acquisition. A longitudinal study of South African adolescent girls who underwent high-frequency testing for incident HIV infection facilitated the identification of bacteria that were associated with reduced risk of HIV acquisition (*Lactobacillus* species other than *L. iners*) or with enhanced risk (*Prevotella melaninogenica*, *Prevotella bivia*, *Veillonella montpellierensis*, *Mycoplasma*, and *Sneathia sanguinegens*). In mice inoculated intravaginally with *Lactobacillus crispatus* or *P. bivia*, the latter organism induced a greater number of activated CD4+ T cells in the female genital tract, a result suggesting that the increased risk of HIV acquisition associated with *P. bivia* may be secondary to the increased presence of target cells. In a separate study, the composition of the vaginal microbiota was shown to modulate the antiviral efficacy of a tenofovir gel microbicide. Although tenofovir reduced HIV acquisition by 61% in women who had a *Lactobacillus*-dominant vaginal microbiota, it reduced HIV acquisition by only 18% in women whose vaginal microbiota comprised primarily *Gardnerella vaginalis* and other anaerobes. This difference in efficacy was due to the ability of *G. vaginalis* to metabolize tenofovir faster than the target cells can take up the drug and convert it into its active form, tenofovir diphosphate. These findings illustrate how microbial ecology can be an important consideration in choosing effective treatment regimens.

RESPONSE TO VACCINATION Second only to the provision of clean water, vaccination has been the most effective public health intervention in the prevention of serious infectious diseases. Its effects are mediated by antigen-specific antibodies and, in some cases, effector T-cell responses. Although vaccines are clearly effective on a population scale, the magnitude of the immune response to vaccines can vary among individuals by tenfold to a hundredfold. Although many factors (e.g., genetics, maternal antibody levels, prior antigen exposures) can affect vaccine immunogenicity, the microbiota is now recognized as another important factor. Analysis of the fecal microbiotas of ~50 Bangladeshi children identified specific taxa that exhibited positive associations (e.g., *Actinomyces*, *Rothia*, and *Bifidobacterium* species) and negative associations (e.g., *Acinetobacter*, *Prevotella*, and staphylococcal species) with responses to vaccines against polio, tuberculosis (bacille Calmette-Guérin), tetanus, and hepatitis B. A study of infants from Ghana revealed an inverse relationship between the fecal abundance of Bacteroidetes and a response to the rotavirus vaccine. Moreover, the nasal microbiota has been implicated as a factor that contributes to the IgA response to live, attenuated influenza vaccines. These correlations based on clinical data have been partially confirmed in animal studies. The best example is the demonstration that the responses to non-adjuvanted viral subunit vaccines (inactivated influenza and polio vaccines) are reliant on the microbiota, whereas the responses to live or adjuvanted vaccines (live attenuated yellow fever, Tdap/alum, an HIV envelope protein/alum vaccine) are not. A causal role for the microbiome influencing vaccine-induced immunity in humans was demonstrated by comparing microneutralization titers following the inactivated influenza vaccine in individuals treated with or without antibiotics, although an antibiotic-dependent effect was only present in subjects who had low levels of preexisting immunity to influenza. These data suggest that the microbiota may serve as an adjuvant for certain vaccine types and in naïve populations. Confirmation of these findings in clinical settings may suggest ways to improve vaccine efficacy in the future.

MECHANISMS OF MICROBIOME-MEDIATED EFFECTS

As highlighted in the examples above, numerous associations have been made between the microbiome and various disease states. These correlations have often been established at broad taxonomic levels, with little or no insight into causality. Given that most clinical studies of these relationships have a fairly small sample size (often <100) and are simultaneously comparing numerous variables (i.e., each of the bacterial species in the microbiota is effectively a different feature being compared), many of these studies may not be adequately powered and therefore may yield false-positive results. Testing of these correlations in animal models of disease has been critical in demonstrating a causal relationship between microbes and specific phenotypes. Because microbiome-wide association studies typically result in a long list of

bacterial taxa that are correlated with a disease, it has been challenging to know which organism to test further in mechanistic studies. Moreover, even if a specific bacterial species is identified in these analyses, there is potentially enough strain-to-strain variation that the "functional" isolate may need to be recovered from the individuals studied; a publicly available representative of the species may not confer the same phenotype.

Despite all these difficulties, a handful of specific microbes have now been linked to disease effects; some examples have been mentioned above. The next layer of challenges relates to identification of the specific mechanisms that underlie these causal relationships. Successes along these lines have been more limited, but approaches are being developed to tackle the issue of defining specific bacterial factors and metabolites that are responsible for the phenotypic changes. Complicating factors are that many organisms, particularly those in the phylum Firmicutes, are not readily genetically tractable and that many of the phenotypes are not easy to assess with high-throughput screening.

BACTERIAL FACTORS

B. fragilis polysaccharide A (PSA) is perhaps the best-studied commensal-derived molecule that has been demonstrated to influence disease outcomes in mouse models. PSA—one of at least eight capsular polysaccharides expressed by *B. fragilis*—has a unique zwitterionic structure that incorporates both a positive and a negative charge within each repeating unit. Studies in which mice have been treated either with isogenic strains of *B. fragilis* that differ in PSA expression or with purified PSA have shown that PSA confers protection—prophylactically and therapeutically—against experimental colitis and MS. PSA is recognized by Toll-like receptor 2 on antigen-presenting cells, particularly plasmacytoid dendritic cells, and—in the setting of inflammation—induces interleukin 10 (IL-10)–producing regulatory T cells (Tregs) that help restrain inflammation.

B. fragilis is also the source of the only other microbiota-based bacterial factor identified thus far: an immunomodulatory glycosphingolipid that affects the numbers of invariant natural killer T (iNKT) cells. It is not clear whether these glycosphingolipids activate or inhibit iNKT cells; results have been discordant, probably because different glycosphingolipid species have been tested. Analysis of a specific purified glycosphingolipid (Bf717) demonstrated that it inhibits endogenous iNKT cell agonists in vitro and in vivo. Treatment of neonatal mice with Bf717 leads to a decreased number of colonic iNKT cells in adulthood and to improved outcomes in a model of colitis.

BACTERIAL METABOLITES

The use of mass spectrometry to detect and profile tens of thousands of different metabolites present in different bodily fluids has offered the promise of deeper insight into microbially mediated processes that underlie disease susceptibility. However, the fact that the overwhelming majority of these metabolites are not annotated, coupled with the sheer volume of data generated, has so far limited the general utility of these untargeted approaches. Instead, interest in more targeted approaches has increased, with a current emphasis on examining the role of short-chain fatty acids (SCFAs) and bile acids.

Short-Chain Fatty Acids Several groups have demonstrated that SCFAs, the intestinal levels of which are largely determined by bacterial metabolism, are important for the induction of Tregs, though there is not agreement on which specific SCFA (propionate, acetate, or butyrate) is most relevant. Wild-type mice colonized with bacteria known to induce colonic Tregs have elevated cecal levels of SCFAs. Colonization with any of three *Bacteroides* species (*B. caccae*, *B. massiliensis*, and *B. thetaiotaomicron*) increases levels of acetate and propionate, whereas colonization with *Parabacteroides distasonis* or a mix of 17 human-derived *Clostridium* species elevates levels of all three SCFAs. In all of these cases, though, the SCFAs inhibit histone deacetylase, with a consequent increase in Foxp3 expression. Notably, microbe-induced SCFA production has not been shown to be critical for Treg induction by any of these organisms. In contrast, there appears to be no correlation between SCFA levels and Treg numbers in mice monocolonized with various Treg-inducing bacterial species. Taken together, these data suggest important heterogeneity in the mechanisms underlying Treg development and do not rule out the possibility of other, redundant mechanisms for Treg induction. In addition to effects on Tregs, SCFAs also promote the epithelial barrier, impact cell proliferation (directionality depends on the specific cell type and SCFA), regulate host metabolism, and provide an energy source to colonocytes.

Bile Acids Bile acids are produced in the liver but then are metabolized by intestinal bacteria to form deconjugated and secondary bile acids. These microbially produced bile acid profiles act through complex signaling pathways to balance the metabolism of lipids and carbohydrates and to affect immune responses. Therefore, bile acids are now being investigated as microbial metabolites that are critical to maintaining human health. As mentioned above, *C. scindens* helps protect mice against CDI through a bile acid–dependent process. Alterations in bile acid profiles due to underlying microbial dysbiosis have also been associated with hepatic and colonic inflammation, hepatic cellular carcinoma, colorectal cancer, and impaired gut motility. Almost all of these relationships have been documented at the level of correlation and, at best, reflect a partial change in phenotype in the setting of bile acid sequestrants (e.g., cholestyramine). Work is ongoing to determine causal relationships between bacterial metabolism of bile acids and changes in host physiology, though the most definitive evidence is that microbe-produced bile acid metabolites influence Treg homeostasis.

Other Bacterial Metabolites Although most work has thus far focused on SCFAs and bile acids, a few notable examples of other bacterial metabolites have been implicated in maintaining health. The microbiota metabolizes tryptophan into various products (e.g., kynurenine, indole and its derivatives) that influence immune function, metabolic diseases, and neuronal function, among other things. Taurine enhances NLRP6 inflammasome–induced colonic IL-18 secretion, while histamine, spermine, and putrescine suppress IL-18 secretion. Desaminotyrosine produced by *Clostridium orbiscindens* confers protection from influenza by inducing type I interferon activity. In both of these cases, the microbiota was initially shown to influence the phenotype, with either untargeted metabolomics or a more targeted screen indicating a potential role for the indicated metabolites. Given the thousands of different bacterial metabolites throughout the body, many more metabolites will undoubtedly be linked to health and disease.

MOVING MICROBIOME SCIENCE FROM BENCH TO BEDSIDE

The numerous microbiome–disease associations identified thus far have generated a great deal of hope that understanding the relevant microbe–host interactions will open the door to unlimited therapeutic applications. Microbiome-based therapies offer several potential benefits. Patients often view such treatment as more "natural" than conventional drug therapy and are therefore more likely to comply with it. Biologically, microbiome-based therapies are more likely to address one of the root causes of disease (microbial dysbiosis) rather than simply affecting the downstream sequelae. Finally, a given microbiome-based therapy may serve as a "polypill" that is effective against several different diseases stemming from similar microbial changes. Despite tremendous interest in therapeutically exploiting the microbiome, there have thus far been few clinical successes along these lines.

The most successful therapeutic application of microbiome science has been the use of FMT, particularly for CDI. As mentioned earlier, FMT involves "transplanting" stool from a healthy individual to a diseased patient, with the idea that the "healthy" microbiota will correct whatever derangement may exist in the ill patient and therefore will alleviate symptoms. Fundamentally, this notion is agnostic as to the specific microbial dysbiosis and holds that any healthy microbiota will be curative. The idea of FMT dates back to at least the fourth century, when traditional Chinese doctors used a "yellow soup" (fresh human fecal suspension) to successfully treat food poisoning and severe

diarrhea. The continued use of FMT through the centuries for the treatment of diarrheal illnesses in both humans and animals, along with the growing appreciation in recent years of the importance of the microbiota, laid the groundwork for using FMT to treat CDI. Since the first major prospective trial assessing FMT for recurrent CDI in 2013, most of the numerous studies of FMT for CDI have demonstrated remarkable efficacy, with an average clinical cure rate of ~85%. The donor stool can be fresh or frozen (use of the latter allows biobanking of samples from a limited number of prescreened donors) and can be administered via nasogastric tube, nasoduodenal tube, colonoscopy, enema, or oral capsules; the cure rate is slightly higher with lower-gastrointestinal administration than with upper-gastrointestinal treatment. The optimal screening, preparation, and concentration of infused donor stool have not yet been determined, and there have been cases of antimicrobial-resistant pathogens transmitted by FMT that have led to mortality. The most common adverse effects of FMT include altered gastrointestinal motility (with constipation or diarrhea), abdominal cramps, and bloating, all of which are generally transient and resolve within 48 h. Although controlled studies of the use of FMT in immunosuppressed patients do not yet exist, meta-analyses of case reports and case series have found no serious FMT-related adverse events in >300 immunocompromised patients.

The successful use and the favorable short-term safety profile of FMT for CDI have led to its expanded application for other indications. At the end of 2020, >350 trials (listed at *ClinicalTrials.gov*) were investigating the efficacy of FMT for a range of indications, including CDI, IBD (ulcerative colitis and Crohn's disease), obesity, eradication of multidrug-resistant organisms, anxiety and depression, cirrhosis, and type 2 diabetes. The few published studies regarding indications other than CDI have generally included small sample sizes and have offered mixed results. In contrast to the successes in CDI, the results have been more varied for patients with IBD, which is perhaps the second-best-studied indication. It is not clear whether these discrepancies are due to heterogeneity in recipients (e.g., in terms of underlying disease mechanisms or endogenous microbiotas), the donor material, and/or the logistical details of FMT administration (e.g., route, frequency, dose). However, these results demonstrate that—under the right circumstances—modulation of the microbiota can be an effective therapy for IBD.

Although FMT offers an important proof of concept that microbiome-based therapies can be effective, treatment is difficult to standardize across large populations because of variability among stool donors and among the endogenous microbiotas of recipients. In addition, FMT is fraught with safety concerns, and its mechanisms of action are unclear. FMT likely represents the first generation of microbiome-based therapies; subsequent generations will include the use of more refined bacterial cocktails, single strains of bacteria, or bacterial products and/or metabolites as the therapeutic intervention. The field of probiotics has a complicated history: many different strains have been tested against a multitude of diseases. Several meta-analyses have combined results across bacterial strains and/or disease indications and have generally concluded that the data are not yet convincing enough to support the use of the tested regimens. It should be noted that the tested organisms have been chosen mainly on the basis of their presumed safety profile rather than in light of a plausible biologic link to disease. The hope is that more focused, mechanistic microbiome studies will identify specific commensal organisms—and their underlying mechanisms of action—that are involved in disease pathogenesis and that will serve as the basis for the next wave of rationally chosen probiotics, a few of which are currently in clinical trials. The main hurdle in this endeavor has been identifying specific microbes that are causally related to protection from disease.

PERSPECTIVE

The medical view of microbes has changed radically, moving from the early-twentieth-century notion that we are engaged in a constant struggle with microbes—an "us-versus-them" mentality that focused on the necessity of eradicating bacteria—to the more recent understanding that we live in a carefully negotiated state of détente with our commensal organisms. Instead of holding a simple view of microbes as enemies to be eliminated with antibiotics, scientists are increasingly recognizing the critical role these organisms play in maintaining human health; loss of these host–microbe interactions in the increasingly sterile environment typical of Western civilization may have predisposed to the increased incidence of autoimmune and inflammatory diseases. The field of microbiome research has made great strides over the past decade in cataloguing the normal microbiota and is now on the cusp of being able to identify clinically actionable microbe–host relationships.

The recent explosion of "–omics" technologies (e.g., metagenomics, metatranscriptomics, metabolomics) has enabled the generation of vast amounts of data, but it is not yet clear how best to integrate data sets in order to gain useful insights into host–microbe relationships. The use of FMT has demonstrated that modulation of an individual's microbiota can effectively treat certain diseases; however, models with which to predict specifically how a microbiota will change after modulation—and what potentially untoward effects these changes might have—are still lacking. Implicit in this limitation is our ignorance about what microbial configuration is optimal and how a given microbiota should be rationally altered to obtain an ideal outcome.

Despite initial hyperbolic hype and a few false starts, microbiome research now stands at the forefront of an ability to treat the fundamental basis of many diseases. As the field continues to mature, it will need to move beyond correlations and address causation. The identification of causal microbes and their mechanisms of action will create a "microbial toolbox" from which relevant bioactive strains can be chosen on a per-patient basis to correct specific underlying microbial dysbioses. In the near future, our knowledge base regarding the microbiome and its relationship to health and disease will be robust enough that this information can be applied in making important treatment decisions.

472 Global Issues in Medicine

Joseph J. Rhatigan, Paul Farmer

WHY GLOBAL HEALTH?

Global health has emerged as an important field within medicine. Some scholars have defined global health as the field of study and practice concerned with improving the health of all people and achieving health equity worldwide, with an emphasis on addressing transnational problems. No single review can do much more than identify the leading problems in applying evidence-based medicine in settings of great poverty or across national boundaries. However, this is a moment of opportunity: only relatively recently have persistent calls for global health equity been matched by an unprecedented investment in addressing the health problems of poor people worldwide. To ensure that this opportunity is not wasted, we must strengthen health systems and improve health care delivery to address the true burden and distribution of disease. This chapter introduces the major international bodies that address health problems; identifies the more significant barriers to improving the health of people who to date have not, by and large, had access to modern medicine; and summarizes population-based data on the most common health problems faced by people living in poverty. Examining specific problems—notably HIV/AIDS **(Chap. 202)** but also tuberculosis **(Chap. 178)**, malaria **(Chap. 224)**, Ebola **(Chap. 210)**, and key "noncommunicable" chronic diseases (NCDs)—helps sharpen the discussion of barriers to prevention, diagnosis, and care as well as the means of overcoming them. This chapter closes by discussing global health equity, drawing on notions of social justice that once were central to international public health but had fallen out of favor during the last decades of the twentieth century.

A BRIEF HISTORY OF GLOBAL HEALTH INSTITUTIONS

Concern about illness across national boundaries dates back many centuries, predating the Black Plague and other pandemics. One of the first organizations founded explicitly to tackle cross-border health issues was the Pan American Sanitary Bureau, which was formed in 1902 by 11 countries in the Americas. The primary goal of what later became the Pan American Health Organization was the control of infectious diseases across the Americas. Of special concern was yellow fever, which had been running a deadly course through much of South and Central America and halted the construction of the Panama Canal. In 1948, the United Nations formed the first truly global health institution: the World Health Organization (WHO). In 1958, under the aegis of the WHO and in line with a long-standing focus on communicable diseases that cross borders, leaders in global health initiated the effort that led to what some see as the greatest success in international health: the eradication of smallpox. Naysayers were surprised when the smallpox eradication campaign, which engaged public health officials throughout the world, proved successful in 1979 despite Cold War tensions.

At the International Conference on Primary Health Care in Alma-Ata (in what is now Kazakhstan) in 1978, public health officials from around the world agreed on a commitment to "Health for All by the Year 2000," a goal to be achieved by providing universal access to primary health care worldwide. Critics argued that the attainment of this goal by the proposed date was impossible. In the ensuing years, a strategy for the provision of selective primary health care emerged. This strategy included four inexpensive interventions collectively known as GOBI: *g*rowth monitoring, *o*ral rehydration, *b*reast-feeding, and *i*mmunizations for diphtheria, whooping cough, tetanus, polio, tuberculosis, and measles. GOBI later was expanded to GOBI-FFF, which also included *f*emale education, *f*ood, and *f*amily planning. Some public health figures saw GOBI-FFF as an interim strategy to achieve "health for all," but others criticized it as a retreat from the bolder commitments of Alma-Ata.

The influence of the WHO waned during the 1980s. In the early 1990s, many observers argued that, with its vastly superior financial resources and its close—if unequal—relationships with the governments of poor countries, the World Bank had eclipsed the WHO as the most important multilateral institution working in the area of health. One of the stated goals of the World Bank was to help poor countries identify "cost-effective" interventions worthy of public funding and international support. At the same time, international financial institutions encouraged many of those nations to reduce public expenditures in health and education in order to stimulate economic growth as part of (later discredited) policies imposing restrictions as a condition for access to credit and assistance through the World Bank, the International Monetary Fund, and regional development banks. There was a resurgence of many diseases—including malaria, trypanosomiasis, and schistosomiasis—in Africa. Tuberculosis, an eminently curable disease, remained the world's leading infectious killer of adults. Half a million women per year died in childbirth during the last decade of the twentieth century, and few of the world's largest philanthropic or funding institutions focused on global health equity.

HIV/AIDS, first described in the medical literature in 1981, precipitated a change. In the United States, the advent of this newly described infectious killer marked the culmination of a series of events that dashed previous hopes of "closing the book" on infectious diseases. In Africa, which would emerge as the global epicenter of the pandemic, HIV disease strained tuberculosis control programs, and malaria continued to claim as many lives as ever: at the dawn of the twenty-first century, these three diseases alone killed nearly 6 million people each year. New research, new policies, and new funding mechanisms were called for. The past two decades have seen the rise of important multilateral global health financing institutions such as the Global Fund to Fight AIDS, Tuberculosis, and Malaria; bilateral efforts such as the U.S. President's Emergency Plan for AIDS Relief (PEPFAR); and private philanthropic organizations such as the Bill & Melinda Gates Foundation. With its 193 member states and 150 country offices, the WHO remains important in matters relating to the cross-border spread of infectious diseases and other health threats. In the aftermath of the epidemic of severe acute respiratory syndrome in 2003, the WHO's International Health Regulations—which provide a legal foundation for that organization's direct investigation into a wide range of global health problems, including pandemic influenza, in any member state—were strengthened and brought into force in May 2007.

Even as attention to and resources for health problems in poor countries grow, the lack of coherence in and among global health institutions may undermine efforts to forge a more comprehensive and effective response. The WHO remains underfunded despite the ever-growing need to engage a wider and more complex range of health issues, such as the Ebola outbreak of 2013–2016 in West Africa. This may be what some have called "the golden age of global health," but leaders of major global health organizations must work together to design an effective architecture that will make the most of opportunities to link new resources for and commitments to global health equity with the emerging understanding of disease burden and the unmet need to create robust and resilient national health systems. To this end, new and old players in global health must invest heavily in *discovery* (relevant basic science), *development* of new tools (preventive, diagnostic, and therapeutic), and modes of *delivery* that will ensure the equitable provision of health products and services to all who need them.

The adoption of the Sustainable Development Goals (SDGs) in 2015 by the United Nations serves as an example of effective cooperation. The SDGs articulate 17 overarching goals across several domains to

be achieved by 2030. Goal 3 specifically relates to global health and contains 13 distinct targets to be met, including reducing maternal and child mortality; ending the epidemics of HIV, tuberculosis, and malaria; and reducing the burden of NCDs.

Included in the SDGs is a commitment to achieve universal health coverage (UHC), providing universal access to high-quality essential health services at an affordable cost worldwide. Championed by the WHO, the World Bank, and many civil society organizations, Goal 3 will measure coverage of 16 essential health services and assess the financial burden of health spending by households in every country.

THE ECONOMICS OF GLOBAL HEALTH

Political and economic concerns have often guided global health interventions. As mentioned, early efforts to control yellow fever were tied to the completion of the Panama Canal. However, the precise nature of the link between economics and health remains a matter for debate. Some economists and demographers argue that improving the health status of populations must begin with economic development; others maintain that addressing ill health is the starting point for development in poor countries. In either case, there is increasing consensus that investments in health care delivery and the control of communicable diseases lead to increased productivity. The question is where to find the necessary resources to start the predicted "virtuous cycle."

During the past two decades, spending on health in poor countries has increased dramatically. According to a study from the Institute for Health Metrics and Evaluation (IHME) at the University of Washington, total development assistance for health worldwide grew to $38.9 billion in 2018—up from $5.6 billion in 1990, but down 3.3% from 2017. In 2018, the leading contributors included the United States, the United Kingdom, and other private philanthropy, with the largest channels of funding being nongovernmental organizations (NGOs) and U.S. bilateral aid agencies. It appears that the growth of development assistance for health has plateaued: from 2013 to 2018, its annualized growth rate was –0.3%, and it is unclear whether its growth will resume in the future.

MORTALITY AND THE GLOBAL BURDEN OF DISEASE

Refining metrics is an important task for global health: only relatively recently have there been solid assessments of the global burden of disease. The first study to look seriously at this issue, conducted in 1990, laid the foundation for the first report on *Disease Control Priorities in Developing Countries* and for the World Bank's 1993 World Development Report *Investing in Health*. Those efforts represented a major advance in the understanding of health status in developing countries. *Investing in Health* has been especially influential: it familiarized a broad audience with cost-effectiveness analysis for specific health interventions and with the notion of disability-adjusted life years (DALYs). The DALY, which has become a standard measure of the impact of a specific health condition on a population, combines absolute years of life lost and years lost due to disability for incident cases of a condition. (See **Fig. 472-1** and **Table 472-1** for an analysis of the global disease burden by DALYs.)

In 2012, the IHME and partner institutions began publishing results from the Global Burden of Diseases, Injuries, and Risk Factors Study 2010 (GBD 2010). GBD 2010 is the most comprehensive effort to date to produce longitudinal, globally ambitious, and comparable estimates of the burden of diseases, injuries, and risk factors. This report reflects the expansion of the available data on health in the poorest countries and of the capacity to quantify the impact of specific conditions on a population. It measures current levels and recent trends for major diseases, injuries, and risk factors worldwide. The GBD 2010 team revised and improved the health-state severity weight system, collated published data, and used household surveys to enhance the breadth and accuracy of disease burden data. Updated reports were released in 2013, 2015, and 2017. As analytic methods and data quality improve, important trends can be identified in a comparison of global disease burden estimates from 1990 to 2017.

GLOBAL MORTALITY

Of the 55.9 million deaths worldwide in 2017, 19% (10.4 million) were due to communicable diseases, maternal and neonatal conditions, and nutritional deficiencies—a marked decrease compared with figures for 1990, when these conditions accounted for 32% of global mortality. Among the fraction of all deaths related to communicable diseases, maternal and neonatal conditions, and nutritional deficiencies, 75% occurred in sub-Saharan Africa and southern Asia. While the proportion of deaths due to these conditions has decreased significantly in the past decade, there has been a dramatic rise in the number of deaths from NCDs, which increased between 2007 and 2017 by 23%. The leading cause of death worldwide in 2017 was ischemic heart disease, accounting for 8.9 million deaths (16% of total deaths). In high-income countries, ischemic heart disease accounted for 17% of total deaths, and in low- and middle-income countries, it accounted for 7% and 17%, respectively. It is noteworthy that ischemic heart disease was responsible for just 5% of total deaths in sub-Saharan Africa **(Table 472-2)**. In second place—causing 11% of global mortality—was stroke, which accounted for 8% of deaths in high-income countries, 6% and 12% in low- and middle-income countries, respectively, and 4% in sub-Saharan Africa. Although chronic obstructive pulmonary disease (COPD) was the third leading cause of death globally and was the fifth leading cause in high-income countries (accounting for 5% of all deaths), this condition did not figure among the top 15 causes in sub-Saharan Africa. Among the 10 leading causes of death in sub-Saharan Africa, six were infectious diseases, with HIV/AIDS, lower respiratory infections, diarrheal diseases, and malaria ranking as dominant contributors to disease burden. In high-income countries, however, only one infectious disease—lower respiratory infection—ranked among the top 10 causes of death.

The GBD 2017 found that the worldwide mortality figure among children under 5 years of age dropped from 16.4 million in 1970 to 11.8 million in 1990 and to 5.4 million in 2017—a decrease that far surpassed predictions. Of childhood deaths in 2017, 2.4 million (44%) occurred in the neonatal period. Just under one-third of deaths among children under 5 years old occurred in southern Asia and slightly more than one-half in sub-Saharan Africa, but only ~1% occurred in high-income countries.

The global burden of death due to HIV/AIDS and malaria was on an upward slope until 2004, but significant progress has been made since then. Global deaths from AIDS fell from 2.0 million in 2006 to 955,000 in 2017, while malaria deaths dropped from 1.2 million to 620,000 over the same period. Despite these improvements, malaria and HIV/AIDS continue to be major burdens in particular regions, with global implications. Although it has only a minor impact on mortality outside sub-Saharan Africa and Southeast Asia, malaria is the fifth leading cause of death of children under 5 years of age worldwide. HIV infection ranked 28th in global DALYs in 1990 but was the 11th leading cause of disease burden in 2017, with sub-Saharan Africa bearing the vast majority of this burden (Fig. 472-1).

The world's population is living longer: global life expectancy has increased significantly over the past 50 years from 58.8 years in 1970 to 73 years in 2017. This demographic change, accompanied by the fact that the prevalence of NCDs increases with age, is dramatically shifting the burden of disease toward NCDs, which have surpassed communicable, maternal, nutritional, and neonatal causes. By 2017, 73% of total deaths at all ages and 62% of all DALYs were due to NCDs. Increasingly, the global burden of disease comprises conditions and injuries that cause disability rather than death.

Worldwide, although both life expectancy and years of life lived in good health have risen, years of life lived with disability have also increased. Globally, the total burden of disability increased by 50% between 1950 and 2017. Despite the higher prevalence of diseases common in older populations (e.g., dementia and musculoskeletal disease) in developed and high-income countries, best estimates from 2017 reveal that disability resulting from cardiovascular diseases, chronic respiratory diseases, and the long-term impact of communicable diseases was greater in low- and middle-income countries. In

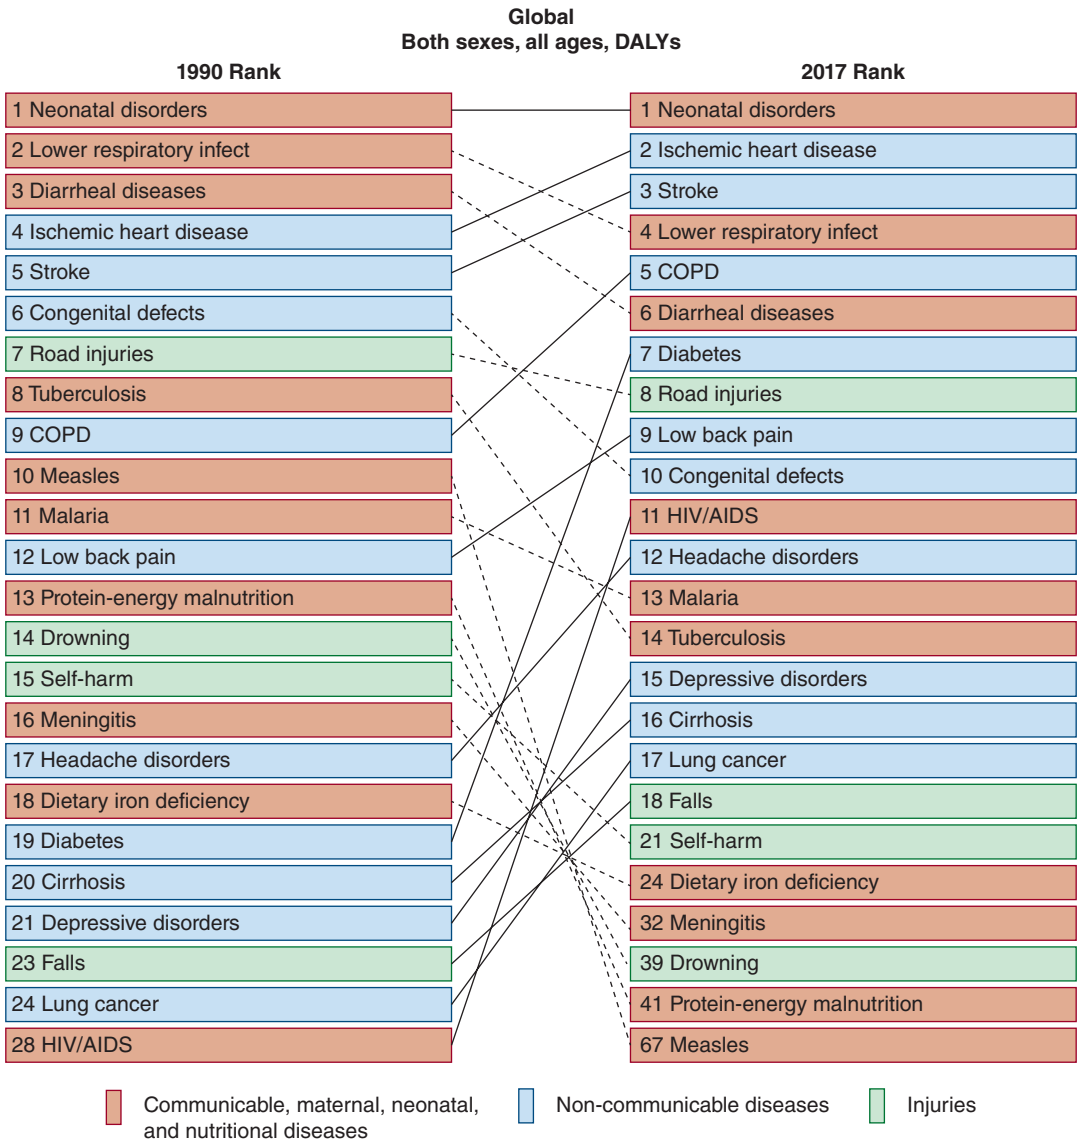

FIGURE 472-1 Global disability-adjusted life-year (DALY) ranks for the top causes of disease burden in 1990 and 2017. COPD, chronic obstructive pulmonary disease. *(From the Institute for Health Metrics and Evaluation [IHME]. GBD Compare. Seattle, WA: IHME, University of Washington, 2017. Available at http://vizhub.healthdata.org/gbd-compare. Accessed May 1, 2020.)*

most developing countries, people lived shorter lives and experienced disability and poor health for a greater proportion of their lives. Indeed, 47% of the global burden of disease occurred in southern Asia and sub-Saharan Africa, which together account for only 38% of the world's population.

HEALTH AND WEALTH

Clear disparities in burden of disease (both communicable and noncommunicable) across country income levels are strong indicators that poverty and health are inherently linked. Numerous studies have documented the link between poverty and health within nations as well as across them. Poverty remains one of the most important root causes of poor health worldwide, and the global burden of poverty continues to be high. Among the 7.3 billion people alive in 2015, 10% (736 million) lived on less than $1.90 (in 2011 U.S. dollars) per day—a standard measurement of extreme poverty—and 25% lived on less than $3.20 per day. Just under one-fifth of all children under the age of 14 worldwide lived in extreme poverty in 2015. The extreme poverty rate has declined steadily since 1990, and by 2015, there were more than one billion fewer people living in poverty despite growth in the global population of more than two billion during that time period. However, improvement has been uneven across the globe. In sub-Saharan Africa, people living in extreme poverty increased from 278 million to 413 million during the same period.

RISK FACTORS FOR DISEASE BURDEN

The GBD study found that the three leading risk factors for global disease burden in 2017 were (in order of frequency) high systolic blood pressure, smoking, and high fasting plasma glucose—a substantial change from 1990, when child wasting was ranked first. Although ranking ninth in 2017, child wasting remains the third leading risk factor for death worldwide among children under 5 years of age. In an era that has seen obesity become a major health concern in many developed countries—and the fourth leading risk factor worldwide—the persistence of undernutrition is cause for consternation. Child wasting is still a dominant risk factor for disease burden in sub-Saharan Africa. In its rural reaches, no health care initiative, however generously funded, will be effective or comprehensive without addressing undernutrition.

In an analysis that examined how specific diseases and injuries are affected by environmental risk, the WHO estimated that 24% of all deaths and 28% of deaths among children <5 years of age in 2016 were due to modifiable environmental factors: some 1.6 million children die every year from causes related to unhealthy environments, including the nearly 300,000 deaths stemming from a lack of access to clean water and sanitation. Many of these modifiable factors lead to child and adult deaths from infectious pathologies; others lead to deaths from malignancies. Etiology and nosology are increasingly difficult to parse with regard to environmental harm. Risk factors such as indoor

TABLE 472-1 Leading Causes of Burden of Disease (DALYs), 2017

DISEASE OR INJURY	DALYs (MILLIONS)	PERCENTAGE OF TOTAL DALYs
World	**2464.9**	**100**
1. Neonatal disorders	185.8	7.4
2. Ischemic heart disease	170.3	6.8

[a]The World Bank classifies high-income countries as those whose gross national income (GNI) per capita is ≥$12,376. Low- and middle-income countries are categorized as low income (GNI per capita, <$1025), lower-middle income (GNI per capita, $1026–$3995), and upper-middle income (GNI per capita, $3996–$12,375) (*http://data.worldbank.org/about/country-classifications*).

Abbreviation: COPD, chronic obstructive pulmonary disease.

air pollution due to use of solid fuels, exposure to secondhand tobacco smoke, and outdoor air pollution account for 55% of DALYs due to lower respiratory infections globally. Various forms of unintentional injury and malaria top the list of health problems to which environmental factors contribute.

The third edition of *Disease Control Priorities* (DCP3), published as a set of serial volumes based on content area, provides evidence-based recommendations and cost-effectiveness analyses for numerous interventions, with attention to strategies for strengthening health systems. Cost-effectiveness analyses that compare relatively equivalent

interventions in order to facilitate sound decisions under constraint are necessary; however, these analyses, as the DCP3 authors acknowledge, are unreliable when based on an incomplete knowledge of cost and evolving evidence of effectiveness. As both resources and objectives for global health initiatives grew, cost-effectiveness analyses (particularly those based on older evidence) sometimes steered policy makers and public health experts toward low-cost but ultimately ineffective interventions or away from higher-priced but effective ones. Thus, we use the term *global health equity* to emphasize the need to ensure equitable access to high-value health interventions. To illustrate these points, it is instructive to look to HIV/AIDS, which in the course of the last four decades has become one of the world's leading infectious causes of adult death.

HIV INFECTION/AIDS

Chapter 202 provides an overview of the global HIV epidemic today. Approximately 36 million people worldwide were living with HIV infection in 2017, and it has been the underlying cause of death for almost 1 million people—especially concentrated in sub-Saharan Africa—annually. As of 2017, 54 countries were on track to meet the 2020 target of 81% antiretroviral therapy (ART) coverage, but only 12 countries are expected to meet the 2030 target of 90% coverage. Here the discussion will be limited to HIV/AIDS in the developing world. Lessons learned from tackling HIV/AIDS in low-resource settings are highly relevant to discussions of other chronic diseases, including NCDs, for which effective therapies have been developed. In the United States, after the mid-1990s, ART transformed HIV infection from an inescapably fatal disease into a manageable chronic illness. Across high-income countries, improved ART has dramatically prolonged life expectancy for people living with HIV infection, which now approaches that of the general population. This success rate exceeds that obtained with almost any treatment for adulthood cancer or for complications of coronary artery disease. In developing countries, treatment has been offered broadly only since 2003. Before 2003, many arguments were raised to justify not moving forward rapidly with ART programs for people living with HIV/AIDS in resource-limited settings. The standard litany included the price of therapy compared with the poverty of patients, the complexity of the intervention, the lack of infrastructure for laboratory monitoring, and the lack of trained health care providers. Narrow cost-effectiveness arguments that created false dichotomies—prevention *or* treatment rather than their synergistic integration—too often went unchallenged by policy makers, public health experts, and health economists. As a cumulative result of these delays in the face of health disparities both old and new, there were millions of premature deaths.

Disparities in access to HIV treatment did give rise to widespread moral indignation and a new type of health activism. In several middle-income countries, including Brazil, public programs have helped bridge the global access gap. Other innovative projects pioneered by international NGOs in diverse settings such as Haiti and Rwanda have established that a simple approach to ART based on intensive community engagement and social and economic support for patients and their community-based health workers can achieve remarkable results **(Fig. 472-2)**.

During the past decade, the availability of ART has increased sharply in the low- and middle-income countries that have borne the greatest burden of the HIV/AIDS pandemic. In 2000, few people living with HIV/AIDS in these nations had access to ART, whereas by 2018, 62% of people living with HIV infection were receiving ART, including 64% of people living with HIV in sub-Saharan Africa and 53% in Southeast Asia. In light of these dramatic gains, coverage targets have grown more ambitious; for example, in 2014, UNAIDS set the 90-90-90 targets, which aimed to have 90% of people living with HIV know their status, 90% of those with HIV treated with ART, and 90% of those on treatment achieving viral load suppression by 2020. These are to be followed by the 95-95-95 targets for 2030, with the objective of ending the AIDS epidemic by 2030.

This scale-up was made possible by several developments: a staggering drop in the cost of generically manufactured ART, the development of a standardized approach to treatment, substantial investments by funders, and the political commitment of governments to afford ART as a public good. Civil-society AIDS activists spurred many of these efforts.

Starting in the early 2000s, a combination of factors, including work by the Clinton HIV/AIDS Initiative and Médecins Sans Frontières, led to the availability of generic ART medications. While first-line ART cost >$10,000 per patient per year in 2000, first-line regimens in low- and middle-income countries are now available for <$75 per year. At the same time, fixed-dose combinations made multidrug regimens easier to administer. Also around this time, the WHO began advocating a public health approach to the treatment of people with AIDS in low-resource settings; this approach promised—thanks to dropping viremia—to lower transmission rates and, if universally available, to end almost all mother-to-child transmission. Derived from models of care pioneered by the NGO Partners In Health and other groups, this approach proposed the use of standard first-line treatment regimens based on a simple five-drug formulary, with a more complex (and more expensive) set of second-line options in reserve. Clinical protocols were standardized, and intensive training packages for health professionals and community health workers were developed and implemented in many countries. Early rollout efforts were supported by new funding from the Global Fund and PEPFAR. In 2003, lack of access to ART was declared a global public health emergency by the WHO and UNAIDS, and those two agencies launched the 3 by 5 Initiative, setting an ambitious target: to have 3 million people in developing countries on treatment by the end of 2005. Many countries set corresponding national targets and have worked to integrate ART into their national AIDS programs and health systems and to harness the synergies between HIV/AIDS treatment and prevention activities. External funding to fight HIV/AIDS in such settings increased dramatically during this period and beyond, rising from $300 million in 1996 to $9.1 billion in 2017. The integration of prevention and care led to a sharp drop in transmission—a 96% decline according to one review of the impact of ART rollout in heavily burdened countries in Africa and the Caribbean.

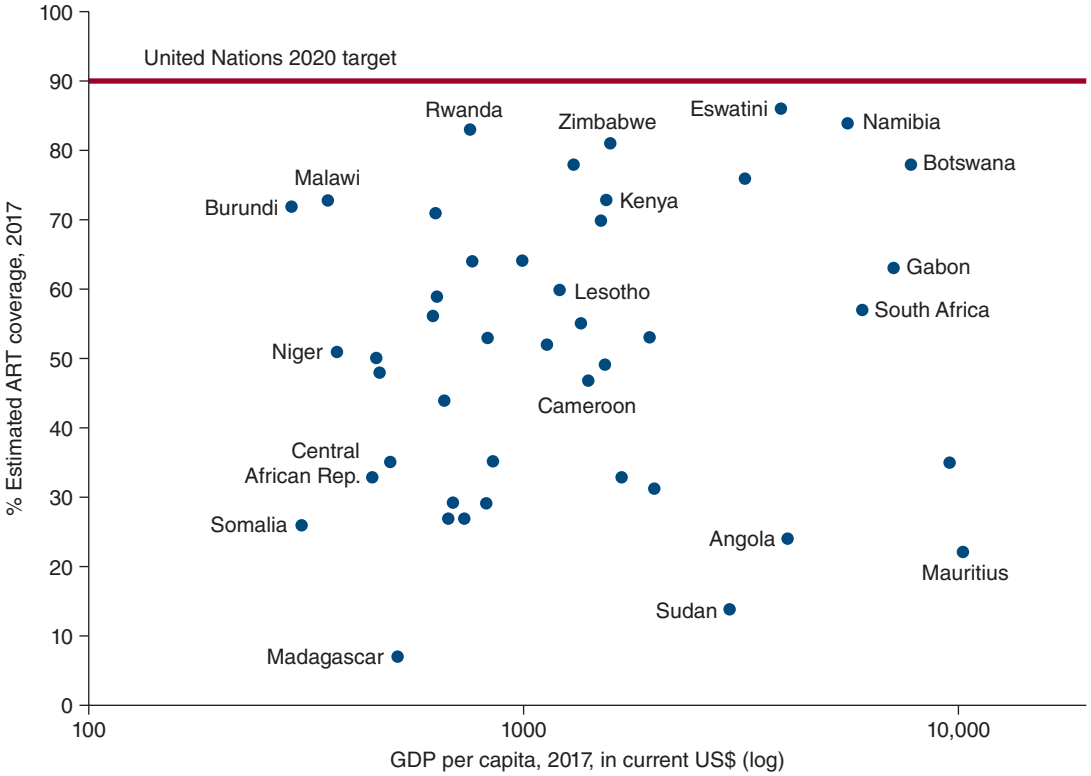

FIGURE 472-3 Antiretroviral therapy (ART) coverage (percentage of people living with HIV who received ART) in sub-Saharan Africa, 2017. *(Source: World Bank; data available through data.worldbank.org.)*

Further lessons with implications for policy and action have come from efforts now under way among lower-income countries. Rwanda provides an example: since 2000, mortality from HIV disease has fallen by 80% as the country—despite its relatively low gross national income **(Fig. 472-3)**—has provided almost universal access to ART. The reasons for this success include strong national leadership, evidence-based policy, cross-sector collaboration, community-based care, and a deliberate focus on a health-systems approach that embeds HIV/AIDS treatment and prevention in the primary health care service delivery platform. As we will discuss later in this chapter, these principles can be applied to other conditions, including NCDs.

TUBERCULOSIS

Chapter 178 provides a concise overview of the pathophysiology and treatment of tuberculosis. In 2017, an estimated 1.2 million people died from *Mycobacterium tuberculosis* infection; this figure made tuberculosis the leading single infectious killer of adults globally. The disease is closely linked to HIV infection in much of the world: of the ~10 million estimated new cases of tuberculosis in 2017, 920,000 occurred among people living with HIV. A much more substantial proportion of the resurgence of tuberculosis registered in southern Africa is attributed to HIV co-infection. Even before the advent of HIV, however, it was estimated that fewer than one-half of all cases of tuberculosis in developing countries were ever diagnosed. Primarily because of the common failure to diagnose and treat tuberculosis, international authorities devised a single strategy to reduce the burden of disease. In the early 1990s, the World Bank, the WHO, and other international bodies promoted the DOTS strategy (*d*irectly *o*bserved *t*herapy using *s*hort-course isoniazid- and rifampin-based regimens) as highly cost-effective. Passive case-finding of smear-positive patients was central to the strategy, as was an uninterrupted drug supply.

DOTS was clearly effective for most uncomplicated cases of drug-susceptible tuberculosis, but several shortcomings were soon identified. First, the diagnosis of tuberculosis based solely on sputum smear microscopy—a method dating from the late nineteenth century—is not sensitive. Many cases of pulmonary tuberculosis and all cases of exclusively extrapulmonary tuberculosis are missed by smear microscopy, as are most cases of active disease in children. Second, passive case-finding relies on the availability of health care services, which is uneven in the settings where tuberculosis is most prevalent. Third, patients with multidrug-resistant tuberculosis (MDR-TB) are by definition infected with strains of *M. tuberculosis* resistant to isoniazid and rifampin; thus, exclusive reliance on these drugs is unwarranted in settings in which drug resistance is an established problem.

The crisis of antibiotic resistance registered in U.S. hospitals is not confined to the industrialized world or to common bacterial infections. While the great majority of patients sick with and dying from tuberculosis are afflicted with strains susceptible to all first-line drugs, a substantial minority of patients with tuberculosis in some settings are infected with strains of *M. tuberculosis* resistant to at least one first-line antituberculosis drug. Globally in 2017, an estimated 4% of all patients with new *M. tuberculosis* infections and 18% of all previously treated patients were infected with rifampin-resistant or MDR strains; most of these cases resulted from primary transmission. It was clear that poor infection control in hospitals and clinics in the face of delays in the initiation of effective therapy led to explosive and lethal epidemics due to these strains. To improve DOTS-based responses to MDR-TB, global health authorities adopted DOTS-Plus, which adds the diagnostics and drugs necessary to manage drug-resistant disease. Even as DOTS-Plus was being piloted in resource-constrained settings, however, new strains of extensively drug-resistant (XDR) *M. tuberculosis* (resistant to isoniazid and rifampin, any fluoroquinolone, and at least one injectable second-line drug) had already threatened the success of tuberculosis control programs in beleaguered South Africa, for example, where high rates of HIV infection had led to a doubling in the incidence of tuberculosis over the preceding decade. Gene probes of cultures of infected sputum and tissues suggest that patients may be infected by more than one strain. Despite the poor capacity for detection of MDR- and XDR-TB in most resource-limited settings, an estimated 558,000 cases of MDR-TB were thought to occur in 2017. Approximately 9% of these cases were caused by XDR strains.

TUBERCULOSIS AND AIDS AS CHRONIC DISEASES: LESSONS LEARNED

Strategies effective against MDR-TB have implications for the management of drug-resistant HIV infection and even drug-resistant malaria,

which, through repeated infections and a lack of effective therapy, has become a chronic disease in parts of Africa (see "Malaria," below). As new therapies, whether for tuberculosis or for hepatitis C infection, become available, many of the problems encountered in the past will recur. Indeed, examining AIDS and tuberculosis as chronic diseases—instead of simply communicable ones—makes it possible to draw a number of conclusions, many of them pertinent to global health equity in general.

First, the chronic infections discussed here are best treated with multidrug regimens to which the infecting strains are susceptible. This is true of chronic infections due to many bacteria, fungi, parasites, or viruses; even acute infections such as those caused by *Plasmodium* species are not reliably treated with a single drug.

Second, charging fees for AIDS prevention and care poses insurmountable problems for people living in poverty, many of whom are unable to pay even modest amounts for services or medications. Like efforts to battle airborne tuberculosis, such services might best be seen as a public good promoting public health. Initially, a subsidy approach will require sustained donor contributions, but many African countries have set targets for increased national investments in health—a pledge that could render ambitious programs sustainable in the long run, as the Rwanda experience suggests. Meanwhile, as local investments increase, the price of AIDS care continues to decrease. The use of generic medications means that ART can now cost <$0.25 per day.

Third, the effective scale-up of pilot projects requires strengthening and sometimes rebuilding of health care systems, including those charged with delivering primary care. In the past, the lack of health care infrastructure has been cited as a barrier to providing ART in the world's poorest regions; however, AIDS resources, which are at last considerable, may be marshaled to rebuild public health systems in sub-Saharan Africa and other HIV-burdened regions—precisely the settings in which tuberculosis is resurgent. Failure to pursue such a health-systems approach after civil wars ended in Sierra Leone and Liberia accounts for much of their extreme vulnerability to Ebola a decade later.

Fourth, the lack of trained health care personnel, most notably doctors and nurses, is incorrectly invoked as a primary reason for failure to treat AIDS in poor countries and must still be addressed. The WHO recommends a minimum of 1 physician per 1000 persons, but many countries, especially in sub-Saharan Africa, fall far short of that target. Specifically, 45% of WHO member states report not achieving that target. In contrast, the United States and Cuba report 2.59 and 8.19 doctors per 1000 population, respectively. Similarly, ~50% of WHO member states report having fewer than three nurses and midwives per 1000 population. Sub-Saharan Africa bears >24% of the global burden of disease but has access to only 3% of the world's health workers. Further inequalities in health care staffing exist within countries. Rural-urban disparities in health care personnel mirror disparities of both wealth and health. For instance, in Sierra Leone, an estimated 70% of the national health workforce is concentrated in urban areas, where just 38% of the population lives. Even community health workers trained to provide first-line services to rural populations often transfer to urban districts.

In what is termed the "brain drain," many physicians and nurses emigrate from their home countries to pursue opportunities abroad, leaving behind health systems that are understaffed and ill-equipped to deal with either emergencies like Ebola or the usual burden of disease. One reason doctors and nurses leave sub-Saharan Africa and other low-income areas is that they lack the tools to practice there. Funding for "vertical" (disease-specific) programs can be used not only to strengthen health systems but also to recruit and train physicians and nurses to underserved regions where they, in turn, can help to train and then work with community health workers in supervising care for patients with AIDS and many other diseases within their communities. Such training should be undertaken even where physicians are abundant, since close community-based supervision represents the highest standard of care for chronic disease, whether in developing or developed countries. The United States, which has a dearth of health care providers in many of its poor and rural communities, has much to learn from Rwanda in this regard.

Fifth, the many barriers to adequate health care and patient adherence that are raised by extreme poverty can be removed only with the deployment of "wrap-around services": food supplements for the hungry, help with transportation to clinics, child care, and housing. Extreme poverty makes it difficult for many patients to comply with therapy for chronic diseases, whether communicable or not. Experience shows, however, that these many barriers can be more readily surmounted than the extreme poverty itself to which chronic disease and acute infection contribute substantially. Indeed, poverty in its many dimensions is far and away the greatest obstacle to the scale-up of treatment and prevention services.

Finally, there is a need for a renewed basic-science commitment to the discovery and development of vaccines; more reliable, less expensive diagnostic tools; and new classes of therapeutic agents. This need applies not only to HIV, tuberculosis, and malaria—against none of which there is an effective vaccine—but also to most other neglected diseases of poverty.

MALARIA

Chapter 224 reviews the etiology, pathogenesis, and clinical treatment of malaria, the world's sixth-ranking infectious killer. In 2017, there were 219 million cases of malaria, and the disease killed 435,000 people; 60% of these deaths occurred among children <5 years old. The poor disproportionately experience the burden of malaria: almost 85% of estimated malaria deaths occur in just 20 countries, and mortality rates are highest in sub-Saharan Africa. Nigeria, the Democratic Republic of the Congo, Tanzania, Angola, Mozambique, and Niger account for more than half of total malaria deaths globally.

Malaria's human cost has been enormous, with the highest toll among children—especially African children—living in poverty. In 2016, U.S. $4.3 billion was spent on malaria worldwide, an 8.5% per year increase since 2000. Macroeconomic analyses estimate that malaria may reduce the per capita gross national product of a disease-endemic country by 50% relative to that of a non–malaria-endemic country. The causes of this drag include impaired cognitive development of children, decreased schooling, decreased savings, decreased foreign investment, and restriction of worker mobility. In light of this enormous cost, it is little wonder that an important review by the economists Sachs and Malaney concludes that "where malaria prospers most, human societies have prospered least."

Microeconomic analyses focusing on direct and indirect costs estimate that malaria may consume >10% of a household's annual income. A recent study in rural Mozambique, where malaria is the leading cause of care-seeking, concluded that the median household cost associated with uncomplicated malaria represents 10–21% of a family's monthly expenditure, while a severe case may exceed the mean monthly expenditure per capita by more than three times, thereby continuing the cycle of poverty and disease.

In part because of differences in vector distribution and climate, resource-rich countries offer few blueprints for malaria control and treatment that are applicable in tropical (and resource-poor) settings. In 2001, African heads of state endorsed the WHO Roll Back Malaria (RBM) campaign, which prescribes strategies appropriate for sub-Saharan African countries. In 2008, the RBM partnership launched the Global Malaria Action Plan (GMAP). This strategy integrates prevention and care and calls for the avoidance of single-dose regimens and an awareness of existing drug resistance; the use of insecticide-treated bed nets (ITNs); indoor residual spraying; artemisinin-based combination therapy (ACT); intermittent preventive treatment during pregnancy; prompt diagnosis; and other vector control measures such as larviciding and environmental management.

Between 2000 and 2015, the global malaria mortality rate was reduced by an estimated 62%, a figure equating to some 6.8 million deaths averted. Again, the experience in Rwanda is instructive: from 2005 to 2012, malaria incidence decreased by 86% and deaths dropped by 76% for the same reasons mentioned earlier in recounting that nation's successes in battling HIV. An eight-fold resurgence in cases

there between 2012 and 2016 has been linked to increased access to health care (and therefore diagnosis), inadequately treated ITNs, mosquito resistance to insecticides, climate change, and transborder movement of people.

Meeting the challenge of malaria control will continue to require careful study of appropriate preventive and therapeutic strategies in the context of an increasingly sophisticated molecular understanding of pathogen, vector, and host. However, an appreciation of the economic and social devastation wrought by malaria—like that inflicted by diarrhea, AIDS, and tuberculosis—on the most vulnerable populations should heighten the level of commitment to critical analysis of ways to implement proven strategies for prevention and treatment.

Funding from the Global Fund, the Gates Foundation, the World Bank's International Development Association, and the U.S. President's Malaria Initiative, along with leadership from public health authorities, is critical to sustain the benefits of prevention and treatment. Building on the growing momentum of the last decade with adequate financial support, innovative strategies, and effective tools for prevention, diagnosis, and treatment, we may yet achieve the goal of a world largely free of malaria.

EBOLA

Chapter 210 provides an overview of the epidemiology, pathogenesis, and clinical manifestations of Ebola virus and Marburg virus infections. The 2013–2016 outbreak of Ebola virus disease in West Africa was the largest documented Ebola epidemic to date, with >28,000 recorded cases and 11,000 recorded deaths.

Prior to the outbreak, the health systems of the three most affected countries—Liberia, Guinea, and Sierra Leone—were among the world's weakest. Histories of extractive colonial and postcolonial commerce, the conditional aid policies of international financial institutions, recent civil conflict, and underresourced health ministries left this part of West Africa bereft of the means to deliver modern medicine and promote public health. In 2013, Sierra Leone had the world's highest maternal mortality ratio, with 1180 deaths per 100,000 live births. According to one estimate, Liberia had just 51 physicians working in the entire country before the Ebola epidemic, or roughly one physician per 100,000 people. Clinics and hospitals were scarce across the region, especially in rural areas, and routinely lacked drugs, supplies, electricity, running water, laboratories, and personal protective equipment for the prevention of nosocomial infection. Such deficits were not surprising given these countries' meager public and private expenditures on health.

The unprecedented scale of the West African Ebola epidemic was largely a symptom of these chronically weak health systems. As a result, clinicians, patients' families, and other caregivers—tasked with nursing the sick and interring the dead, but lacking the means to do so safely—faced disproportionately high risks of Ebola infection. Health facilities with poor infection control and unsafe burials served as amplifiers of transmission.

The quest to contain Ebola in West Africa was one of the largest global public health efforts at that time, but it was far from ambitious clinically. As in previous Ebola outbreaks, preventing new infections was often prioritized over improving survival among those already infected, leading to substandard care for most West African patients and high case-fatality rates—by WHO estimates, ~70%. However, in settings in which quality supportive and critical care could be provided, clinical outcomes among Ebola-infected patients affirmed that Ebola virus disease is treatable, even in the absence of specific antiviral therapies and experimental drugs.

As with efforts to combat AIDS and tuberculosis, the global response to Ebola reveals the unintended consequences of pitting preventive strategies against therapeutic ones—and the pull of debates about scarcity. Misguided (and often contradictory) public health messaging, distrust of disease-control and social mobilization teams, punitive containment measures, and the unavailability of safe Ebola treatment units capable of delivering effective clinical care deterred individuals from presenting to health facilities, reporting symptomatic patients and their contacts, and cooperating with epidemic response activities. The resulting epidemic of mistrust facilitated the further spread of new infections by impeding surveillance, timely diagnosis, contact tracing, and patient isolation.

In August 2018, a new Ebola outbreak was detected in eastern Democratic Republic of the Congo (DRC) and soon became the world's second largest on record. In June 2020, when it was declared over, it had sickened ~3500 people and killed two-thirds of them. Containment was complicated by armed conflict in the affected region, which had long experienced strife, impoverishment, and colonial and postcolonial extraction, feeding a well-founded suspicion of foreign intervention.

Despite these challenges, responders benefitted from the arrival of new tools to prevent, diagnose, and treat Ebola. A new vaccine was extensively deployed using a ring vaccination strategy. There was significant progress in the quality of supportive care provided to patients in DRC, with more routine monitoring, improved access to clinical laboratory services, better staffing of treatment centers, and more aspirational clinical protocols. Nevertheless, the overall case-fatality rate in DRC reveals that these welcome medical innovations did not reach everyone in need of them.

COVID-19

In the early months of the COVID-19 pandemic, many health systems in high-income countries were strained to treat the surge of patients afflicted by it. The pandemic revealed deep structural deficiencies in our collective global ability to recognize and contain such "novel" pathogens. Although SARS-CoV-2 is "novel" in relation to our human immune systems, its rapid march across the globe followed the familiar pattern of many pandemic pathogens before it, such as HIV, tuberculosis, and cholera. It has particularly high attack rates among vulnerable populations, such as people experiencing homelessness and nursing home residents, and in poor communities where insufficient housing, food insecurity, and marginal employment in low-paid service jobs have resulted in inability to safely social distance and quarantine. The United States suffered during the early parts of this pandemic from underinvestment in public health systems that can provide surveillance testing at scale and perform robust contact tracing. We share a deep hope that this pandemic may catalyze a broader recognition about the effects of poverty on health, about the need to achieve universal access to health care for all the world's people, and about the urgency of strengthening global public health systems.

"NONCOMMUNICABLE" CHRONIC DISEASES

Although the burden of communicable diseases—especially HIV infection, tuberculosis, and malaria—still accounts for the majority of deaths in resource-poor regions within sub-Saharan Africa and in the poorest reaches of several first-world cities, 73% of all deaths worldwide in 2017 were attributed to NCDs. Although we use this term to describe cardiovascular diseases, cancers, diabetes, and chronic lung diseases, this usage masks important distinctions. For instance, two significant NCDs in low-income countries, rheumatic heart disease (RHD) and cervical cancer, represent the chronic sequelae of infections with group A *Streptococcus* and human papillomavirus, respectively, and it is in these countries that the burden of disease due to NCDs is rising most rapidly: a little more than three-quarters of deaths attributable to NCDs occur in low- and middle-income countries, which also account for 85% of all early NCD-related deaths—a figure representing ~15 million people and exceeding the total number of deaths due to AIDS, tuberculosis, and malaria combined. By 2030, NCDs will account for 55 million deaths annually worldwide if no additional action is taken. The recent increase in resources for and attention to communicable diseases is both welcome and long overdue, but developing countries are already carrying a "double burden" of communicable and noncommunicable diseases.

Diabetes, Cardiovascular Disease, and Cancer: A Global Perspective In contrast to tuberculosis, HIV infection, and malaria—diseases caused by single pathogens that damage multiple organs—cardiovascular diseases reflect injury to a single organ system downstream of a variety of insults, both infectious and noninfectious.

Some of these insults result from rapid changes in diet and labor conditions; others are of a less recent vintage. The burden of cardiovascular disease in low-income countries represents one consequence of decades of neglect of health systems. Furthermore, cardiovascular research and investment have long focused on the ischemic conditions that are increasingly common in high- and middle-income countries.

Predictions of an imminent rise in the share of deaths and disabilities due to NCDs in developing countries have led to calls for preventive policies to improve diet, increase exercise, and restrict tobacco use, along with the prescription of multidrug regimens for persons at high-level vascular risk. Although this agenda could do much to prevent pandemic NCDs, it will do little to help persons with established heart disease stemming from nonatherogenic pathologies.

The misperception of cardiovascular diseases as a problem primarily of elderly populations in middle- and high-income countries has contributed to the neglect of these diseases by global health institutions, including regionally focused ones. Even in Eastern Europe and Central Asia, where the collapse of the Soviet Union was followed by a catastrophic surge in cardiovascular disease deaths (mortality rates from ischemic heart disease nearly doubled between 1991 and 1994 in Russia, for example), the modest flow of overseas development assistance to the health sector during these troubled years focused on the communicable causes that accounted for <1 in 20 excess deaths during that period.

DIABETES The International Diabetes Federation reports that the number of diabetic adult patients in the world is expected to increase from 463 million in 2019—1 in 11 adults—to 700 million by 2045. Already, a significant proportion of diabetic patients live in developing countries where, because those affected are far more frequently between ages 40 and 59, the complications of micro- and macrovascular disease take a far greater toll. Globally, these complications are a major cause of disability and reduced quality of life: a high fasting plasma glucose level ranks third among risks for disability and global mortality. The GBD 2017 estimates that diabetes accounted for 1.4 million deaths in 2017; 84% of these deaths occurred in low- and middle-income countries.

CARDIOVASCULAR DISEASE Because systemic investigation of the causes of stroke and heart failure in sub-Saharan Africa has begun only recently, little is known about the impact of elevated blood pressure in this portion of the continent. Modestly elevated blood pressure in the absence of tobacco use in populations with low rates of obesity may confer little risk of adverse events in the short run. In contrast, persistently elevated blood pressure above 180/110 mmHg goes largely undetected, untreated, and uncontrolled in this part of the world. In the cohort of men assessed in the Framingham Heart Study, the prevalence of blood pressures above 210/120 mmHg—severe hypertension—declined from 1.8% in the 1950s to 0.1% by the 1960s with the introduction of effective antihypertensive agents. Although debate continues about appropriate screening strategies and treatment thresholds, Africa's rural health centers, run largely by nurses, must quickly gain access to antihypertensive medications.

The epidemiology of heart failure also reflects inequalities in risk factor prevalence and in access to therapy. The reported burden of this condition has remained unchanged since the 1950s, but the causes of heart failure and the age of the people affected vary across the globe. Heart failure as a consequence of pericardial, myocardial, endocardial, or valvular injury is a leading cause of hospitalization in the United States and Europe, representing 2.5% of all hospitalizations, and is estimated to account for a substantial proportion of medical admissions in hospitals in low-income countries as well. In high-income countries, coronary artery disease and hypertension among the elderly account for most cases of heart failure. Among the world's poorest 1 billion people, however, heart failure reflects poverty-driven exposure of children and young adults to rheumatogenic strains of streptococci and cardiotropic microorganisms (e.g., HIV, *Trypanosoma cruzi*, enteroviruses, *M. tuberculosis*), untreated high blood pressure, and nutrient deficiencies. The mechanisms underlying other causes of heart failure common in these populations—such as idiopathic dilated cardiomyopathy, peripartum cardiomyopathy, and endomyocardial fibrosis—remain unclear.

In stark contrast to the extraordinary lengths to which clinicians in wealthy countries will go to treat ischemic cardiomyopathy among elderly patients, little attention has been paid to young patients with nonischemic cardiomyopathies in resource-poor settings. Nonischemic cardiomyopathies, such as those due to hypertension, RHD, and chronic lung disease, account for >90% of cases of cardiac failure in sub-Saharan Africa and include poorly understood entities such as peripartum cardiomyopathy (which has an incidence in rural Haiti of 1 per 300 live births) and HIV-associated cardiomyopathy. Lessons learned in the scale-up of chronic care for HIV infection and tuberculosis may be illustrative as progress is made in establishing the means to deliver heart-failure medications to these patients.

Some of the lessons learned from the chronic infections discussed above are, of course, relevant to cardiovascular disease, especially those classified as NCDs but caused by infectious pathogens. Integration of prevention and care remains as important today as in 1960 when Paul Dudley White and his colleagues found little evidence of myocardial infarction in the region near the Albert Schweitzer Hospital in Lambaréné, Gabon, but reported that "the high prevalence of mitral stenosis is astonishing." They termed it a duty to integrate prevention with penicillin prophylaxis and care, including medical management and surgery, when indicated. "The same responsibility," they agreed, "exists for those with correctable congenital cardiovascular defects."

RHD affects almost 40 million people worldwide, with >1.3 million new cases each year. Among the 834,000 cases of pediatric RHD, 38% occur in sub-Saharan Africa. A meta-analysis of data on heart failure in sub-Saharan Africa found that RHD was the third most common cause of heart failure in the region. This disease, which may cause endocarditis or stroke, leads to >285,000 deaths per year—almost all occurring in developing countries. A survey of the global burden of RHD from 1990 through 2015 found that the highest age-standardized death rates occurred in Oceania, South Asia, and sub-Saharan Africa, with 1.5% of Oceania's population and 1% of the populations in South Asia and sub-Saharan Africa living with the disease in 2015. Results from 14 low- and middle-income countries included in the Global Rheumatic Heart Disease Registry showed that mortality was significantly higher among patients living in low-income countries and among the less educated. Recent studies in Rwanda and Ethiopia have confirmed a high prevalence of RHD among schoolchildren, including those that are asymptomatic. In part because the prevention of RHD has not advanced since the disease's disappearance in wealthy countries, no part of sub-Saharan Africa has eradicated RHD despite examples of success in Costa Rica, Cuba, and some Caribbean nations.

Strategies to eliminate RHD may depend on active case-finding, with confirmation by echocardiography, among high-risk groups as well as on efforts to expand access to surgical interventions among children with advanced valvular damage. Partnerships between established surgical programs and areas with limited or nonexistent facilities may help expand the capacity to provide lifesaving interventions to patients who otherwise would die early and painfully. Such partnerships can speed the further development of regional centers of excellence equipped to provide consistent, accessible, high-quality services to those now without them.

CANCER Low- and middle-income countries accounted for ~70% of the 10 million deaths due to cancer worldwide in 2017. By 2030, annual mortality from cancer is expected to increase to >13 million deaths—with developing countries experiencing a sharper increase than developed nations. "Western" lifestyle changes may be responsible for the increased incidence of cancers of the breast, colon, and prostate among populations in low- and middle-income countries, but historic realities, sociocultural and behavioral factors, genetics, and poverty itself already have a profound impact on cancer-related mortality and morbidity rates. Cancer-causing infections, such as human papillomavirus, hepatitis B virus, and *Helicobacter pylori*, are responsible for up to 25% of cancer cases in low- and middle-income countries. Infectious causes of cancer will continue to have a much larger impact

in developing countries. Environmental and dietary factors, such as indoor air pollution and high-salt diets, also contribute to increased rates of certain cancers (e.g., lung and gastric cancers). Tobacco use (both smoking and chewing) is the most important source of increased mortality rates from lung and oral cancers. In contrast to decreasing tobacco use in many developed countries, the number of smokers is growing in developing countries, especially among women and young persons.

For many reasons, outcomes of malignancies are far worse in developing countries than in developed nations. As currently funded, overstretched health systems in poor countries are not capable of early detection; at the time of tissue diagnosis, the majority of patients already have incurable malignancies. Treatment of cancers is available for only a very small number of mostly wealthy citizens in most poor countries, and even when treatment is available, the range and quality of services are often substandard. Yet this need not be the future. Twenty years ago, MDR-TB and HIV infections were widely deemed untreatable in settings of great poverty. The feasibility of creating innovative programs that reduce technical and financial barriers to the provision of care for treatable malignancies among the world's poorest populations is now clear **(Fig. 472-4)**. Several middle-income countries, including Mexico, have expanded publicly funded cancer care to reach poorer populations. This commitment of resources has dramatically improved outcomes for cancers, from childhood leukemia to cervical cancer.

Prevention of Noncommunicable Diseases False dichotomies, including those pitting prevention against care, persist in global health and reflect, in part, outmoded paradigms or a limited understanding of shifts in disease burden and causality as well as the dramatic variations in risk within a single nation. Moreover, such dichotomies or debates are sometimes politicized as a result of vested interests. Although globalization has had many positive effects, one negative effect has been the growth in both developed and developing countries of well-financed lobbies that have aggressively promoted unhealthy dietary changes and increased consumption of alcohol and tobacco. The WHO's 2003 Framework Convention on Tobacco Control represented a major advance, committing all of its signatories to a set of policy measures shown to reduce tobacco consumption.

The WHO estimates that 80% of all cases of cardiovascular disease and type 2 diabetes as well as 40% of all cancers can be prevented through healthier diets, increased physical activity, and avoidance of tobacco. These estimates mask large local variations. Although some evidence indicates that population-based measures can have some impact on these behaviors, it is sobering to note that increasing obesity levels have not been reversed in any population. Tobacco avoidance may be the most important and most difficult behavioral modification of all. In the twentieth century, 100 million people worldwide died of tobacco-related diseases; it is projected that >1 billion people will die of these diseases in the twenty-first century, with the vast majority of those deaths in developing countries. Today, ~80% of the world's 1.1 billion smokers live in low- and middle-income countries. If trends continue, tobacco-related deaths will increase to 8 million per year by 2030, with 80% of those deaths in low- and middle-income countries. However, there is well-proven evidence that changes in policy, such as taxes on tobacco and indoor and workplace smoking bans, are effective in decreasing the number of people using tobacco, reducing the amount of tobacco consumed, and preventing young people from starting to use tobacco.

MENTAL AND NEUROLOGIC HEALTH

In 2017, ~792 million people worldwide lived with a mental health disorder, including >548 million people suffering from depression and anxiety disorders. One in four patients visiting a health service has at least one mental, neurologic, or behavioral disorder, but most of these disorders are neither diagnosed nor treated. Almost 800,000 people die by suicide every year, and major depression is the fifth leading cause of years lost to disability in the world today. Most low- and middle-income countries devote <1% of their health expenditures to mental health.

Increasingly effective therapies exist for many of the major causes of mental disorders. One of the greatest barriers to delivery of such therapies is the paucity of skilled personnel. Most sub-Saharan African countries have only a handful of psychiatrists, for example; almost all of them practice in cities and are unavailable within the public sector or to patients living in poverty. Among the few patients who are fortunate enough to see a psychiatrist or neurologist, fewer still are able to adhere to treatment regimens: several surveys of already diagnosed patients ostensibly receiving daily therapy have revealed that, among the poor, multiple barriers prevent patients from taking their medications as prescribed. In one study from Kenya, no patients being seen in an epilepsy clinic had therapeutic blood levels of antiseizure medications, even though all had been prescribed these drugs. Moreover, many patients in this study had no detectable blood levels of these agents. The same barriers that prevent the poor from having reliable access to insulin or ART prevent them from benefiting from antidepressant, antipsychotic,

and antiepileptic agents. To alleviate this problem, some authorities are proposing the training of health workers to provide community-based adherence support, counseling services, and referrals for patients in need of mental health services. One such program instituted in Goa, India, used lay counselors and resulted in a significant reduction in symptoms of common mental disorders among the target population.

CONCLUSION: TOWARD A SCIENCE OF IMPLEMENTATION

There is a long way to go before evidence-based internal medicine is applied effectively among the world's poor. Public health strategies draw largely on quantitative methods—epidemiology, biostatistics, and economics. Clinical practice, including the practice of internal medicine, draws on a rapidly expanding knowledge base and remains focused on individual patient care; clinical interventions are rarely population-based. However, global health equity depends on avoiding the false dichotomies of the past: neither public health nor clinical approaches alone are adequate to address the problems of global health. The integration of prevention and care, along with adequate funding, has shown that complex infectious diseases such as HIV/AIDS and tuberculosis are not impossible to manage, even though drug resistance and lack of effective health systems have complicated such work. Beyond what is usually termed communicable disease—i.e., in the arena of chronic diseases such as cardiovascular disease and mental illness—global health is a nascent endeavor. Efforts to address any one of these problems in settings of great scarcity need to be integrated into broader efforts to strengthen failing health systems and alleviate the growing personnel crisis within these systems. Such efforts must include the building of platforms for care delivery that are robust enough to incorporate new preventive, diagnostic, and therapeutic technologies rapidly in response to changes both in the burden of disease and in the needs not met by existing paradigms and systems of care delivery.

Academic medical centers have tried to address this "know-do" gap as new technologies are introduced and assessed through clinical trials, but the reach of these institutions into settings of poverty is limited in rich and poor countries alike. When such centers link their capacities effectively to the public institutions charged with the delivery of health care to the poor, great progress can be made. For these reasons, scholarly work and practice in the field once known as "international health" and now often designated *global health equity* are changing rapidly. That work is still informed by the tension between clinical practice and population-based interventions, between analysis and action, and between prevention and care.

A number of university hospitals are developing training programs for physicians with an interest in global health. In medical schools across the United States and in other wealthy countries, interest in global health has exploded. One study has shown that >25% of medical students take part in at least one global health experience prior to graduation. Half a century or even a decade ago, such high levels of interest would have been unimaginable.

At least half of the world's population lacks reliable access to essential health services; the consequence is millions of preventable deaths each year. An absolute majority of these premature deaths occur in Africa, with the poorer regions of Asia not far behind. They include deaths from vaccine-preventable illness, deaths during childbirth, deaths from infectious diseases that might be cured with access to antibiotics and other essential medicines, deaths from malaria that would have been prevented by ITNs and access to therapy, and deaths from waterborne illnesses. Other excess mortality is attributable to the inadequacy of efforts to develop new preventive, diagnostic, and therapeutic tools.

The development of tools must be followed quickly by their equitable distribution. Those funding the discovery and development of new tools typically neglect the concurrent need for strategies to make them available to the poor. Indeed, some would argue that the biggest challenge facing those who seek to address this outcome gap is the lack of practical means of delivery in the most heavily affected regions. When new preventive and therapeutic tools are developed without concurrent attention to delivery or implementation, one encounters what are sometimes termed "perverse effects": even as new tools are developed, inequalities of outcome—lower morbidity and mortality rates among those who can afford access, with sustained high morbidity and mortality among those who cannot—grow in the absence of an equity plan to deliver the tools to those most at risk. Preventing such a future is the most important goal of global health.

473 Emerging and Reemerging Infectious Diseases

George W. Rutherford, Jaime Sepúlveda

THE CONCEPT OF EMERGING INFECTIOUS DISEASES

Pathogenic organisms have been a constant companion of humans, their livestock, and their cultivated plants throughout evolution. Over the centuries, new organisms emerged as ecology changed or as humans crossed ecologic barriers such as deserts, mountains, and oceans. Throughout history, there have been severe epidemics of infectious diseases, with devastating consequences to human populations over vast geographic regions. From the Plague of Justinian in Europe in the sixth century, to the Black Death in the fourteenth century, to the five cholera pandemics of the nineteenth century, to the 1918 Spanish influenza pandemic, to the ongoing HIV/AIDS pandemic, to the SARS-CoV-2 (COVID-19) pandemic, the death toll in human populations has been enormous. The concept of emerging infectious diseases arose in the 1970s and 1980s with the recognition of several "new" diseases, such as legionellosis, HIV infection, Lyme disease, and toxic shock syndrome and was later expanded to include reemerging infectious diseases—that is, infectious diseases such as tuberculosis that reappeared after having been controlled. In 1991, the Institute of Medicine (IOM), now the National Academy of Medicine, convened a multidisciplinary committee to elucidate emerging microbial threats to health, with particular reference to the United States. In its report,

the committee defined an emerging infectious disease as a disease "of infectious origin whose incidence in humans has either increased within the past two decades or threatens to increase in the near future." In the year following the publication of the committee's report, large outbreaks of *Escherichia coli* O157:H7 infection, cryptosporidiosis, and hantavirus pulmonary syndrome spurred the development of a national plan to recognize and interdict emerging and reemerging infectious disease threats by the Centers for Disease Control and Prevention (CDC). Since then, the list of emerging and reemerging viral, bacterial, fungal, and parasitic diseases has grown to include multiple infections and syndromes. Examples of emerging and reemerging infectious diseases, as of 2020, are shown in **Table 473-1**.

The reasons for the emergence of previously unrecognized diseases and the reemergence of diseases that have previously been largely under control are legion. At its core, however, emergence has to do with genetic changes in disease agents or changes in ecology, including human behavior. The IOM committee listed six primary reasons for disease emergence or reemergence: human demographics and behavior, technology and industry, economic development and land use, international travel and commerce, microbial adaptation and change, and breakdown of public health measures. A disease can emerge or reemerge for one or more of these reasons. For example, the worldwide spread of severe acute respiratory syndrome (SARS) began as a species crossover, most likely involving transmission of a previously unknown coronavirus of horseshoe bats to Himalayan palm civets that were subsequently captured and transported to live-animal (i.e., "wet") markets in Guangzhou, China, for human consumption. The SARS coronavirus was then transmitted to humans—most likely by restaurant workers—and from them to medical personnel and eventually to individuals around the world. This spread had nothing to do with migratory patterns of bats or civets but was, instead, a consequence of human travel. The cities most affected by SARS—Hong Kong, Beijing, and Toronto—became involved because of rapid human movement via international passenger aircraft. While likely more complex than originally thought, the emergence of SARS-CoV-2 in Wuhan, China, in December 2019 was also thought to involve an intermediate animal host—the pangolin—that had likely been infected in the wild by a bat and then brought to a wet market. From Wuhan, the virus was transmitted throughout China, then throughout Asia and the Pacific, and then to Europe, North and South America, and Africa through human international air travel, resulting in a pandemic rivaling the 1918–1919 influenza A H1N1 pandemic.

Additional factors can now be included on this list. Either therapeutic or acquired immunosuppression (e.g., as in HIV infection) can render populations susceptible to infections that have not previously been recognized, such as that with human herpesvirus 8—the cause of Kaposi's sarcoma. Climate change, in particular, can expand the host range of disease-transmitting vectors. In addition, the weaponization of pathogenic organisms for biological terrorism or warfare can lead, at least theoretically, to prolonged chains of human-to-human transmission. One factor is clear: the preponderance of emerging infectious diseases are zoonotic in origin. The authors of a 2008 review calculated that 60.3% of all emerging infectious disease events from 1940 to 2004 were zoonotic in origin, and 71.8% of these zoonotic events originated in wildlife.

In this chapter, we review the recent changing epidemiology of seven emerging or reemerging infectious viral diseases that exemplify some of the IOM's principles for emergence: infections caused by West Nile virus, dengue virus, Ebola virus, Zika virus, and, most recently, SARS-CoV-2, as well as measles and poliomyelitis—two recently resurging viral diseases that are preventable with existing vaccines but that resurged in 2020. This list is clearly not exhaustive but highlights a few prominent instances of the recent emergence of infectious diseases and their root causes.

TABLE 473-1 Examples of Emerging and Reemerging Infectious Diseases

VIRAL AND PRION	BACTERIAL AND RICKETTSIAL	FUNGAL AND PARASITIC
Chikungunya virus infection	Anaplasmosis	*Candida auris* infection
Congo-Crimean hemorrhagic fever[a]	Anthrax	Coccidioidomycosis
Variant Creutzfeldt-Jakob disease	Carbapenem-resistant *Enterobacterales*	*Cryptosporidium parvum* infection
Dengue	Lyme disease	*Cyclospora cayetanensis* infection
Ebola virus, Marburg virus infection[a]	*Vibrio cholerae* O139 infection	Drug-resistant malaria
Enterovirus D68 infection	Diphtheria	
Hantavirus (Sin Nombre, Seoul) infection	Ehrlichiosis	
Hendra virus, Nipah virus infection	*Escherichia coli* O157:H7 infection	
Hepatitis C	*E. coli* O154:H4 infection	
Hepatitis E	*Legionella pneumophila* infection	
HIV-1 and -2 infection	Plague	
Human herpesvirus 6, 8 infection	Vancomycin-resistant *Staphylococcus aureus* infection	
Human T-lymphotropic virus 1 and 2 infection	Streptococcal toxic shock syndrome	
Influenza A H1N1pdm, H5N7, H7N7, H7N9	Tuberculosis	
Lassa fever[a]		
Lyssavirus infection		
Middle East respiratory syndrome (MERS)[a]		
Monkeypox		
Nipah virus infection[a]		
Rift Valley fever virus infection[a]		
Severe acute respiratory syndrome (SARS)[a,b]		
SARS-CoV-2 (COVID-19)[c]		
West Nile virus infection		
Whitewater Arroyo virus infection		
Yellow fever		
Zika		

[a]Designated by the World Health Organization in 2015 as the highest-priority diseases for research and development. [b]Caused by SARS coronavirus (SARS-CoV). [c]Caused by SARS coronavirus type 2 (SARS-CoV-2).

EXAMPLES OF EMERGING INFECTIOUS DISEASES

WEST NILE VIRUS

West Nile virus (WNV) is a flavivirus that was originally discovered in Uganda in 1937 and emerged as a cause of neurologic disease in humans and equines. WNV exists in nature in an enzootic cycle that involves certain birds and mosquitoes, particularly those of the genera *Culex* and *Aedes*. Humans, horses, and other vertebrates are incidental hosts and, except through blood transfusion, are unlikely to transmit WNV because levels of viremia are insufficiently high to infect mosquitoes. When originally described, WNV was believed to cause a mild febrile illness, but subsequent experience showed that it caused neuroinvasive disease in some cases. Cases of neuroinvasive disease were described first in an outbreak among elderly patients in Israel and subsequently in humans and horses in the Mediterranean basin, India, and South Africa. By the 1990s, outbreaks had been reported from Romania, Russia, and Central Asia; these outbreaks were probably a result of seasonal bird migrations from endemic Mediterranean countries, with introduction of infected mosquitoes and the establishment of infection in local bird species.

An explosive outbreak of WNV infection began in the United States in the summer of 1999 and initially involved infection of birds of the family Corvidae (e.g., American crows and blue jays) that were susceptible to neuroinvasive disease. The first human cases appeared in New York City

that same summer. Thereafter, sufficient numbers of birds more resistant to neuroinvasive disease and mosquitoes of the genus *Culex* became infected, and an enzootic cycle was established in North America. Over the next 3 years, WNV spread across the continental United States, Canada, and Mexico and became an important cause of human and equine neurologic disease. The WNV clade causing the North American outbreak was the same (clade 1a) as that causing disease in the Middle East, Europe, North Africa, and parts of Asia.

In 2019, 971 cases of WNV infection in humans, including 633 cases of neuroinvasive disease, were reported in the United States; these figures are certainly gross underestimates of the actual number of cases. There were 60 deaths, almost all from neuroinvasive disease and almost all among the elderly. An additional 90 cases were reported in horses from 25 states despite the availability of a reasonably protective equine vaccine. Human cases were reported from 40 states; only Hawaii has been consistently free of the disease. Infected mosquito pools were even more widespread; Maine, Minnesota, Vermont, and West Virginia were the only states in the continental United States to be free of all WNV activity. Thus, from an initial introduction into New York City, WNV has successfully established itself across North America and infected an estimated 2.6–6.1 million people in the United States (1.1% of the population).

Why did this happen? First, microorganisms and larger organisms, such as plants and animals, have been exchanged between the Old and New Worlds since the initial voyages of exploration in the fifteenth and sixteenth centuries. However, it is the advent of modern high-speed transportation that allows vectors, such as mosquitoes, to move between continents in hours or days as opposed to months or years. In the most likely scenario for the introduction of WNV into North America, a single viremic mosquito was accidentally transported from an area endemic for clade 1a WNV to New York City in the cargo hold of an airplane in 1999. The original strain associated with the 1999 outbreak (NY99) had caused outbreaks in Tunisia and Israel in 1997 and 1998, respectively; this information suggests that one of those countries was the source. The imported strain in turn infected corvids, which in turn infected more competent mosquitoes, establishing an enzootic life cycle in North America that involved at least three *Culex* species and multiple species of birds. This scenario represents a successful invasion of WNV into a new ecologic niche.

The likelihood that WNV will gradually disappear from North America is low. The virus has many avian hosts and more than one mosquito vector; it has undergone at least one successful mutation in the North American outbreak, thereby becoming infectious to *Culex piperans* and *Culex tarsalis*—mosquitoes with a broad range in the western United States. Moreover, the occurrence of outbreaks in 19 consecutive years in North America suggests that WNV has been successfully introduced onto the continent and will remain endemic for years to come.

DENGUE VIRUS

Dengue is the most important of the human arboviral infections, with almost half of the world's population at risk. Occurring in the range of *Aedes aegypti* mosquitoes, dengue virus infection imposes a heavy burden of morbidity and mortality worldwide, with as many as 50–200 million infections, 500,000 severe cases, and 20,000 deaths annually. Dengue virus is a flavivirus and exists in four serotypes (DENV1–4) that circulate independently of one another; immunity to one serotype does not confer immunity to the others.

Dengue is transmitted primarily by *Ae. aegypti* and secondarily by *Ae. albopictus*. The original life cycle of dengue virus was most likely similar to that of yellow fever virus, consisting of sylvatic transmission from mosquitoes to nonhuman primates and back to mosquitoes; over the past few centuries, the virus has adapted to an urban and periurban mosquito–human–mosquito cycle as well. Dengue and its more severe manifestations, dengue hemorrhagic fever and dengue shock syndrome, were first described in outbreaks in Japan in 1943 and Hawaii in 1945. However, clinically similar diseases had been reported during the previous two centuries in a geographic band extending from India south to Queensland, Australia, and east through Polynesia; in addition, there had been occasional outbreaks in areas as disparate as Greece, Panama, and southern Texas.

The ecology of dengue changed dramatically in the second half of the twentieth century. This change was led by the successful invasion of the global tropics by *Ae. aegypti* after World War II, coincident with the postwar dispersion of troops and materiel. From its ancestral roots in Southeast Asia, all four dengue serotypes have now spread globally. DENV2 was introduced into West Africa by the 1960s and established both sylvatic enzootic nonhuman primate and urban endemic human cycles. Travel and commerce facilitated dissemination, probably through both viremic human hosts and infected mosquitoes. In the Americas in particular, a campaign to eradicate *Ae. aegypti*, which is also the principal vector of yellow fever, failed in the mid-1970s, and both *Ae. aegypti* and dengue virus, especially DENV2, rapidly reinvaded their prior habitat; thus, dengue reemerged as a major arboviral disease extending from the southern United States in the north through northern Argentina in the south. Recent outbreaks have occurred along the U.S.-Mexico border and in the state of São Paulo in Brazil, where DENV1, DENV2, and DENV4 are co-circulating.

Dengue's emergence and spread have been intimately linked to human activity. In particular, globalization, with the movement of viremic people and mosquitoes through modern transportation of both passengers and goods, has been critical to dengue's success. One particular adaptation has also facilitated its urban spread: *Aedes* is able to breed in standing water associated with human habitation, such as cisterns, ornamental ponds, puddles, and water trapped in abandoned tires. This ability of *Aedes* has allowed dengue to be one of the only three known arboviruses (the others being yellow fever and Zika) that are adapted to an urban environment and can replicate entirely in a mosquito-to-human cycle. Together, these factors have led to widespread dengue transmission in a band extending across the tropics worldwide, a host range that will likely expand with warmer and wetter weather due to climate change.

EBOLA AND MARBURG VIRUSES

Ebola virus is a filovirus that most likely exists in a sylvatic cycle in bats in Central and West Africa. Four strains are known to cause human disease. The first outbreak was described in Zaire in 1976. Since then, 31 outbreaks have been reported across tropical Africa, ranging in size from tens of cases to tens of thousands of cases in the West African outbreak of 2013–2016.

The life cycle of Ebola virus in the wild is not fully understood. There is evidence for sustained transmission in fruit bats, with occasional nonhuman primate spillover infections. It has been speculated that humans become infected from contact with infected bats or nonhuman primates, but, once an index case has occurred, essentially all transmission is from human to human due to contact with blood and other body fluids. Preparing bodies for burial has been an especially efficient means of transmission. In addition, health care providers who do not wear adequate personal protective equipment while caring for Ebola patients are particularly vulnerable to acquiring infection. In the 2013–2016 West African epidemic, there was only a single zoonotic introduction, and all subsequent transmission was from human to human.

The principal cause of Ebola outbreaks prior to the West African outbreak was the migration of humans into sylvatic areas, with enzootic transmission and accidental infection. In West Africa, only a single case had been recognized in Côte d'Ivoire before the 2013–2016 outbreak in the Republic of Guinea, Liberia, and Sierra Leone. It has been speculated that cultivation of palm oil attracted fruit bats, who feed on palm fruit; if so, environmental modification from dense tropical forests to palm oil plantations may have been a contributory cause. Other evidence suggests that the index patient—a 2-year-old boy—was exposed to insectivorous free-tailed bats (*Mops condylurus*). Whatever the initial event, the explosive amplification that occurred in these countries and in the seven countries to which cases were exported was due to an inadequate medical and public health infrastructure. In fact, when Ebola virus was imported to countries with more functional public health systems, such as Nigeria, transmission was extinguished within three generations.

Other filovirus outbreaks have involved the transport of infected primates for medical research. The original Marburg virus outbreak, which occurred in Marburg and Frankfurt, West Germany, and Belgrade, Yugoslavia, in 1967, was likely caused by the importation of African vervet monkeys (*Cercopithecus aethiops*) from Uganda for medical research. This outbreak resulted in 31 human cases and 7 deaths. In addition, an outbreak among five crab-eating macaques (*Macaca fascicularis*) imported from the Philippines and infected with Reston Ebola virus—a strain nonpathogenic for humans—led to an epizootic in northern Virginia in 1989, eventually resulting in the culling of >500 primates. This outbreak had no human cases associated with it, although epidemiologic investigation identified a handful of asymptomatic primate handlers who were seropositive for Reston Ebola virus. Since 1989, four additional outbreaks have been recognized in *Cynomolgus* monkeys imported from the Philippines to the United States and Italy.

Another reservoir of Ebola virus infection has been identified: the semen of patients who have survived Ebola infection. The occurrence of several small clusters of sexually transmitted cases developing up to 284 days after symptom onset indicates prolonged carriage of Ebola virus in the testes. Moreover, the virus may remain viable over the long term in the vitreous humor.

Thus, Ebola represents a spillover event to humans and nonhuman primates from their interaction with certain species of infected and infectious bats. Contact with either the bats themselves or an infected nonhuman primate leads to infection of an index patient, which leads in turn to ongoing transmission from humans to humans. Several factors clearly contribute to the continued transmission. First, medical and public health systems are weak in severely affected countries. This inadequacy was especially apparent in the 2018–2020 outbreak in eastern Democratic Republic of the Congo, where insecurity due to ongoing armed conflict greatly amplified the epidemic. As experience with Ebola grows and the capacity for surveillance and response improves, numbers of secondary cases can fall; for example, in five outbreaks in Uganda stretching from 2000 to 2012, the numbers of secondary cases and the geographic spread of the outbreaks decreased with each new introduction. Second, behavioral factors contribute, in particular, funeral practices that bring mourners into close contact with infectious blood and tissues during preparation of a body for burial. Third, the areas in which the initial waves of transmission occur are often remote; thus, recognition of the outbreak can be delayed, and, as in both the West African and the current Congolese outbreaks, highly mobile populations can travel to larger cities to seek care.

Two new preventive vaccines, monoclonal antibody therapy, and portable isolation facilities are now available, and a ring vaccination strategy has now been successfully employed. The widespread transmission seen both in West Africa and especially in the 2018 outbreak in eastern Democratic Republic of the Congo were limited where all these measures were employed rapidly and with sufficient coverage.

ZIKA VIRUS

Zika virus is a flavivirus that is transmitted by *Aedes* mosquitoes and was originally described as an infection of nonhuman primates in Uganda in 1947. The first human cases were reported in Uganda in 1962 and 1963. Zika was thought to be an illness causing a mild rash and fever in humans in tropical Africa and southern Asia. The clinical and serologic similarity of Zika virus infection to dengue virus infection may have caused some outbreaks to be missed. Since 2007, an Asian lineage of Zika virus has spread from the Western Pacific (initially, Yap Island) through Polynesia and on to Easter Island, Chile, where it was documented in 2014. From Polynesia, it also spread to Brazil, most likely through viremic travelers attending the world Va'a World Sprint Championships (Polynesian canoe racing) in Rio de Janeiro in the late summer of 2014. From there, Zika virus spread hemisphere-wide, following the host range of *Ae. aegypti*. Forty-eight countries in the Americas—all except Canada and Chile—reported autochthonously acquired Zika virus infections during the 2014–2016 outbreak. In the United States, locally acquired cases were diagnosed in Florida, Texas, Puerto Rico, the U.S. Virgin Islands, and American Samoa; >35,000 cases were reported from Puerto Rico alone in 2016. Cases have continued to occur at lower levels, with 102 cases reported in the United States and its territories in 2019; 73 of these cases were from Puerto Rico and were most likely acquired autochthonously rather than imported.

As Zika virus spread through the Americas, a parallel epidemic of fetal microcephaly appeared; this epidemic was both temporally and geographically associated with the spread of Zika virus. More than 1.6 million cases of Zika virus infection, including 41,473 cases in pregnant women and 1950 cases of Zika-associated microcephaly, were reported from Brazil alone in 2015 and 2016. Data from a large registry of Zika-exposed pregnancies in the U.S. territories show that the overall risk of microcephaly following confirmed Zika virus infection is ~5%, ranging from 8% for infection in the first trimester to 4% for infection in the third trimester. Other fetal complications include stillbirth, neural tube defects, eye abnormalities, and sensorineural deafness. Complications in adults occur in about one of every thousand cases and include Guillain-Barré syndrome, encephalitis, leukopenia, and thrombocytopenic purpura. Moreover, it is now recognized that Zika virus can be transmitted sexually and via blood transfusion.

Thus, the introduction of Zika into the Americas represents viral invasion of a new ecosystem already widely populated by a highly competent mosquito host with an established urban habitat and an immunologically inexperienced human population. The invasion by Zika virus is in many ways similar to the original dengue virus invasion in the Americas in the 1950s and to the introduction of WNV into North America in 1999. Both the original importation of Zika virus and its establishment of new foci in the Americas (e.g., Florida and the Caribbean) were consequences of modern travel. Zika's spread has also been linked to climate variations, deforestation, and urban poverty.

SARS-COV-2

SARS-CoV-2 is a coronavirus of the beta-coronavirus lineage **(Chap. 199)**. It is closely related to SARS-CoV, the causative agent of SARS, and to the Middle East respiratory syndrome (MERS) virus and is transmitted primarily through droplet transmission and secondarily through aerosol or airborne transmission; unlike SARS-CoV infection, outbreaks of SARS-CoV-2 infection have not been linked to fomite transmission. The first human cases of the clinical disease caused by SARS-CoV-2—COVID-19—were reported in December 2019 from Wuhan, a large city in Hubei Province, China, eventually leading to an outbreak with >70,000 reported cases in that city. The phylogenetic origins of SARS-CoV-2 are clear. It is an enzootic infection of bats, one of several bat-adapted beta-coronavirus infections that have been recognized. How it crossed into humans is less clear. Originally, as early cases centered around a wet market in Wuhan, it was thought that transmission most likely occurred via an infected intermediate host sold in the market: the pangolin, an animal heavily trafficked for its scales. However, subsequent investigations have suggested that the virus may have been in circulation a month or two earlier in China and sporadically in Western Europe and the United States soon thereafter. What is clear is that SARS-CoV-2 caused an explosive outbreak in Wuhan and subsequently spread from China to Iran, Western Europe, and North America and from those regions to the rest of the world. This spread has been aided by an utter lack of preexisting immunity in humans, although it has been speculated that prior infection with alpha-coronaviruses, which are common causes of upper respiratory tract infections, may have some modest protective effect. Twenty-one months later, 218 million cases and >4.5 million deaths have been reported worldwide; in terms of number of deaths, the most affected countries are the United States, India and Brazil. SARS-CoV-2 infection and its clinical disease, COVID-19, were the third leading cause of death in the United States in 2020.

Clinically, SARS-CoV-2 infection causes upper and lower respiratory tract disease. What complicates the control of its transmission is that ~40% of infected individuals never develop acute symptoms and one-third of transmission from symptomatic individuals occurs during the presymptomatic period. While the period of high-level

viral shedding and infectiousness is short (on the order of 3–5 days), patients who develop lower respiratory tract symptoms requiring more intensive care are likely infectious for up to 2 weeks, necessitating strong infection control measures, especially for aerosol-generating procedures.

The SARS-CoV-2 pandemic resulted from a species crossover from bats to humans (possibly through an intermediate host). What human behavior facilitated that crossover is unclear and may have had to do with population pressure and human intrusion into previously unoccupied semitropical forests where bats roost. What is clear, however, is that international travel led to transmission across the globe, first to international ports of entry and then throughout affected countries. In the United States, for instance, original introductions occurred in Seattle, Los Angeles, San Francisco, and New York City, with explosive subsequent expansion in the New York City region during the first wave of the pandemic in March and April of 2020. Control of the pandemic has thus far hinged on social distancing interventions and universal masking. Countries that have done a better job of implementing those interventions, such as Australia, New Zealand, Singapore, South Korea, Taiwan, and Vietnam, have been substantially less impacted than countries that have not. As of this writing, two mRNA vaccines and an adenovirus-vectored vaccine have been deployed in the United States, with approximately 52% of the population fully vaccinated; if they are accepted by a large proportion of the population, these vaccines may lead to levels of immunity sufficiently high to achieve herd immunity and epidemic control. Nowadays, all sorts of conspiracy theories are circulating in social media around COVID-19 vaccines, as has been the case with polio and measles vaccines in the past. Moreover, with disease currently reported in almost every country, it is unlikely that, even with high levels of vaccination, SARS-CoV-2 will be eliminated. Possibly, it will become a sporadic disease and part of the differential diagnosis of severe respiratory viral infection.

POLIOVIRUS

Poliovirus is an RNA enterovirus of the family Picornaviridae. It is the causative pathogen of poliomyelitis, a disease of the central nervous system. Poliovirus is transmitted through the oral-fecal route. Until recently, there were three serotypes of wild poliovirus in nature: PV1, PV2, and PV3. In 1988, all member countries of the World Health Organization (WHO) committed to eradicating poliomyelitis by the year 2000. Thanks to massive immunization campaigns, PV2 was declared eradicated in 2015 and PV3 in 2019. Thus, only wild PV1 still exists and is confined to two countries: Pakistan and Afghanistan.

Poliomyelitis has existed since ancient times. Egyptian steles from 1400 B.C. depict victims of the disease. It probably existed at low endemicity for centuries, until epidemics occurred first in Europe in the nineteenth century and later in the United States in the early to mid-1900s. Although the virus was isolated in 1909, it was not until 1955 that Jonas Salk succeeded in creating an inactivated polio vaccine (IPV). In 1961, Albert Sabin developed an oral polio vaccine (OPV). Both vaccines have advantages and disadvantages. OPV is affordable and easy to administer, provides individual protection, decreases transmission, and—through fecal viral shedding—induces immunity in nonvaccinees. The main disadvantages of OPV are that it may rarely cause paralysis (1 case per 2.4 million doses) and that the vaccine virus may revert to neuropathogenic form if circulating in places with low vaccination prevalence (see below). OPV is also less efficacious in locations with unsanitary conditions because of competition with other enteroviruses. IPV is both safe and efficacious and is preferred to OPV in industrialized countries. However, it is more costly to produce and requires administration by injection. In addition, it does not produce gut immunity and therefore does not contribute to elimination of transmission in outbreaks.

As mentioned above, the attenuated virus in OPV can mutate and regain both the neurovirulence and the transmissibility properties of wild poliovirus, leading to outbreaks of polio in underimmunized populations. This mutated virus is known as circulating vaccine-derived poliovirus (cVDPV). Unfortunately, the current COVID-19 pandemic crisis led the WHO to suspend polio vaccination in all critical countries, with the consequence that the number of polio cases has increased substantially—both those caused by wild poliovirus strains (137 cases in Pakistan and Afghanistan) and those caused by the vaccine-derived strain (751 cases in 24 countries by the end of November 2020).

Twenty years after establishment of the aspirational goal of eradicating polio by 2000, a combination of factors, such as civil war, other violence, conspiracy theories, verticality of programs, a less-than-perfect vaccine, and now the COVID-19 pandemic, has led to a reconsideration of time lines and strategies.

MEASLES VIRUS

The virus causing measles **(Chap. 205)**, a serious exanthematic disease, is an RNA virus of the paramyxovirus family. Measles virus is the most contagious human pathogen and is particularly lethal in malnourished or immunocompromised children. In addition to the measles virus, the genus *Morbillivirus* includes two similar animal viruses: canine distemper virus and rinderpest virus. The latter has been now eradicated, thanks to the immunization of cattle. The measles virus evolved from rinderpest in cattle, probably between the eleventh and twelfth centuries in the Middle East. Thus, measles originated as a zoonosis.

Through history, measles has wrought havoc in unexposed populations. Indigenous peoples in the Americas were devastated in the sixteenth century with the arrival of Europeans. The virus requires a minimal population size of ~250,000 to remain endemic. With increasing birth cohorts and urbanization, measles was a common cause of death in children during the past two centuries. Before the vaccine was introduced in 1963, up to 8 million children died from measles each year. Even by 1980, with a highly efficacious vaccine in place, 2.6 million people died of this preventable disease.

There are no animal reservoirs for measles, the virus is very stable, and there is a highly efficacious, safe, and affordable vaccine. Therefore, measles is the ideal candidate for eradication through mass vaccination. If measles had been targeted for eradication instead of polio in 1988, the disease would have been eliminated some time ago.

Measles virus is airborne and can remain suspended in air for hours indoors after a cough or sneeze. Measles can be transmitted from 4 days before the rash appears to 4 days afterward. The virus causes immunosuppression, which can last for months or years after infection. This immune amnesia renders children more vulnerable to other infectious diseases. It is estimated that an index patient can infect as many as 12–18 unprotected people. This number is known as the *reproduction number* or *Ro*. For comparison, the *Ro* is ~2 for Ebola virus and ~2.5 for SARS-CoV-2.

According to the WHO, there was a vast global resurgence of measles in the past few years, with the highest number of reported cases in 23 years in 2019. That year, nine countries accounted for three-quarters of the cases reported: the Central African Republic, the Democratic Republic of the Congo, Georgia, Kazakhstan, Madagascar, North Macedonia, Samoa, Tonga, and Ukraine. The outbreak of measles in the Democratic Republic of the Congo is the largest recorded in any single country in decades, with >300,000 cases and 6500 deaths. Madagascar, Ukraine, and the Philippines were facing large outbreaks in 2020. The fact is that measles outbreaks are occurring in every region of the world, including in rich countries, as a consequence of years of declining vaccination coverage. As some experts say, the problem is not vaccine failure, but failure to vaccinate.

The COVID-19 pandemic has forced many countries to suspend or postpone vaccination campaigns, including for measles. This tragic situation will surely contribute to larger measles outbreaks globally. Another contributing factor is vaccine hesitancy among some groups of parents **(Chap. 3)**. The false claim that measles vaccination might be linked to autism fostered a movement against vaccines in general and measles-containing vaccines in particular. This opposition began in wealthy countries but is spreading to other regions. During recent measles outbreaks, antivaccination messages had more online links than messages favoring vaccination. Understanding the causes behind decreased vaccination coverage will be critical to the eventual eradication of measles virus.

CONTROL OF EMERGING INFECTIOUS DISEASES

Humans will continue to experience outbreaks of emerging and reemerging infectious diseases. Emerging diseases will most likely come from two sources. The first source consists of organisms that have acquired new genetic materials from other strains of the same species or from different species altogether. An example is influenza A virus, in which strains can acquire new genetic material through a process called *reassortment*. If the new gene is a hemagglutinin gene, the resulting reassortant virus will have a new surface hemagglutinin that is unrecognized immunologically by most human populations. An interesting case is influenza A H1N1 virus, which emerged in 2009 from the reassortment of H1N1 swine influenza virus with human seasonal H3N2 influenza virus, North American avian influenza virus, and Eurasian avian-origin swine influenza viruses. Despite a worldwide pandemic, people born before 1950 were relatively spared because they had earlier exposure to an H1N1 strain sufficiently similar to provide them with cross-immunity. Another example is *E. coli* O157:H7, which acquired a virulence gene from *Shigella*, probably as the result of horizontal genetic exchange. The resulting organism and several other serotypes of *E. coli* that have acquired the gene constitute the leading cause of hemolytic-uremic syndrome worldwide. The second source for emergence of infections consists of existing organisms entering new ecologic niches and spreading broadly, often through insect vectors, to immunologically naïve humans—as occurred with WNV and Zika virus. In a variation on this theme, humans can enter new ecosystems and become infected with organisms to which they have no immunity. An organism's epidemic potential will be determined by whether it is largely incapable of leaving the human host to continue onward via human-to-human transmission (e.g., *Coccidioides*) or can be efficiently transmitted from human to human (e.g., SARS-CoV-2, HIV, and Ebola virus).

In its 1994 strategic plan to address emerging infectious disease threats, the CDC listed four goals: (1) to detect, promptly investigate, and monitor emerging pathogens, the diseases they cause, and the factors influencing their emergence; (2) to integrate laboratory science and epidemiology in order to optimize public health practice; (3) to enhance communication of public health information about emerging diseases and ensure prompt implementation of prevention strategies; and (4) to strengthen local, state, and federal public health infrastructures in order to support surveillance and implement prevention and control programs. Much of this plan has been implemented. The concept of "emerging infectious diseases" has been broadly accepted, and molecular biological methods have improved to the point that, for example, the SARS coronavirus was completely sequenced in a matter of days. In addition, there has been an increasing recognition of the "one health" concept: the nexus among human, livestock, wildlife, and plant health and the development of surveillance systems to provide early warnings of emerging and reemerging infections. New vaccines and new vector-control agents are important promising weapons in the struggle to contain existing diseases; two highly effective messenger RNA vaccines for SARS-CoV-2 were deployed beginning in December 2020, Ebola vaccines are being widely employed in the current outbreak in the Democratic Republic of the Congo, and dengue vaccine is effective, although only in the United States, its use is limited to children 9–16 years old who have laboratory evidence of prior dengue infection. Moreover, a new vector-control technique involving deliberate infection of the *Aedes* population with *Wolbachia*, a bacterial genus that inhibits the transmission of arbovirus from mosquito hosts, is being evaluated.

The WHO has developed new international health regulations that are designed, in part, to facilitate the recognition and reporting of infectious disease threats. However, as evidenced by the current SARS-CoV-2 pandemic and the 2013–2016 Ebola virus epidemic in West Africa, additional capacity and new forms of global health governance and response may be required. Clearly, robust, flexible, and timely responses will be needed to control emerging and reemerging infections.

474 Primary Care and Global Health

Tim Evans, Kumanan Rasanathan

The twentieth century witnessed the rise of an unprecedented global health divide. Industrialized or high-income countries experienced rapid improvement in standards of living, nutrition, health, and health care **(Chap. 7)**. Meanwhile, in low- and middle-income countries with much less favorable conditions, health and health care progressed much more slowly. The scale of this divide is reflected in the current extremes of life expectancy at birth, with Japan at the high end (84 years) and Lesotho at the low end (51 years). This 33-year difference reflects the daunting range of health challenges faced by low- and middle-income countries. These nations must deal not only with a complex mixture of diseases (both infectious and chronic) and illness-promoting conditions but also, and more fundamentally, with the fragility of the foundations underlying good health (e.g., sufficient food, water, sanitation, and education) and of the systems necessary for universal access to good-quality health care and public health. In the last decades of the twentieth century, the need to bridge this global health divide and establish health equity was increasingly recognized. The Declaration of Alma-Ata in 1978 crystallized a vision of justice in health, regardless of income, gender, ethnicity, or education, and called for "health for all by the year 2000" through primary health care. While progress since the declaration is remarkable, >40 years later and in the midst of a global pandemic of COVID-19, much remains to be done to achieve global health equity.

This chapter looks first at the nature of the health challenges that underlie the health divide in low- and middle-income countries. It then outlines the values and principles of a primary health care approach, with a focus on primary care services. Next, the chapter reviews the experience of low- and middle-income countries in addressing health challenges through primary care and a primary health care approach. Finally, the chapter identifies how current challenges and global context, in particular, the global pandemic, shape an agenda for the renewal of primary health care and primary care, allied to the movement to achieve universal health coverage.

PRIMARY CARE AND PRIMARY HEALTH CARE

The term *primary care* has been used in many different ways: to describe a level of care or the setting of the health system, a set of treatment and prevention activities carried out by specific personnel, a set of attributes for the way care is delivered, or an approach to organizing

health systems that is synonymous with the term *primary health care*. In 1996, the U.S. Institute of Medicine encompassed many of these different usages, defining primary care as "the provision of integrated, accessible health care services by clinicians who are accountable for addressing a large majority of personal health care needs, developing a sustained partnership with patients, and practicing in the context of family and community."[1] We use this definition of *primary care* in this chapter. Primary care performs an essential function for health systems, providing the first point of contact when people seek health care, dealing with most problems, and referring patients onward to other services when necessary. As is increasingly evident in countries of all income levels, without strong primary care, health systems cannot function properly or address the health challenges of the communities they serve.

Primary care is only one part of a primary health care approach. The Declaration of Alma-Ata, drafted in 1978 at the International Conference on Primary Health Care in Alma-Ata (now Almaty in Kazakhstan), identified many features of primary care as being essential to achieving the goal of "health for all by the year 2000." However, it also identified the need to work across different sectors, address the social and economic factors that determine health, mobilize the participation of communities in health systems, and ensure the use and development of technology that was appropriate in terms of setting and cost. The declaration drew from the experiences of low- and middle-income countries in trying to improve the health of their people following independence. Commonly, these countries had built hospital-based systems similar to those in high-income countries. This effort had resulted in the development of high-technology services in urban areas while leaving the bulk of the population without access to health care unless they traveled great distances to these urban facilities. Furthermore, much of the population lacked access to basic public health measures. Primary health care efforts aimed to move care closer to where people lived, to ensure their involvement in decisions about their own health care, and to address key aspects of the physical and social environment essential to health, such as water, sanitation, and education.

After the Declaration of Alma-Ata, many countries implemented reforms of their health systems based on primary health care. Most progress involved strengthening of primary care services; unexpectedly, however, much of this progress was seen in high-income countries, most of which constructed systems that made primary care available at low or no cost to their entire populations and that delivered the bulk of services in primary care settings. This endeavor also saw the reinforcement of family medicine as a specialty to provide primary care services. Even in the United States (an obvious exception to this trend), it became clear that the populations of states with more primary care physicians and services were healthier than those with fewer such resources.

Progress was also made in many low- and middle-income countries. However, the target of "health for all by the year 2000" was missed by a large margin. The reasons were complex but partly entailed a general failure to implement all aspects of the primary health care approach, particularly work across sectors to address social and economic factors that affect health and provision of sufficient human and other resources in order to make possible the access to primary care attained in high-income countries. Furthermore, despite the consensus in Alma-Ata in 1978, the global health community rapidly became fractured in its commitment to the far-reaching measures called for by the declaration. Economic recession tempered enthusiasm for primary health care, and momentum shifted to programs concentrating on a few priority measures such as immunization, oral rehydration, breastfeeding, and growth monitoring for child survival. Success with these initiatives supported the continued movement of health development efforts away from the comprehensive approach of primary health care and toward programs that targeted specific public health priorities. This approach was reinforced by the need to address the HIV/AIDS epidemic. By the 1990s, primary health care had fallen out of favor in many global-health policy circles, and low- and middle-income countries were being encouraged to reduce public sector spending on health and to focus on cost-effectiveness analysis to provide a package of health care measures thought to offer the greatest health benefits.

HEALTH CHALLENGES IN LOW- AND MIDDLE-INCOME COUNTRIES

Low- and middle-income countries, defined by a per capita gross national income of <$12,535 (U.S.) per person per year, account for >85% of the world's population. Average life expectancy in these countries lags far behind that in high-income countries: whereas the average life expectancy at birth for a girl in high-income countries is 83 years, it is only 65 years for a girl in low-income countries. This discrepancy has received growing attention over the past 50 years. Initially, the situation in poor countries was characterized primarily in terms of high fertility and high infant, child, and maternal mortality rates, with most deaths and illnesses attributable to infectious or tropical diseases among remote, largely rural populations. With growing adult (and especially elderly) populations and changing lifestyles linked to global forces of urbanization, a new set of health challenges characterized by chronic diseases, environmental overcrowding, and road traffic injuries has emerged rapidly **(Fig. 474-1)**. The majority of tobacco-related deaths globally now occur in low- and middle-income countries, and the risk of a child's dying from a road traffic injury in Africa is more than twice that in Europe. Thus, low- and middle-income countries in the twenty-first century face a full spectrum of health challenges—infectious, chronic, and injury-related—at much higher incidences and prevalences than are documented in high-income countries and with many fewer resources to address these challenges.

Addressing these challenges, however, does not mean simply waiting for economic growth. Analysis of the association between wealth and health across countries reveals that, for any given level of wealth, there is a substantial variation in life expectancy at birth that has persisted despite overall global progress in life expectancy during the past 40 years **(Fig. 474-2)**. Health status in low- and middle-income countries varies enormously. Nations such as Cuba and Costa Rica have life expectancies and childhood mortality rates similar to or even better than those in high-income countries; in contrast, countries in sub-Saharan Africa and the former Soviet bloc have at times experienced significant reverses in these health markers, particularly in the 1990s.

As Angus Deaton stated in the World Institute for Development Economics Research annual lecture on September 29, 2006, "People in poor countries are sick not primarily because they are poor but because of other social organizational failures, including health delivery, which are not automatically ameliorated by higher income." This analysis concurs with classic studies of the array of societal factors explaining good health in poor settings such as Cuba and Kerala State in India in the 1980s. Analyses conducted over the past four decades indeed show that rapid health improvement is possible in very different contexts. That some countries continue to lag far behind can be understood through a comparison of regional differences in progress in terms of life expectancy over this period **(Fig. 474-3)**.

As average levels of health vary across regions and countries, so too do they vary within countries **(Fig. 474-4)**. Indeed, disparities within countries are often greater than those between high-income and low-income countries. For example, if low- and middle-income countries could reduce their overall childhood mortality rate to that of the richest one-fifth of their populations, global childhood mortality could be decreased by 40%. Disparities in health are mostly a result of social and economic factors such as daily living conditions, access to resources, and ability to participate in life-affecting decisions. In most countries, the health care sector actually tends to exacerbate health inequalities (the "inverse-care law"); because of neglect and discrimination, poor and marginalized communities are much less likely to benefit from public health services than those that are better off. Reforming health systems toward people-centered primary care provides an opportunity to reverse these negative trends.

Health services have failed to make their contribution to reducing these pervasive social inequalities by ensuring universal access to existing, scientifically validated, low-cost interventions such as insecticide-treated bed nets for malaria, taxes on cigarettes, short-course chemotherapy for tuberculosis, antibiotic treatment for pneumonia, dietary modification and secondary prevention measures for high blood pressure and high cholesterol levels, and water treatment and oral rehydration therapy for diarrhea. Despite decades of "essential packages" and "basic" health campaigns, the effective implementation of what is already known to work with requisite scale and quality appears (deceptively) to be difficult.

Recent analyses have begun to focus on "the how" (as opposed to "the what") of health care delivery, exploring why health progress is slow and sluggish despite the abundant availability of proven

interventions for health conditions in low- and middle-income countries. Three general categories of reasons are being identified: (1) shortfalls in performance of health systems; (2) stratifying social conditions; and (3) skews in science.

SHORTFALLS IN PERFORMANCE OF HEALTH SYSTEMS

Specific health problems often require the development of specific health interventions (e.g., tuberculosis requires short-course chemotherapy). However, the delivery of different interventions is often facilitated by a common set of resources or functions: money or financing, trained health workers, and facilities with reliable supplies fit for multiple purposes. Unfortunately, health systems in most low- and middle-income countries are largely dysfunctional across these core functions.

In the large majority of low- and middle-income countries, the level of public financing for health is woefully insufficient: whereas high-income countries spend, on average, >7% of the gross domestic product on health, middle-income countries spend <3%, and low-income countries <2%. External financing for health through various donor channels grew rapidly in the first decade of the twenty-first century but has grown more slowly in the second decade to its current level of $37 billion. While these funds for health are significant, they represent <2% of total health expenditures in low- and middle-income countries and therefore are neither a sufficient nor a long-term solution to chronic underfinancing. In Africa, 70% of health expenditures come from domestic sources. The predominant form of health care financing—charging patients at the point of service—is the least efficient and the most inequitable, tipping millions of households into poverty annually.

Health workers, who represent another critical resource, are often inadequately trained and supported in their work especially in locations with the greatest needs. Recent estimates indicate a shortage of >18 million health workers, constituting a crisis that is greatly exacerbated by the migration of health workers from low- and middle-income countries to high-income countries. Sub-Saharan Africa carries 24% of the global disease burden but has only 3% of the health workforce **(Fig. 474-5)**.

Critical diagnostics and drugs often do not reach patients in need because of supply-chain failures. Moreover, facilities fail to provide good-quality and safe care: new evidence suggests much higher rates of adverse events among hospitalized patients in low- and middle-income countries than in high-income countries. Weak government planning, regulatory, monitoring, and evaluation capacities are associated with rampant, unregulated commercialization of health services and chaotic fragmentation of these services as donors "push" their respective priority programs. With such fragile foundations, it is not surprising that low-cost, affordable, validated interventions are not reaching those who need them.

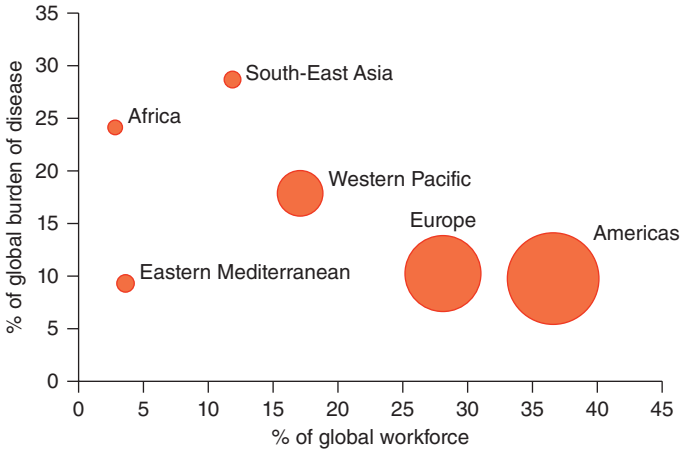

FIGURE 474-5 Global burden of disease and health workforce. *(Reproduced with permission from World Health Organization: Working together for health, 2006.)*

STRATIFYING SOCIAL CONDITIONS

Health care delivery systems do not exist in a vacuum but rather are embedded in a complex of social and economic forces that often stratify opportunities for health unfairly. Most worrisome are the pervasive forces of social inequality that serve to marginalize populations with disproportionately large health needs (e.g., the urban poor; illiterate mothers). Why should a poor slum dweller with no income be expected to come up with the money for a bus fare needed to travel to a clinic to learn the results of a sputum test for tuberculosis? How can a mother living in a remote rural village and caring for an infant with febrile convulsions find the means to get her child to appropriate care? Shaky or nonexistent social security systems, dangerous work environments, isolated communities with little or no infrastructure, and systematic discrimination against racialized minorities are among the myriad forces with which efforts for more equitable health care delivery must contend.

SKEWS IN SCIENCE

While science has yielded enormous breakthroughs in health in high-income countries, with some spillover to low- and middle-income countries, many important health problems continue to affect primarily low- and middle-income countries whose research and development investments are deplorably inadequate. The past two decades have seen growing efforts to right this imbalance with research and development investment for new drugs, vaccines, and diagnostics that effectively cater to the specific health needs of populations in low- and middle-income countries. For example, the TB Alliance has revitalized a previously "dry" pipeline for new tuberculosis drugs. In 2019, their new drug (pretomanid) received U.S. Food and Drug Administration approval as part of a triple oral regimen (bedaquiline, pretomanid, and linezolid) [BPaL]) that treats extensively drug-resistant tuberculosis faster, better, and cheaper.

As discussed above, the primary constraint on better health in low- and middle-income countries is related less to the availability of health technologies and more to their effective delivery. Underlying these health delivery challenges is a major bias regarding what constitutes legitimate "science" to improve health equity. The lion's share of health research financing is channeled toward the development of new technologies—drugs, vaccines, and diagnostics; in contrast, virtually no resources are directed toward research on how health care delivery systems can become more reliable and overcome adverse social conditions. The complexity of systems and social context is such that this issue of delivery requires an enormous investment in terms not only of money but also of scientific rigor, with the development of new research methods and measures and the attainment of greater legitimacy in the mainstream scientific establishment.

These common challenges to low- and middle-income countries partly explain the resurgence of interest in the primary health care approach and the emergence of a global movement toward universal health coverage, now enshrined as one of the Sustainable Development Goal targets adopted in Agenda 2030 by all countries at the United Nations in September 2015. In some countries (mostly middle-income), significant progress has been made in expanding coverage by health systems based on primary care and even in improving indicators of population health. More countries are embarking on the creation of primary care services despite the challenges that exist, particularly in low-income countries. Even when these challenges are acknowledged, there are many reasons for optimism that low- and middle-income countries can accelerate progress in building primary care as a key vehicle toward achieving universal health coverage.

PRIMARY HEALTH CARE IN THE TWENTY-FIRST CENTURY

The new millennium has seen a resurgence of interest in primary health care as a means of addressing global health challenges but also of familiar obstacles to its implementation. This interest has been driven by many of the same issues that led to the Declaration of Alma-Ata: rapidly increasing disparities in health between and within countries, spiraling costs of health care at a time when many people lack quality care, dissatisfaction of communities with the care they are able to access, failure to address changes in health threats, especially noncommunicable disease epidemics, and most recently, global failures in preparing for and responding to the COVID-19 pandemic. These challenges require a comprehensive approach and strong health systems with effective primary care. Global health development agencies have partially recognized that sustaining gains in public health priorities such as HIV/AIDS and pandemic preparedness requires not only robust health systems but also the tackling of social and economic factors related to disease incidence and progression. Weak health systems have proved a major obstacle to delivering new technologies, such as COVID-19 vaccines and antiretroviral therapy, to all who need them. We discuss experiences in low- and middle-income countries in relation to primary care in greater detail below. First, we consider the features of primary health care and primary care as currently understood.

REVITALIZATION OF PRIMARY HEALTH CARE

At the 2019 World Health Assembly (an annual meeting of all countries to discuss the work of the World Health Organization [WHO]), a resolution was passed reaffirming the principles of the Declaration of Alma-Ata and the need for national health systems to be based on primary health care. This resolution reframed primary health care as three components: (1) primary care and essential public health functions as the core of integrated health services; (2) empowered people and communities; and (3) multisectoral policy and action. This reframing itself drew on the 2008 WHO World Health Report, which asserted that a primary health care approach was necessary "now more than ever" to address global health priorities, especially in terms of disparities and new health challenges.

The 2008 World Health Report highlighted four broad areas for reform (Fig. 474-6). One of these areas—the need to organize health care so that it places the needs of people first—relates to the necessity for strong primary care in health systems and what this requirement entails. The other three areas also relate to primary care. All four areas require action to move health systems in a direction that will reduce disparities and increase the satisfaction of those they serve.

Universal Coverage Reforms to Improve Health Equity

Despite progress in many countries, most people in the world can receive health care services only if they can pay at the point of service. Disparities in health are caused not only by a lack of access to necessary

FIGURE 474-6 The four reforms of primary health care renewal. *(Reproduced with permission from World Health Organization: Primary Health Care: Now More Than Ever. World Health Report 2008.)*

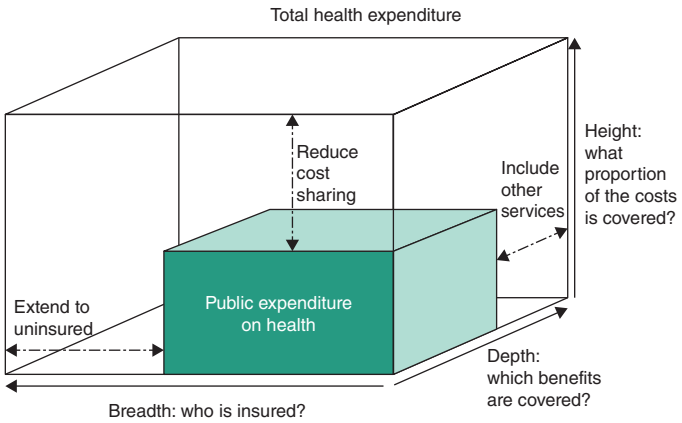

FIGURE 474-7 Three ways of moving toward universal coverage.

health services but also by the impact of expenditure on health. More than 100 million people are still being driven into extreme poverty each year by health care costs, with countless others deterred from accessing services at all. Moving toward prepayment financing systems for universal coverage, which ensure access to a comprehensive package of services according to need without precipitating economic ruin, has therefore emerged as a major priority in low- and middle-income countries. Increasing coverage of health services can be considered in terms of three axes: the proportion of the population covered, the range of services underwritten, and the percentage of costs paid (Fig. 474-7). Moving toward universal health coverage requires ensuring the availability of health care services to all, eliminating barriers to access, and organizing pooled financing mechanisms, such as taxation or insurance, to remove user fees at the point of service. It also requires measures beyond financing, including expansion of health services in poorly served areas, improvement in the quality of services provided to marginalized communities, and increased coverage of other social services that significantly affect health (e.g., education).

Service Delivery Reforms to Make Health Systems People-Centered Health systems have often been organized around the needs of those who provide health care services, such as clinicians and policymakers. The result is a centralization of services or the provision of vertical programs that target single diseases. The principles of primary health care, including the development of primary care, reorient care around the needs of the people to whom services cater. This "people-centered" approach aims to provide health care that is both more effective and appropriate.

The increase in noncommunicable diseases in low- and middle-income countries offers a further stimulus for urgent reform of service delivery to improve chronic disease care. As discussed above, large numbers of people currently fail to receive relatively low-cost interventions that have reduced the incidence of these diseases in high-income countries. Delivery of these interventions requires health systems that can address multiple problems and manage people over a long period within their own communities, yet many low- and middle-income countries are only now starting to adapt and build primary care services that can address noncommunicable diseases and communicable diseases requiring chronic care. Even some countries (e.g., Iran) that have had significant success in reducing communicable diseases and improving child survival have been slow to adapt their health systems to rapidly accelerating noncommunicable disease epidemics.

People-centered care requires a safe, comprehensive, and integrated response to the needs of those presenting to health systems, with treatment at the first point of contact or referral to appropriate services. Because no discrete boundary separates people's needs for health promotion, curative interventions, and rehabilitation services across different diseases, primary care services must address all presenting problems in a unified way. Meeting people's needs also involves improved communication between patients and their clinicians, who must take the time to understand the impact of the patients' social context on the problems they present with. This enhanced understanding is made possible by improvements in the continuity of care so that responsibility transcends the limited time people spend in health care facilities. Primary care plays a vital role in navigating people through the health system; when people are referred elsewhere for services, primary care providers must monitor the resulting consultations and perform follow-up. All too often, people do not receive the benefit of complex interventions undertaken in hospitals because they lose contact with the health care system once discharged. Comprehensiveness and continuity of care are best achieved by ensuring that people have an ongoing personal relationship with a care team.

Public Policy Reforms to Promote and Protect the Health of Communities Public policies in sectors other than health care are essential to reduce disparities in health and to make progress toward global public health targets. The 2008 final report of the WHO Commission on Social Determinants of Health provided an exhaustive review of the multisectoral policies required to address health inequities at the local, national, and global levels. Advances against major challenges such as HIV/AIDS, tuberculosis, emerging infections, cardiovascular disease, cancers, and injuries require effective collaboration with sectors such as transport, housing, labor, agriculture, urban planning, trade, and energy. The COVID-19 pandemic has underscored the importance of multisectoral action to protect health; countries that have been most successful in managing the pandemic have been those best able to coordinate across their societies to implement nonpharmaceutical health measures and build social solidarity. Similarly, while tobacco control provides a striking example of what is possible if different sectors work together toward health goals, the lack of implementation of many evidence-based tobacco control measures in most countries just as clearly illustrates the difficulties encountered in such multisectoral work and the unrealized potential of public policies to improve health.

Leadership Reforms to Make Health Authorities More Reliable The Declaration of Alma-Ata emphasized the importance of participation by people in their own health care. In fact, participation is important at all levels of decision-making. Contemporary health challenges require new models of leadership that acknowledge the role of government in reducing disparities in health but that also recognize the many types of organizations that provide health care services. Governments need to guide and negotiate among these different groups, including nongovernmental organizations (NGOs) and the private sector, and to provide strong regulation where necessary. This difficult task requires a massive reinvestment in leadership and governance capacity, especially if action by different sectors is to be effectively implemented. Moreover, disadvantaged groups and other actors are increasingly expecting that their voices and health needs will be included in the decision-making process. The complex landscape for leadership at the national level is mirrored in many ways at the international or global level. The transnational character of health and the increasing interdependence of countries with respect to outbreak diseases, climate change, security, migration, and agriculture place a premium on more effective global health governance.

EXPERIENCES WITH PRIMARY CARE IN LOW- AND MIDDLE-INCOME COUNTRIES

Aspects of the primary health care approach described above, with an emphasis on primary care services, have been implemented to varying degrees in many low- and middle-income countries over the past half-century. As discussed above, some of these experiences inspired and informed the Declaration of Alma-Ata, which itself led many more countries to attempt to implement primary health care. This section describes the experiences of a selection of low- and middle-income countries in improving primary care services that have enhanced the health of their populations.

Before Alma-Ata, few countries had attempted to develop primary care on a national level. Rather, most focused on expanding primary care services to specific communities (often rural villages), making use of community volunteers to compensate for the absence of facility-based

care. In contrast, in the post–World War II period, China invested in primary care on a national scale, and life expectancy doubled within roughly 20 years. The Chinese expansion of primary care services included a massive investment in infrastructure for public health (e.g., water and sanitation systems) linked to innovative use of community health workers. These "barefoot doctors" lived in and expanded care to rural villages. They received a basic level of training that enabled them to provide immunizations, maternal care, and basic medical interventions, including the use of antibiotics. Through the work of the barefoot doctors, China brought low-cost universal basic health care coverage to its entire population, most of which had previously had no access to these services.

In 1982, the Rockefeller Foundation convened a conference to review the experiences of China along with those of Costa Rica, Sri Lanka, and the state of Kerala in India. In all of these locations, good health care at low cost appeared to have been achieved. Despite lower levels of economic development and health spending, all of these jurisdictions, along with Cuba, had health indicators approaching—or in some cases exceeding—those of developed countries. Analysis of these experiences revealed a common emphasis on primary care services, with expansion of care to the entire population free of charge or at low cost, combined with community participation in decision-making about health services and coordinated work in different sectors (especially education) toward health goals. During the more than three decades since the Rockefeller meeting, some of these countries have built on this progress, while others have experienced setbacks. Recent experiences in developing primary care services show that the same combination of features is necessary for success. For example, Brazil—a large country with a dispersed population—made major strides in increasing the availability of health care from 1980 to 2010. The Brazilian Family Health Program expanded progressively across the country to reach universal coverage. This program provided communities with free access to primary care teams made up of primary care physicians, community health workers, nurses, dentists, obstetricians, and pediatricians. These teams were responsible for the provision of primary care to all people in a specified geographic area—not only those who access health clinics. Moreover, individual community health workers were responsible for a named list of people within the area covered by the primary care team. Solid evidence indicated that the Family Health Program has contributed to impressive gains in population health, particularly in terms of childhood mortality and health inequities **(Fig. 474-8)**. Nevertheless, systemic inequalities, magnified during the COVID-19 crisis, highlight how continued progress is not guaranteed, and efforts to implement and expand a primary health care approach need to adapt to new health and political challenges.

Chile has also built on its existing primary care services in the past two decades, aiming to improve the quality of care and the extent of coverage in remote areas, above all for disadvantaged populations. This effort has been made in concert with measures aimed at reducing social inequalities and fostering development, including social welfare benefits for families and disadvantaged groups and increased access to early-childhood educational facilities. As in Brazil, these steps have improved maternal and child health and have reduced health inequities. In addition to directly enhancing primary care services, Brazil and Chile have instituted measures to increase both the accountability of health providers and the participation of communities in decision-making. In Brazil, national and regional health assemblies with high levels of public participation are integral parts of the health policy-making process. Chile has instituted a patient's charter that explicitly specifies the rights of patients in terms of the range of services to which they are entitled.

Other countries that have made recent progress with primary health care include Bangladesh, once one of the poorest countries in the world and still relatively poor. Since achieving its independence from Pakistan in 1971, Bangladesh has seen a dramatic increase in life expectancy, and childhood mortality rates are now lower than those in neighboring nations such as India and Pakistan. The expansion of access to primary care services has played a major role in these achievements. This progress has been spearheaded by a vibrant NGO community that has focused its attention on improving the lives and livelihoods of poor women and their families through innovative and integrated microcredit, education, and primary care programs. The above examples, along with others from the past 40 years in countries such as Thailand, Rwanda, Ethiopia, Turkey, Viet Nam, and Oman, illustrate how the implementation of a primary health care approach, with a greater emphasis on primary care, has led to better access to health care services—a trend that has not been seen in many other low- and middle-income countries. This trend, in turn, has contributed to improvements in population health and reductions in health inequities. However, as these nations have progressed, other countries have shown how previous gains in primary care can easily be eroded. In sub-Saharan Africa, undermining of primary care services contributed to catastrophic reversals in health outcomes catalyzed by the HIV/AIDS epidemic. Countries such as Botswana and Zimbabwe implemented primary health care strategies in the 1980s, increasing access to care and making impressive gains in child health. Both countries were severely affected by HIV/AIDS, with pronounced decreases in life expectancy. However, Zimbabwe has also seen political turmoil, a decline of health and other social services, and the flight of health personnel, whereas Botswana has maintained primary care services to a greater extent and has managed to organize widespread access to antiretroviral therapy for people living with HIV/AIDS. China provides a particularly striking example of how changes in health policy relevant to the organization of health systems **(Fig. 474-9)** can have rapid, far-reaching consequences for population health. Even as the 1982 Rockefeller conference was celebrating China's achievements in primary care, its health system was unraveling. The decision to open up the economy in the early 1980s led to rapid privatization of the health sector and the breakdown of universal health coverage. As a result, by the end of the 1980s, most people, especially the poorer segments of the population, were paying directly out of pocket for health care, and almost no Chinese had insurance—a dramatic transformation. The "barefoot doctor" schemes collapsed, and the population either turned to care paid for at hospitals or simply became unable to access care. This undermining of access to primary care services in the Chinese system and the resulting increase in impoverishment due to illness contributed to the stagnation of progress in health in China at the same time that incomes in that country increased at an unprecedented rate. Reversals in primary care have meant that China now increasingly faces health care issues similar to those faced by India, although the country has more recently implemented measures to restore universal health coverage, with significant success. In both countries, rapid economic growth has been linked to lifestyle changes and noncommunicable

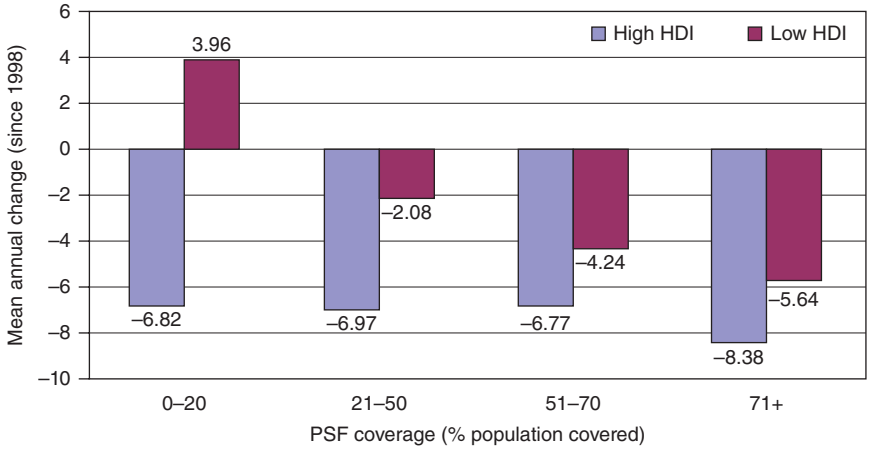

FIGURE 474-8 Improvements in childhood mortality following the Family Health Program in Brazil. HDI, Human Development Index; PSF, Program Saúde da Família (Family Health Program). *(Source: Ministry of Health, Brazil.)*

disease epidemics. The health care systems of the two nations share two negative features that are common when primary care is weak: a disproportionate focus on specialty services provided in hospitals and unregulated commercialization of health services. China and India both saw expansion of private hospital services that cater to middle-class and urban populations who can afford care; at the same time, hundreds of millions of people in rural areas struggled to access basic services. Even in the former groups, a lack of primary care services has been associated with late presentation with illness and with insufficient investment in primary prevention approaches. This neglect of prevention poses a risk of large-scale epidemics of cardiovascular disease, which could endanger continued economic growth. In addition, the health systems of both countries now depend for the majority of their funding on out-of-pocket payments by people when they use services. Thus, substantial proportions of the population must sacrifice other essential goods as a result of health expenditure and may even be driven into poverty by this cost. The commercial nature of health services with inadequate or no regulation has also led to the proliferation of charlatan providers, inappropriate care, and pressure for people to pay for expensive and sometimes unnecessary care. Commercial providers have limited incentives to use interventions (including public health measures) that cannot be charged for or that are what the person who is paying can afford.

Faced with these problems, China and India have implemented measures to strengthen primary health care. China has increased government funding of health care, has taken steps toward restoring health insurance, and has enacted a target of universal access to primary care services. India has similarly mobilized funding to greatly expand primary care services in rural areas and duplicated this process in urban settings. Both countries are increasingly using public resources from their growing economies to fund primary care services.

These encouraging trends are illustrative of new opportunities to implement a primary health care approach and strengthen primary care services in low- and middle-income countries. Over the past decade, all countries have adopted universal health coverage—the provision of quality health services in a timely manner at affordable cost—and the primary health care approach remains key to achieving this.

OPPORTUNITIES TO BUILD PRIMARY CARE IN LOW- AND MIDDLE-INCOME COUNTRIES

Global public health targets will not be met unless health systems are significantly strengthened. More money is currently being spent on health than ever before. In 2017, global health spending totaled $7.8 trillion (U.S.)—more than double the amount spent a decade earlier. Although most expenditure occurs in high-income countries, spending in many emerging middle-income countries has rapidly accelerated, as has the allocation of monies for this purpose by both governments in and donors to low-income countries. These twin trends—greater emphasis on building health systems based on primary care and allotment of more money for health care—provide opportunities to address many of the challenges discussed above in low- and middle-income countries.

Accelerating progress requires a better understanding of how global health initiatives can more effectively facilitate the development of primary care in low-income countries. A review by the WHO Maximizing Positive Synergies Collaborative Group looked at programs funded by the Global Fund to Fight AIDS, Tuberculosis and Malaria; the Global Alliance for Vaccines and Immunization (GAVI); the U.S. President's Emergency Plan for AIDS Relief (PEPFAR); and the World Bank (HIV/AIDS). This group found that global health initiatives had improved access to and quality of the targeted health services and had led to better information systems and more adequate financing. The review also identified the need for better alignment of global health initiatives with other national health priorities and systematic exploitation of potential synergies. If global health initiatives implement programs that work in tandem with other components of national health systems without undermining staffing and procurement of supplies, they have the potential to contribute substantially to the capacity of health systems to provide comprehensive primary care services.

In the context of the current pandemic, global health initiatives appear even more important. The imperative of vaccinating the world's population against SARS-CoV-2 has led to the creation of the multibillion-dollar COVAX facility to ensure equitable access to COVID-19 vaccines. The pandemic has also limited access to essential health services, particularly for mothers and children. As such, efforts like the Global Financing Facility for every mother and child remain important catalysts for universal access to life-saving services. The general trend is to coordinate this funding in order to reduce fragmentation of national health systems and to concentrate more on strengthening these systems. Comprehensive primary care in low-income countries must inevitably deal with the rapid emergence of chronic diseases and the growing prominence of injury-related health problems; thus, international health development assistance must become more responsive to these needs.

Beyond funding for health services, other opportunities exist. Increased social participation in health systems can help build primary care services. In many countries, political pressure from community advocates for more holistic and accountable care as well as entrepreneurial initiatives to scale up community-based services through NGOs have accelerated progress in primary care without major increases in funding. Participation of the population in the provision of health care services and in relevant decision-making often drives services to cater to people's needs as a whole rather than to narrow public health priorities.

Participation and innovation can help address critical issues related to the health workforce in low- and middle-income countries by establishing effective people-centered primary care services. Many primary care services do not need to be delivered by a physician or a nurse. Multidisciplinary teams can include paid community workers who have access to a physician if necessary but who can provide a range of health services on their own. In Ethiopia, >38,000 community health workers have been trained and deployed to improve access to primary care services, and there is increasing evidence that this measure is contributing to better health outcomes. In India, >600,000 community health advocates have been recruited as part of expanded rural primary care services. In Niger, the deployment of community health workers to deliver essential child health interventions (as a component of integrated community case management) has had impressive results in reducing childhood mortality and decreasing disparities. After the Declaration of Alma-Ata, experiences with community health workers were mixed, with particular problems regarding levels of training and lack of payment. Current endeavors are not immune from these concerns. However, with access to physician support and the deployment of teams, some of these concerns may be addressed. Growing evidence from many countries indicates that shifting appropriate tasks to primary care workers who have had shorter, less expensive training than physicians will be essential to address the human resources crisis.

Finally, recent improvements in information and communication technologies, particularly mobile phone and Internet systems, have created the potential for systematic implementation of e-health, telemedicine, and improved health data initiatives in low- and middle-income countries. These developments raise the tantalizing possibility that health systems in these countries, which have long lagged behind those in high-income countries but are less encumbered by legacy systems that have proved hard to modernize in many settings, could leapfrog their wealthier counterparts in exploiting these technologies. Although the challenges posed by poor or absent infrastructure and investment in many low- and middle-income countries cannot be underestimated and will need to be addressed to make this possibility a reality, the rapid rollout of mobile networks and their use for health and other social services in many low-income countries where access to fixed telephone lines was previously very limited offer great promise in building primary care services in low- and middle-income countries. To a partial extent, this potential has been demonstrated and even realized in many countries during the COVID-19 pandemic, with greatly increased uptake of the use of telemedicine and clinical support via digital means.

CONCLUSION

As concern continues to mount about glaring inequities in global health, there is a growing commitment to redress these egregious shortfalls, as exemplified by the central place of equity in the United Nations' Sustainable Development Goals adopted in 2015, including a specific target on the achievement of universal health coverage in all countries by 2030. This commitment begins first and foremost with a clear vision of the fundamental importance of health in all countries, regardless of income. The values of health and health equity are shared across all borders, and primary health care provides a framework for their effective translation across all contexts.

The translation of these fundamental values has its roots in four types of reform that reflect the distinct but interlinked challenges of (re)orienting a society's resources on the basis of its citizens' health needs: (1) organizing health care services around the needs of people and communities; (2) harnessing services and sectors beyond health care to promote and protect health more effectively; (3) establishing sustainable and equitable financing mechanisms for universal health coverage; and (4) investing in effective leadership of the whole of society. This common primary health care agenda highlights the striking similarity, despite enormous differences in context, in the nature and direction of the reforms that national health systems must undertake to promote greater equity in health. This shared agenda is complemented by the growing reality of global health interconnectedness due, for example, to shared microbial threats, bridging of ethnolinguistic diversity, flows in migrant health workers, and mobilization of global funds to support the neediest populations. Embracing solidarity in global health while strengthening health systems through a primary health care approach is fundamental to sustained progress in global health.

The shortfalls in health system performance, stratification of social conditions leading to unfair differences in health, and skews in science that undermine the realization of "Health for All" have never been more glaringly visible than during the COVID-19 pandemic. But they also have never commanded such global political attention at the highest level. Out of this crisis, then, is a once-in-a-lifetime opportunity to recast global and national systems to enable the genuine implementation of the primary health care approach in all countries.

475 Health Effects of Climate Change

Eugene T. Richardson, Maxine A. Burkett, Paul E. Farmer

Climate change refers to the effects of accumulated greenhouse gases (GHGs) in the atmosphere on long-term weather patterns. Anthropogenic emissions—in particular from the burning of fossil fuels and land conversion—have increased mean global temperatures by approximately 1° Celsius above preindustrial levels. Extreme weather events, including heatwaves and natural disasters (e.g., wildfires, droughts, and floods), are becoming more frequent and lead to resource scarcity (including access to safe drinking water and food), increased environmental pollution and degradation, violent conflict, and precarious migration. The climate crisis thus has direct consequences for human health, the practice of medicine, and the stability of health care systems and as such represents a health emergency. **See Chap. 125 for an overview of climate science.**

EFFECTS OF CLIMATE CHANGE ON HEALTH

The World Health Organization predicts that between 2030 and 2050, there will be an additional 250,000 deaths per year globally from climate-sensitive diseases. These include deaths from infectious diseases (Chap. 125); respiratory, cardiovascular, and renal disease; heat-related illness, injury, and trauma; mental illness; and malnutrition (Fig. 475-1). As with much of the global burden of disease, this increase in mortality will be disproportionately borne by low- and middle-income countries (LMICs) whose health infrastructures have been weakened by neocolonialism and structural adjustment. Within wealthier countries such as the United States, climate change will amplify existing health disparities between white people and black, indigenous, and Latinx populations.

AIR POLLUTION AND SYNERGISTIC EFFECTS

Asthma and Other Respiratory Ailments Climate change exacerbates the negative health effects of harmful air pollutants (e.g., particulate matter, ozone, sulfur dioxide, and nitrogen dioxide). While increases in fine particulate matter (<2.5 microns—$PM_{2.5}$) are a function of wildfires and the burning of fossil fuels, the latter is the predominate driver of anthropogenic climate change. In 2016, exposure to ambient air pollution and/or household air pollution was estimated to cause 7.1 million premature deaths worldwide per year, making it the largest global environmental risk factor for reversible death and disability (see Chap. 289 for an overview).

By increasing ground-level ozone and/or particulate matter concentrations in some regions, the higher temperatures associated with climate change will directly increase the global burden and severity of asthma (Chap. 287), the respiratory effects of allergies (Chap. 352), rhinosinusitis, chronic obstructive pulmonary disease (COPD), respiratory tract infections, interstitial lung disease, and lung cancer, resulting in increased hospital admissions and premature death. Figure 475-2 illustrates potential pathophysiologic mechanisms by which this may occur.

Cardiovascular Disease Cardiovascular (CV) complications of climate change share similar mechanisms with climate-sensitive respiratory disease. Concentrations of $PM_{2.5}$ are the most important environmental risk factor for myocardial infarction, cerebrovascular disease, heart failure, hypertension, diabetes mellitus, arrhythmias, and venous thromboembolism.

Studies have shown that the relative risk of acute CV events is increased 1–3% in the setting of short-term elevations of $PM_{2.5}$. Longer-term exposures convey an amplified risk (~10%), which is partially attributable to the exacerbation of chronic conditions (e.g., hypertension and diabetes). This holds true for areas with low mean concentrations of $PM_{2.5}$ (i.e., where risk is determined by recurring short-term elevations). The biologic pathways whereby $PM_{2.5}$ promotes these complications are complex and multifactorial (Fig. 475-3).

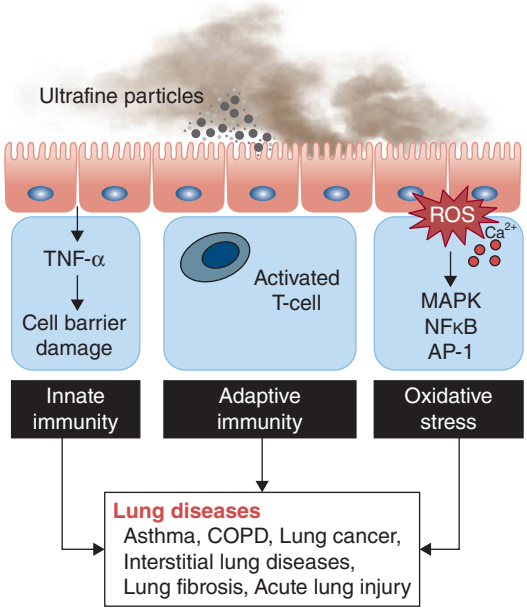

FIGURE 475-2 Mechanisms of ultrafine particle–induced respiratory health effects. *(Source: GD Leikauf et al: Mechanisms of ultrafine particle-induced respiratory health effects. Exp Mol Med 52:329, 2020.)*

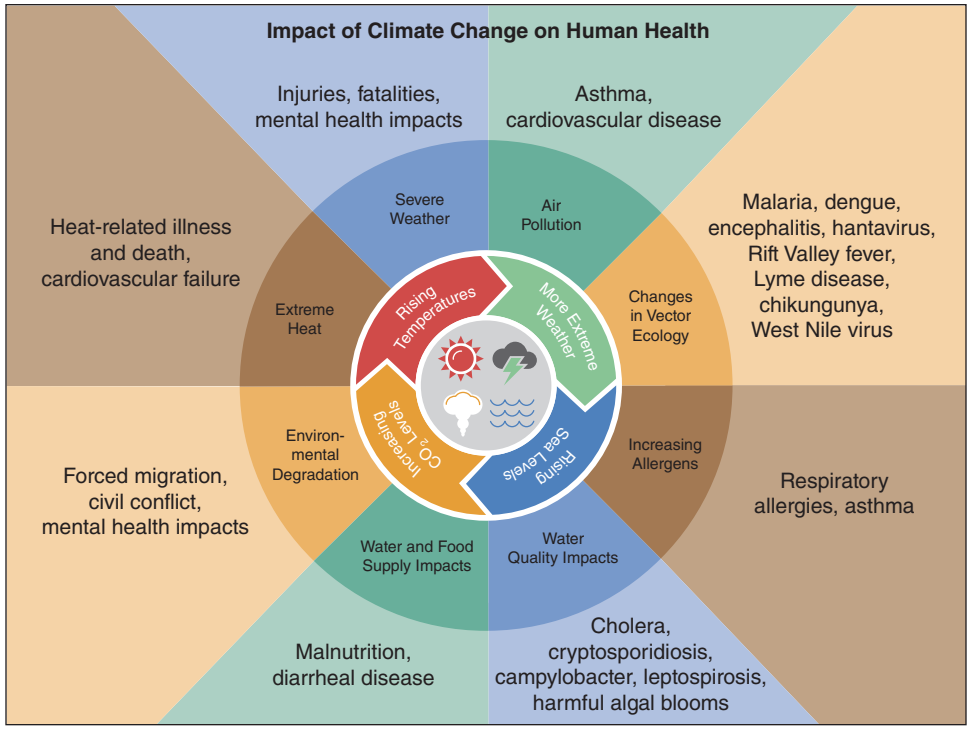

FIGURE 475-1 Climate change impacts a wide range of health outcomes. This slide illustrates the most significant climate change impacts (rising temperatures, more extreme weather, rising sea levels, and increasing carbon dioxide levels), their effect on exposures, and the subsequent health outcomes that can result from these changes in exposures. *(Source: https://www.cdc.gov/climateandhealth/effects/default.htm.)*

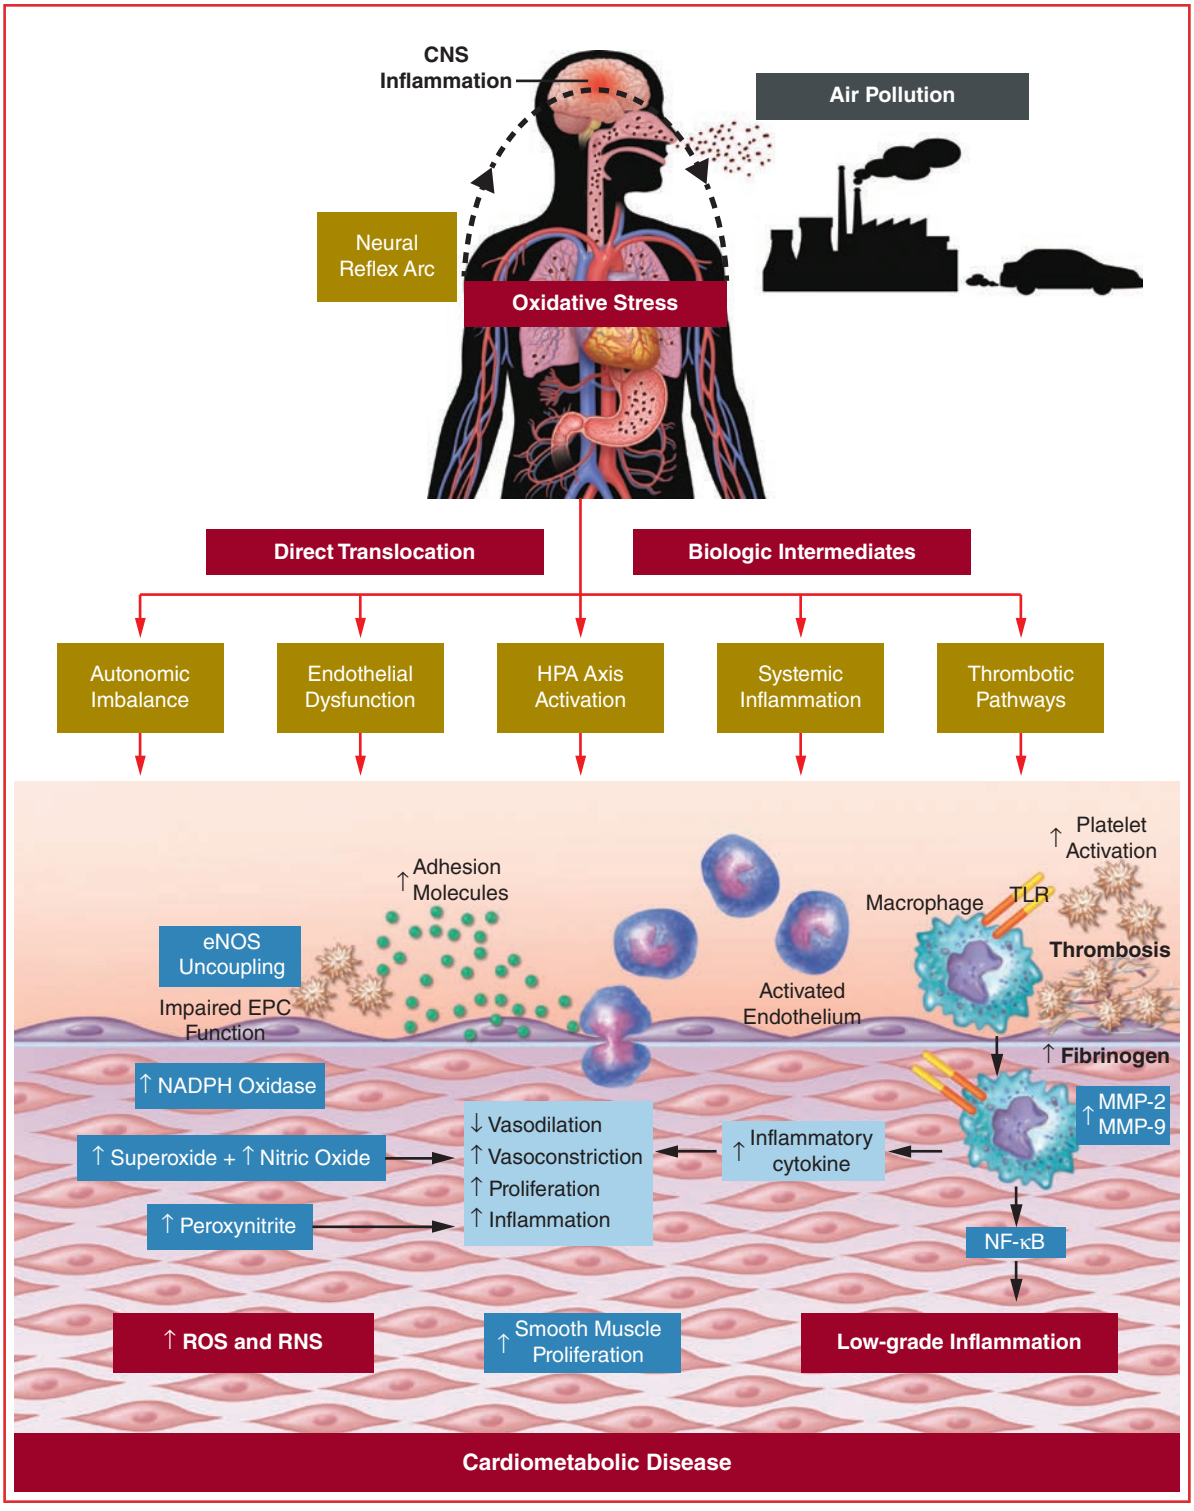

FIGURE 475-3 Biologic pathways whereby $PM_{2.5}$ promotes cardiovascular events. *(Reproduced with permission from S Rajagopalan: Air pollution and cardiovascular dsease JACC state-of-the-art review. J Am Coll Cardiol 72:2054, 2018.)*

For clinicians, there are subtle management strategies to bear in mind for climate-sensitive CV disease. For example, in new heart-failure patients, prescribers should be judicious about starting diuretics (especially diuretic-ACE inhibitor combinations) before the summer months or in areas with increased heatwaves in order to avoid exacerbating dehydration or heat-related illness. These patients may also benefit from increasing potassium uptake. Figure 475-4 presents personal- and local-level interventions to reduce climate-sensitive disease associated with air pollution.

Pregnancy Women exposed to high temperatures and air pollution may be more likely to experience serious adverse pregnancy outcomes. A systematic review of studies across diverse U.S. populations found a statistically significant association of $PM_{2.5}$, ozone, and heat exposure with preterm birth, low birth weight at term, and stillbirth. As these environmental exposures become more common with climate change, an increased incidence of these complications is likely.

Potential pathophysiologic mechanisms for these outcomes are multifactorial: preterm birth may result from hematogenous transport of inhaled $PM_{2.5}$ and varied noxious chemicals and subsequent systemic inflammation or perturbation of the autonomic nervous system; low birth weight could be caused by the cumulative effect of alterations in maternal cardiac, pulmonary, and renal function, placental inflammation, and direct exposure to oxidative stress; and stillbirth may involve

FIGURE 475-4 Social ecological interventions to reduce exposures or susceptibility to air pollution. *(Reproduced with permission from S Rajagopalan: Air pollution and cardiovascular disease JACC state-of-the-art review. J Am Coll Cardiol 72:2054, 2018.)*

derangements in oxygen transport, DNA damage, and direct placental injury. Extreme heat events may lead to adverse pregnancy outcomes through dehydration and subsequent alterations in thermoregulation, blood viscosity, uterine blood flow, placental-fetal exchange, amniotic fluid volume, and hormone release (e.g., prostaglandin or oxytocin).

These risks are disproportionately borne by black mothers. Thus, failure to reduce air pollution to the WHO guideline level of 10 μg/m^3 compounds structural racism.

HEAT-RELATED ILLNESSES

Renal Disease Various populations of agricultural workers who labor in hot climates around the world have been noted to suffer from chronic kidney disease (CKD), even those without common risk factors such as diabetes mellitus, hypertension, glomerular disease, or HIV. Although the cause has not been identified, potential mechanisms include genetic polymorphisms, nephrotoxicity secondary to agrochemicals or heavy metals, and heat-associated injury **(Fig. 475-5)**.

Heat Exhaustion and Heatstroke Please see **Chap. 465** for an overview of heat-related illnesses. These include heat cramps, heat exhaustion, and heatstroke and can be expected to increase in incidence as temperatures rise. Certain communities suffer from significant peaks in average temperature resulting from the urban heat island effect, which in the United States is related to policies such as redlining, racial covenants, and strategic underinvestment in neighborhoods segregated through such policies. Possible preventive measures include developing clear heatwave strategies and establishing early warning systems, mapping vulnerable populations, enhancing green space, and providing cool-down zones. It is important that clinicians provide guidance about heat-related illnesses prior to the start of summer because waiting for heat warnings will not obviate risk. Medication storage is an issue, especially for those that are carried by patients (e.g., epinephrine injections, naloxone, insulin). Evidence is not robust, but there are some data to suggest that exposure to extreme heat (e.g., leaving an albuterol inhaler in a vehicle on a hot day) can impair delivery mechanisms and/or degrade active ingredients of the medication itself.

NATURAL DISASTERS, COASTAL FLOODING, AND DISPLACEMENT

Injury and Trauma While models predict fewer cyclones and hurricanes in a warmer late-twenty-first-century climate, they do forecast events of higher average intensity, precipitation, and the number and occurrence days of very intense category 4 and 5 storms **(Fig. 475-6)**. Such natural disasters would be expected to result in injuries and trauma seen in contemporary storms of high intensity (albeit with higher frequency), but there are other ways climate change will affect the incidence of physical trauma.

Studies have shown associations between anomalously warm temperatures and increased deaths from drownings (from people swimming

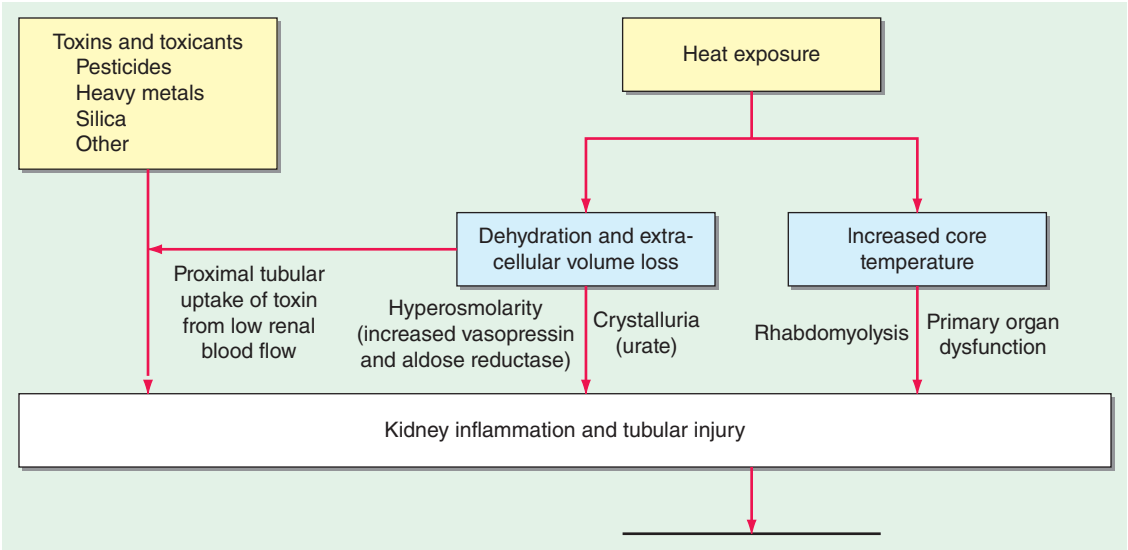

FIGURE 475-5 Possible mechanisms for the development of chronic kidney disease of unknown cause in agricultural communities. *(From RJ Johnson et al: Chronic Kidney Disease of Unknown Cause in Agricultural Communities. longer and more frequently), transportation accidents (driving performance worsens at higher temperatures and traffic increases), and assaults (potentially from increased alcohol consumption and illicit drug use). These deaths were partly offset by decreased falls, especially among the elderly, in warmer years.

In addition, as more than half the world's population lives within 60 km of the ocean, rising sea levels will destroy homes, medical infrastructure, and other essential services, including sewage treatment systems and drinking water supplies. In concert with climate impacts such as extreme heat and lack of freshwater, subsequent displacement and migration will lead to increased mental illness, food insecurity, and communicable disease.

Finally, extreme sudden-onset events can affect the availability of medications through medical supply chain disruptions. Loss of electricity during intense storms can also compromise vaccination programs and the availability of needed medications. For example, in

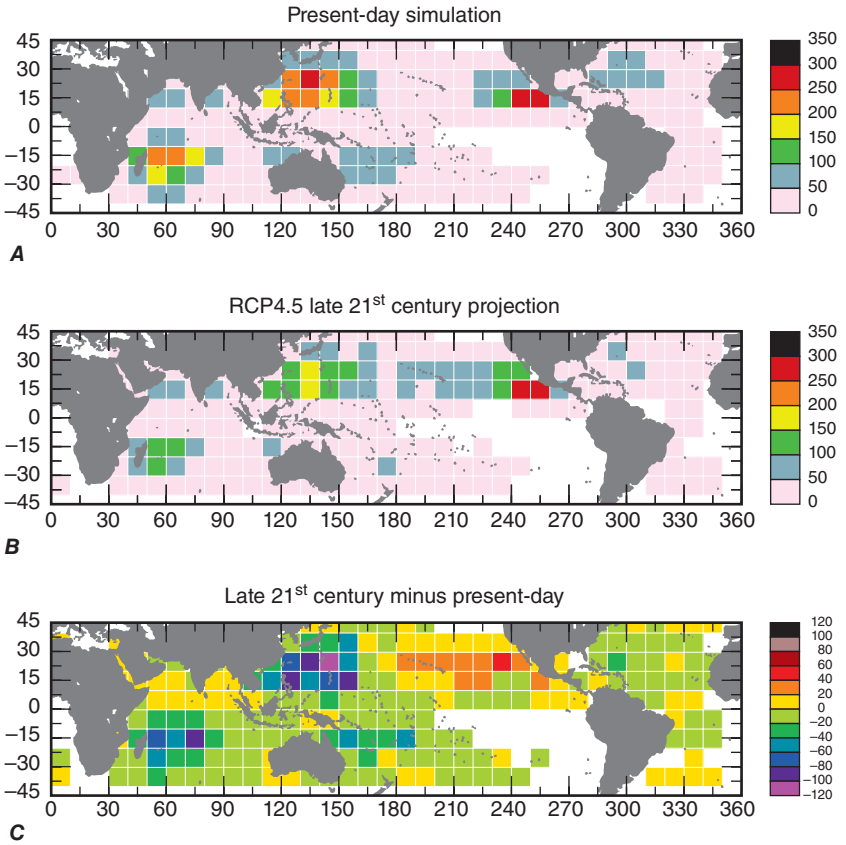

FIGURE 475-6 Simulated occurrence of all tropical storms (tropical cyclones with winds exceeding 17.5 m s^{-1}) for (***A***) present-day or (***B***) late-twenty-first-century (RCP4.5; CMIP5 multimodel ensemble) conditions; unit: storms per decade. Simulated tropical cyclone tracks were obtained using the GFDL hurricane model to resimulate (at higher resolution) the tropical cyclone cases originally obtained from the HiRAM C180 global mode. Occurrence refers to the number of days, over a 20-year period, in which a storm exceeding 17.5 m s^{-1} intensity was centered within the 10° × 10° grid region. (***C***) Difference in occurrence rate between late-twenty-first century and present day [(***B***) minus (***A***)]. *White regions* are regions where no tropical storms occurred in the simulations [in (***A***) and (***B***)] or where the difference between the experiments is zero [in (***C***)]. *(Source: TR Knutson et al: Global projections of intense tropical cyclone activity for the late twenty-first century from dynamical downscaling of CMIP5/RCP4.5 scenarios. J Clim 28:7203, 2015 © American Meteorological Society. Used with permission.)*

2017 Hurricane Maria interrupted the production of essential drugs and intravenous (IV) fluids manufactured in Puerto Rico, resulting in nationwide shortages in the United States. Providers should ensure that patients with electricity-dependent medical devices have a reasonable contingency plan in case of power outages while noting that climate-related displacements can interrupt patients' access to medications for chronic diseases and limit access to clinical care in general.

Mental Illness As of 2020, an estimated 80 million people (i.e., 1% of humanity) were forcibly displaced from their homes, mainly on account of violent conflict. It is expected that millions more will be displaced in response to the effects of climate change. This has ramifications for mental health (as do natural disasters) where resultant psychosocial stress can lead to an increased incidence of anxiety, depression, and posttraumatic stress disorder (PTSD). Increased temperatures have also been found to be associated with higher rates of suicide and domestic violence. Lastly, regarding clinical practice, many psychoactive prescription drugs can interfere with thermoregulation; their use therefore confers added risk during extreme heat events.

FOOD SECURITY AND OCEAN RESOURCES

Malnutrition Climate change threatens food and nutritional security through decreased crop yields in the setting of changes in precipitation, desertification, severe weather events, temperature extremes, GHG emissions, ocean warming and acidification, coastal inundation affecting dryland agriculture and aquaculture, and increasing competition from weeds and pests (Fig. 475-7). Livestock and fish production are also projected to decline. For many, food will be less available, less nutritious, and more expensive.

As chronic noncommunicable diseases, both undernutrition (Chap. 334) and obesity (Chap. 401)—which affect approximately 2 billion people worldwide—share common drivers with climate change. Current dietary practices (through land conversion and overconsumption of ruminant meats) contribute to excess GHGs, decreases in biodiversity, and depletion of water supplies. Variable rainfall and increased flooding, which can contaminate freshwater supplies, will make water security a defining challenge of this century.

Plant-based diets have the potential to decrease GHG emissions; improve food security in LMICs; reduce mortality from stroke, type 2 diabetes mellitus, coronary heart disease, and cancer by 6–10%; and reduce diet-related GHGs by 29–70% by 2050 compared with a reference diet (Fig. 475-8).

INFECTIONS AND DIARRHEAL DISEASE

(See Chap. 115)

POTENTIAL SOLUTIONS

Reductions in GHG emissions will require health professionals to voice their evidence-based understandings of climate-sensitive pathologies to lobby for political action. Other important systemic interventions in health care include achieving universal health coverage (including financial risk protection); equitable access to quality essential health care services as well as safe, effective, and affordable medicines and vaccines; making health care and health systems net-zero carbon; adding a climate-change lens to existing lines of research; improving data quality and enhancing, standardizing, and integrating data collection in LMICs and the tropics; and anticipating and correcting disaster-related health care system failures, such as impacts to supply chains or loss of electric power resulting from extreme weather events.

Interventions related to environmental policy include advocating for a tighter particulate-matter air-quality standard, supporting institutional divestment from fossil fuels, and advocating for the rapid drawdown of emissions and negative emissions strategies. Ecosocial interventions, supported by national or global institutions, include the distribution of clean cookstoves globally, switching to plant-based diets, decreased air travel, reducing air conditioner use, and increased

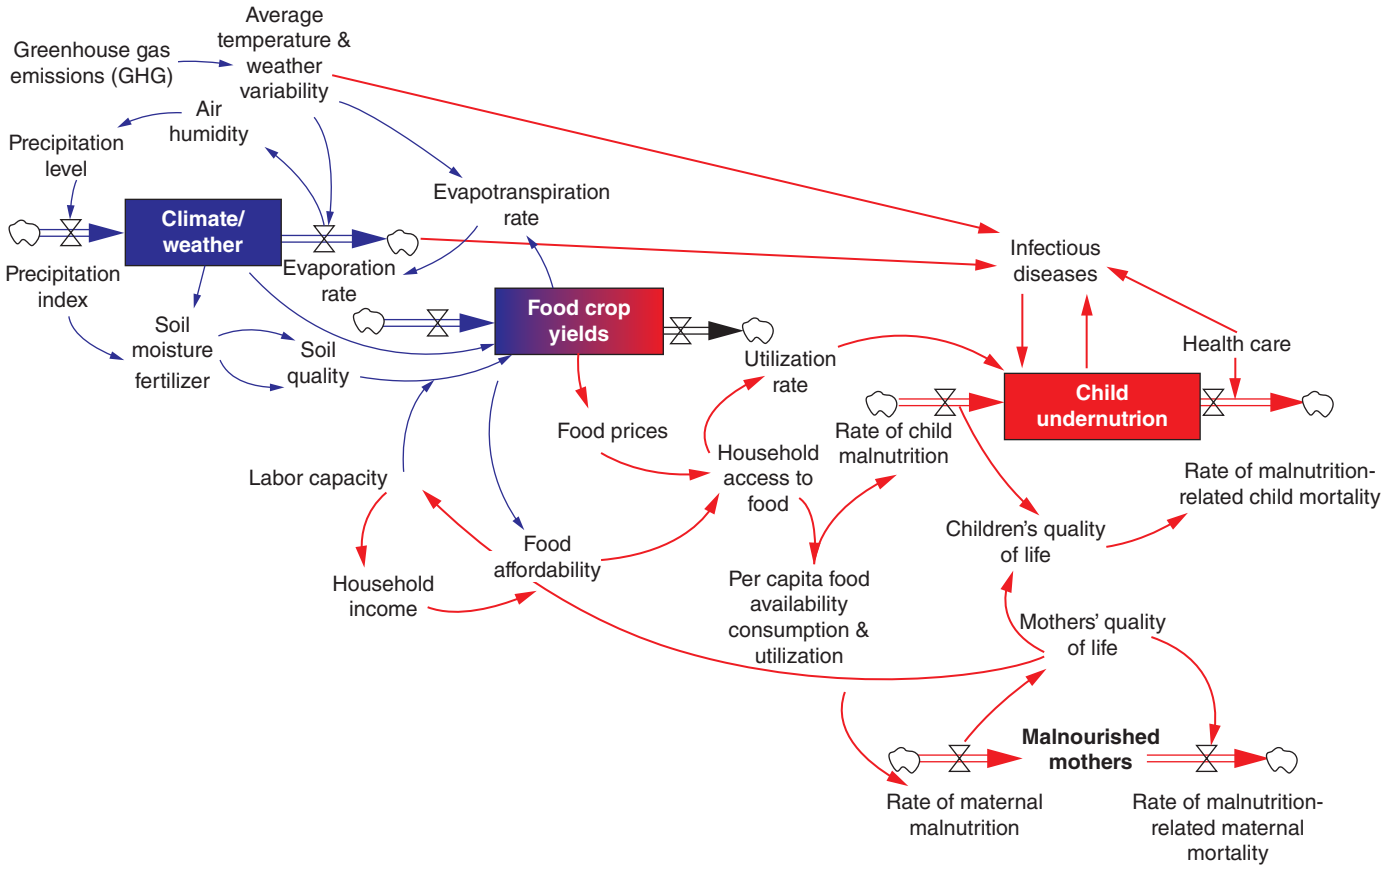

FIGURE 475-7 Complex pathways from climate/weather variability to undernutrition in subsistence farming households. The factors involved in and the probable impacts of weather variables on crop yields (*blue arrows*) and of food crop yields on undernutrition (*red arrows*). *(Reproduced with permission from RK Phalkey et al: Climate change impacts on childhood undernutrition. access to more public transportation. Finally, advocating for wealth-redistribution schemes (e.g., reparations, progressive taxation, debt cancellation, improved safety nets, underemployment insurance) to empower disadvantaged populations to cope with climate hazards will have positive ancillary effects on the social determinants of health, the administration of health services, and the outcomes of clinical interventions.

CONCLUSIONS

Without sweeping reductions in GHG emissions, over the next 50 to 100 years models predict increases in average global temperature of 2–5°C (with localized highs), rising sea levels, and more frequent and severe extreme-weather events, with resultant complications for population health globally. The hostile consequences of climate change will disproportionately affect vulnerable and marginalized groups, particularly those whose ability to cope with climate hazards is curtailed by systemic racism, colonial legacies, illicit financial flows, and human rights failings.

Health care professionals find themselves on the front line of the climate crisis and remain, in many settings, sources of information and counsel. In order to mitigate the impact of climate-sensitive diseases and resulting health disparities, they must continue to extend their clinical purview to environmental determinants and structural interventions.

476 Biology of Aging

Rafael de Cabo, David Le Couteur

AGING

The dramatic increase in the population of older people is one of the most significant changes in human history. In the past few years, the number of people over the age of 65 exceeded that of children under the age of 5 for the first time, and by 2050, older people will likely outnumber children under the age of 14 **(Fig. 476-1)**.

Old age is associated with an inexorable increase in the incidence of chronic disease, multimorbidity, and mortality. In developed nations, older people are living longer due to advances in medical care and technology, but at the cost of longer periods of disability and the iatrogenic burdens associated with intensive medical care of multiple diseases, such as polypharmacy. Establishing the relationship between aging and disease, particularly noncommunicable disease, is one of the most important goals for biomedical research. Recent studies in animal models have confirmed that the aging process is malleable, raising the prospect that medical care in the future may treat aging itself rather than multiple age-related diseases.

Aging is usually defined as a progressive process associated with deterioration in structure and function, leading to increased susceptibility to disease and mortality, and is often associated with impaired reproductive capacity. There are statistical, biological, and phenotypic components to aging. From the statistical perspective, aging in humans is associated with an exponential risk of mortality with time (Gompertz law of mortality). The biological mechanisms of aging are encompassed by the "hallmarks of aging," which describe the key cellular mechanisms underpinning aging. The phenotypic components of aging include chronic diseases and age-related syndromes that are often the target of medical interventions **(Fig. 476-2)**.

A fundamental feature of aging is that for any quantitative factor that can be measured in a population, the range of variability of values for that factor increases with age.

EVOLUTIONARY THEORIES OF AGING

Evolutionary theories of aging attempt to explain why aging, which impairs health and survival, has evolved, and why there is so much variability in life span across taxa. Most theories are based on the concept that in the wild, age-related mortality is secondary to extrinsic causes, such as predation, injury, and infection, and evolutionary selection pressure is generated by early life survival and reproductive success. Therefore, selection pressure to maintain health and extend life beyond early reproductive years is minimal. In fact, traits may evolve that are beneficial in early life and for reproduction but are harmful if the animal lives to an older age. These theories were set out by the classic "antagonistic pleiotropy" and "mutation accumulation" theories of aging.

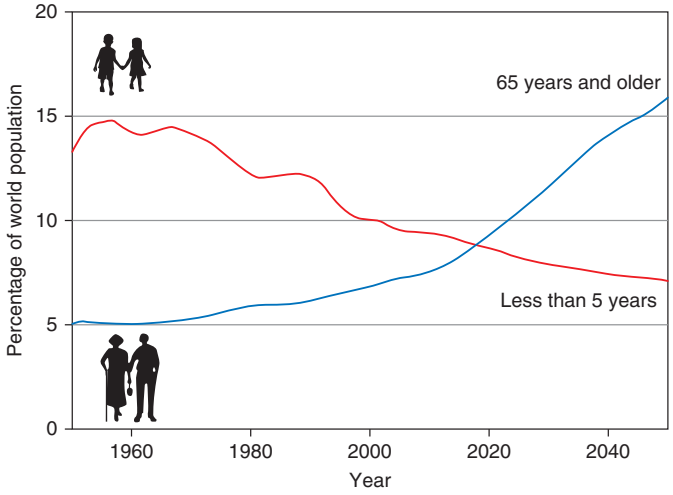

FIGURE 476-1 Globally, the people over the age of 65 years now exceed children under the age of 5 years.

Aging is nonadaptive, meaning that it has not been shaped by evolution; it can be considered to be the consequence of evolutionary neglect and is not usually considered to be genetically programmed. However, many genes influence the aging process, and the initiating process of aging most likely involves stochastic, nonprogrammed changes in nuclear maintenance that influence gene expression and repair.

A common theme in the evolutionary theories of aging is that a trade-off exists between aging and reproduction. Animals with high extrinsic mortality tend to have short lives, small bodies, and greater reproductive output, while animals with low extrinsic mortality, such as humans and other primates, tend to have longer lives, larger bodies, and fewer offspring. Moreover, some interventions that delay aging also reduce reproductive potential. The disposable soma theory of aging explicitly hypothesizes that evolution selects strategies that prioritize utilization of finite resources to maintain germ cells necessary for reproduction rather than the soma (non-germ cells), hence leading to age-related accumulation of damage to the soma.

There are many exceptions to these theories in the animal kingdom **(Fig. 476-3)**. Some animals undergo "negligible senescence," meaning that no obvious biological changes of aging are noted and the rate of mortality does not increase with time. These include some strains and species of clams, sharks, hydra, and worms. The longest living vertebrate is the Greenland shark, which may live up to nearly 400 years. On the other hand, a few animals undergo programmed aging and death. These are the semelparous animals such as Pacific salmon and marsupial mice. In other animals, including humans, later life survival is influenced by evolution through what is called the grandmother effect. In these species, survival of offspring depends upon the care provided by their long-lived grandmothers. This also explains the development of an unusually long post-reproductive period of life in humans. Aging remains a mystery. For every generalization, exceptions can be found. For example, a mouse and a bat are very closely related genetically, but the mouse lives about 2 years and a bat up to 25 years. Differences like these are unexplained.

THE HALLMARKS OF AGING

Aging is associated with a range of molecular processes that are remarkably similar between species. These hallmarks of aging are the mechanistic pathways that are considered to be the underlying cause of aging. The processes are highly interconnected, and impairment of one process will impact the others (Fig. 476-2). Interventions that alter the behavior of each of these pathways (via genetic manipulation, pharmacologic treatments, or nutritional interventions) influence aging and life span of laboratory animals, such as mice, fruit flies (*Drosophila melanogaster*), and worms (*Caenorhabditis elegans*). Each of the hallmarks is a potential target for pharmacotherapies that might delay aging and the onset of age-related morbidity and increase both healthy life span (health span) and total life span.

Genomic Instability The integrity of DNA is vulnerable to many exogenous (e.g., irradiation, chemicals) and endogenous (e.g., oxidative stress) stressors that often generate random DNA lesions such as point mutations, translocations, and chromosomal anomalies. A variety of mechanisms exist to repair these anomalies, but the mechanisms are affected by genetic alterations in the repair machinery and by a decrease in their efficiency with age. Mitochondrial DNA is especially susceptible to damage with aging because of its proximity to free radicals produced during oxidative phosphorylation and the lack of histones and repair mechanisms in this organelle. Genetic manipulation of

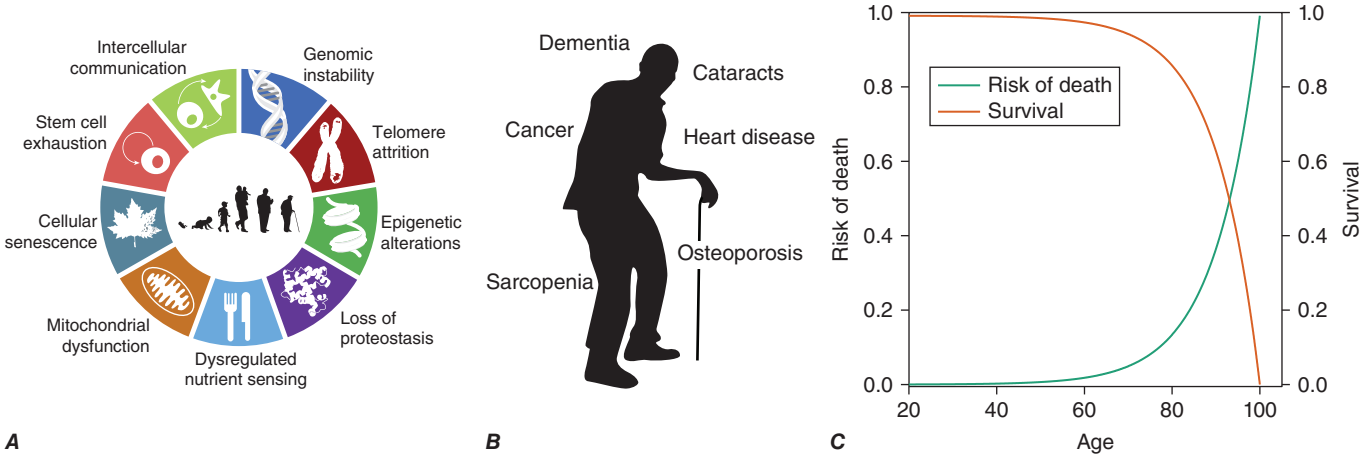

FIGURE 476-2 Definitions of aging include (A) a biological component, which is encapsulated by the nine hallmarks of aging, (B) a phenotypic component which includes many chronic non-communicable diseases, and (C) a statistical component which in most species is an exponential (Gompertz) increase in the risk of mortality with age.

nuclear and mitochondrial DNA repair mechanisms shortens life span in mice, while human premature aging syndromes are associated with deficiencies in genes necessary for nuclear maintenance. For example, Werner's syndrome is caused by mutations in a RecQ helicase gene (*WRN*) required for repair of double-strand breaks, and Hutchinson-Guildford progeria syndrome is caused by mutations in the lamin A gene (*LMNA*) required for structural support of the nucleus.

FIGURE 476-3 Some species undergo negligible senescence while others, such as the semelparous animals, undergo programmed aging and death. In some long-lived species, including humans, there is a prolonged post-reproductive period of life which may be secondary to the beneficial effects of grandmothers on the survival of infants.

Telomere Attrition Telomeres are repeat sequences at the ends of linear chromosomes that counteract the inability of DNA polymerase to replicate the tips of chromosomes. In humans, telomeres consist of a redundant TTAGGG sequence repeated several thousand times. Some cells (e.g., germ cells, tumor cells) contain telomerase, which can reform telomeres that are shortened during replication. In most cells, after multiple divisions, the telomeres are truncated to a point where cell division cannot continue. In cell culture, this number of divisions is called the Hayflick limit, and cells that cannot undergo further division are said to have entered a phase of replicative cellular senescence. Some studies in humans have found that telomere length in blood cells decreases with age, while mice that have been genetically manipulated to have short or long telomeres have decreased and increased life spans, respectively.

Epigenetic Alterations Multiple systems regulate gene expression, such as DNA methylation, histone modification, and chromatin remodeling. All of these processes change with age, leading to altered transcription of genes, especially those involved with inflammation, mitochondrial function, and autophagy pathways. The "epigenetic clock" is a consistent age-related pattern of DNA methylation changes in human blood samples that reflect chronologic age. Histones are proteins that package DNA into nucleosomes to influence DNA availability for transcription. The sirtuins are a family of nicotinamide adenine dinucleotide (NAD)–dependent enzymes that regulate histones through deacetylation, thus eliciting beneficial effects on aging and life span. For example, overexpression of sirtuins and their activation by drugs such as resveratrol increase life span in model organisms.

Loss of Proteostasis Damaged proteins in cells are removed by the autophagy-lysosomal system and the ubiquitin-proteosome system. These processes are impaired with aging, which can lead to the formation of intracellular and extracellular aggregates of damaged proteins and other cellular components, such as lipofuscin, Lewy bodies, neurofibrillary tangles, and amylin **(Fig. 476-4)**. Both caloric restriction and inhibition of mechanistic target of rapamycin (mTOR) can activate autophagy and delay aging. Autophagy is also necessary for the removal of damaged mitochondria (mitophagy), and age-related impairment of mitophagy contributes to syndromes such as sarcopenia and frailty.

Deregulated Nutrient Sensing Nutrition has a profound effect on aging in all species. One of the most important nutritional interventions that influences aging is caloric restriction (CR). CR involves providing animals with less food (usually ~30–50% less than what is given to controls fed *ad libitum*). Long-term CR extends life span while delaying the onset of many age-related pathologies and diseases. Several interconnected pathways mediate the effects of nutrition and CR on aging and age-related conditions through downstream effectors **(Fig. 476-5)**, and drugs have been developed that act on these pathways

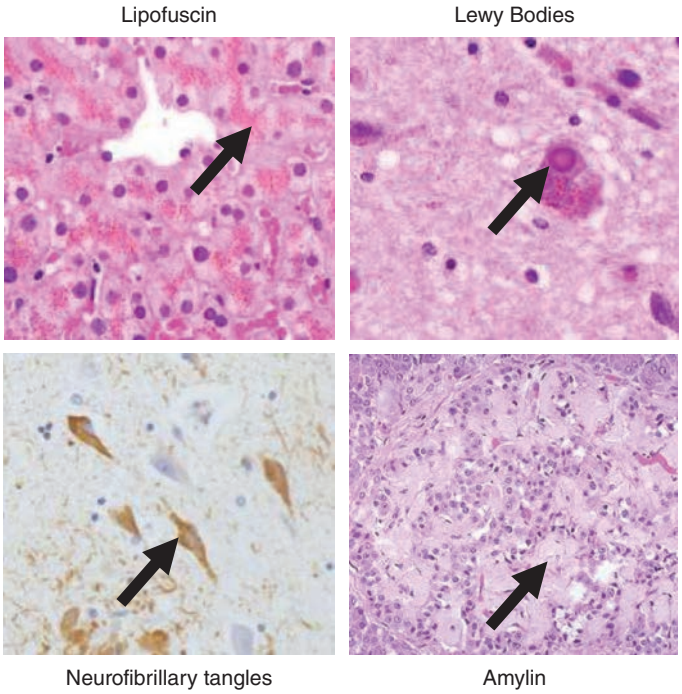

FIGURE 476-4 Impaired proteostasis with old age contributes to the accumulation of lipofuscin in the liver, Lewy bodies in the substantia nigra, neurofibrillary tangles in neurones and amylin in beta islet cells.

to replicate some of the effects of CR. These so-called "CR mimetics" have been shown to increase life span regardless of calorie intake. These key nutrient-sensing pathways include the following:

1. **Insulin and insulin-like growth factor (IGF)-1 signaling pathway.** Animals with genetic downregulation of this pathway have a longer life span, and this includes the very long-living Methuselah mice with knock out of the growth hormone (GH) receptor. Humans with GH receptor deficiency (Laron syndrome) have less cancer and diabetes. Many of the downstream effectors belong to the FOXO (forkhead box O) family of transcription factors, with genetic variation in some FOXO genes being associated with human longevity.
2. **mTOR pathway.** This pathway is activated by amino acids and the insulin/IGF-1 signaling pathway and, therefore, can be manipulated by dietary protein intake. Inactivation of mTOR by dietary restriction or rapamycin is associated with reduced protein synthesis and increased autophagy, leading to increased life span.
3. **Sirtuins.** The sirtuin family of NAD^+-dependent deacetylases encompasses seven members in mammals that are activated in response to low energy supply. Sirtuins regulate gene expression via histone deacetylation and mitochondrial biogenesis. Increased sirtuin activity induced by genetic manipulation, CR mimetics, or NAD supplementation has been associated with increased life span.
4. **Adenosine monophosphate (AMP)–activated protein kinase (AMPK).** Dietary energy restriction is associated with high levels of AMP in cells, which triggers the activation of AMPK. Observational studies in humans have suggested that metformin impacts age-related conditions. Human clinical trials of metformin are planned to determine its effects on aging.
5. **Fibroblast growth factor 21 (FGF21).** Dietary protein restriction increases the production and release of FGF21 into the blood, with a subsequent increase in AMPK signaling and insulin sensitivity. Overexpression of FGF21 increases life span in mice.

Mitochondrial Dysfunction Age-related changes in mitochondria include increased electron leakage with a subsequent decrease in ATP production, primarily due to impaired complex IV activity. Accumulation of mitochondrial DNA damage and swollen mitochondria with disrupted cristae results in impaired mitochondrial function, which leads to increased generation of superoxide radicals and hydrogen peroxide. Human mitochondria DNA frequently develops a truncation at a typical site that gives the aberrant mitochondria a proliferative advantage, and they become the predominant type of mitochondria in aging cells. As a consequence, age-associated oxidative damage to fat, proteins, and DNA occurs, forming the basis of the free radical theory of aging. Antioxidants have been investigated as an antiaging intervention but to no avail. Many of the nutritional and pharmacologic interventions that delay aging are associated with increased mitochondrial biogenesis mostly via upregulation or activation of the transcriptional coactivator PGC1α.

Cellular Senescence Senescent cells have stopped dividing as a result of either telomere shortening or other damage mediated by the INK4/ARF system. Senescent cells (sometimes called zombie cells) accumulate in various tissues with increasing age. They produce a wide range of inflammatory cytokines collectively called the senescence-associated secretory phenotype (SASP). SASP contributes to systemic inflammation. Genetic manipulation aimed at eliminating senescent cells that express INK4 and pharmacologic interventions with drugs

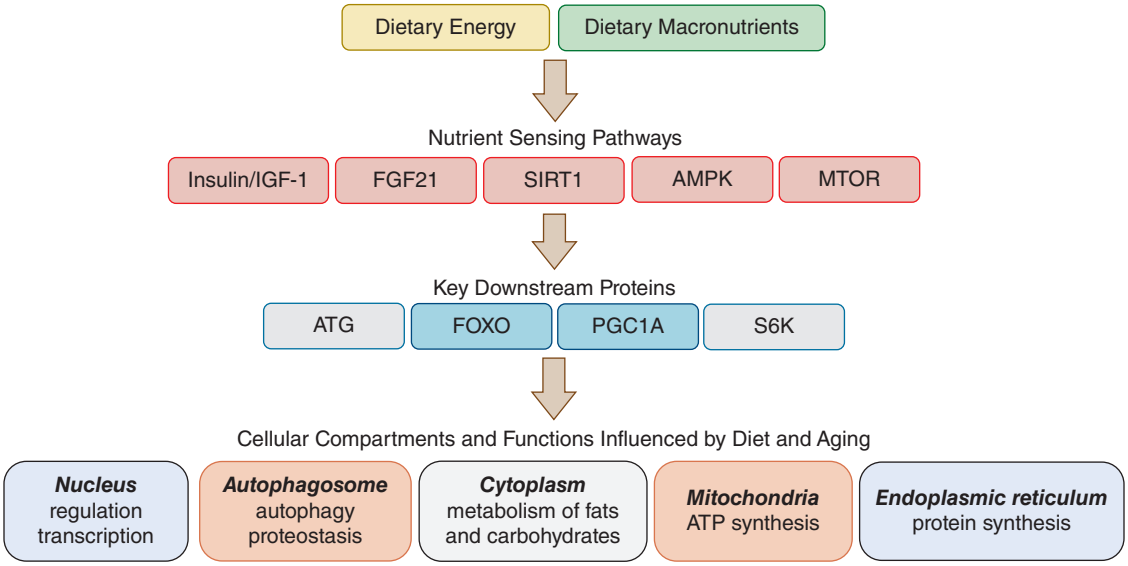

FIGURE 476-5 Nutrient sensing pathways. The main molecular switches that respond to changes in dietary intake (red boxes: Insulin/IGF1, MTOR, AMPK, SIRT1, FGF21) influence a range of downstream effectors (some of these are shown in the grey boxes). These regulate key cellular processes (green boxes), such as metabolism of fat and carbohydrates (CHO), autophagy, mitochondria, and protein synthesis. CHO, carbohydrate.

that eradicate senescent cells (called senolytics; e.g., dasatinib, quercetin, fisetin) delay the progression of age-related pathologies.

Stem Cell Exhaustion The age-associated reduction in the number of stem cells is probably due to replicative senescence and telomere shortening. Transplantation of pluripotent stem cells from young donors to old recipients extends life span in mice and may improve frailty in humans. Another strategy involves induction of genes that regulate stem cells (Yamanaka factors: OCT4, SOX2, KLF4, MYC), which delays aging in progeria mouse models.

Altered Intracellular Communication and Inflammation Aging is associated with low-grade activation of the innate immune system, leading to elevated circulating levels of interleukin (IL) 6, tumor necrosis factor-α (TNF-α), and other molecules such as C-reactive protein and elevation of erythrocyte sedimentation rate. This change in intracellular communication, called inflammaging, may be secondary to several factors including SASP, chronic infection with cytomegalovirus, obesity, leaky gut, and activation of the nuclear factor-κB (NF-κB) pathway. Inflammation is a key factor in the pathogenesis of many chronic diseases and, in particular, frailty.

GEROSCIENCE AND THE RELATIONSHIP BETWEEN AGING AND DISEASE

An unequivocal relationship exists between aging and disease, and old age is the major risk factor for most chronic diseases. The nature of the relationship has been the source of debate for millennia. On one hand, it has been argued that aging is similar to any other disease and, therefore, is amenable to therapeutic interventions. On the other hand, it has been argued that aging is an inevitable and untreatable process that increases the risk for diseases. Regardless, a marked and often exponential increase in the prevalence and incidence of most chronic diseases occurs with age, and the main burden on noncommunicable diseases is carried by older people. The burden of disease is usually captured by units called disability-adjusted life-years (DALYs), which quantify both years of life lost (compared to remaining life expectancy) and years lived with disability. DALYs emphasize the impact of disease on younger people because of their greater remaining life expectancy. Even so, DALYs increase dramatically beyond age 60, particularly for cardiovascular, neurologic, and cancer-related conditions (Fig. 476-6). In addition, several conditions are generally considered to be primarily age-related disorders, including dementia, sarcopenia, frailty, and osteoporosis. These conditions are very rare below the age of 50.

Geroscience refers to the study of the relationship between aging biology and disease. Aging leads to impairment of many physiologic systems that will increase susceptibility to disease. For example, aging is associated with marked changes in immune function. Immunosenescence refers to age-related deterioration of the responsiveness of the immune system to infection and other antigenic challenges caused by (1) thymic involution with reduced naïve T cells and impaired memory T cells, (2) a reduction in hematopoietic stem cells, and (3) impaired function of antigen-presenting cells. Aging is associated with many endocrine changes, most notably a reduction in sex steroids and growth hormone, which contribute to sarcopenia and osteoporosis. Vascular changes, including increased arterial stiffness that leads to high peripheral vascular resistance and microvascular pathology, have an obvious link with cardiovascular disease, but also probably contribute to other conditions such as dementia, osteoarthritis, and sarcopenia.

Although the usual dogma is that aging is a process that increases susceptibility to diseases, the relationship between chronic disease and aging may be much more fundamental. The pathogenesis of most chronic diseases includes one or more of the hallmarks of aging, and differences between disease and normal aging are defined by a quantitative difference in the expression of these hallmarks and the tissues that are affected. Likewise, the difference between aging and disease in terms of the clinical features is often based on quantitative differences. Therefore, a continuum exists between aging and many chronic diseases. These are often separated by so-called "pre-diseases" or "subclinical diseases," which are evidence of this continuum. Therefore, chronic disease can be considered to be a manifestation of aging that is predominant in a particular tissue. The presence of several chronic diseases, termed *multimorbidity*, represents aging-associated changes that are more advanced in several tissues. Frailty can be defined as a multisystem aging syndrome, where aging-related changes are present in most tissues, leading to multiple deficits and impaired function.

Aging is the main risk factor for chronic disease, and chronic diseases can be considered to be a manifestation of the biological changes of aging. Therefore, treatments that target aging may not only delay aging and increase life span but also reduce or delay chronic diseases. The "longevity dividend" refers to the concept whereby an intervention that impacts the aging process can delay the onset of a wide range of age-related diseases and syndromes.

STRATEGIES THAT INCREASE HEALTH SPAN AND DELAY AGING

Aging is an intrinsic feature of human life whose manipulation has fascinated humans ever since becoming conscious of their existence. Several long-term experimental interventions (e.g., resveratrol, rapamycin, spermidine, and metformin) may open doors for pharmacologic

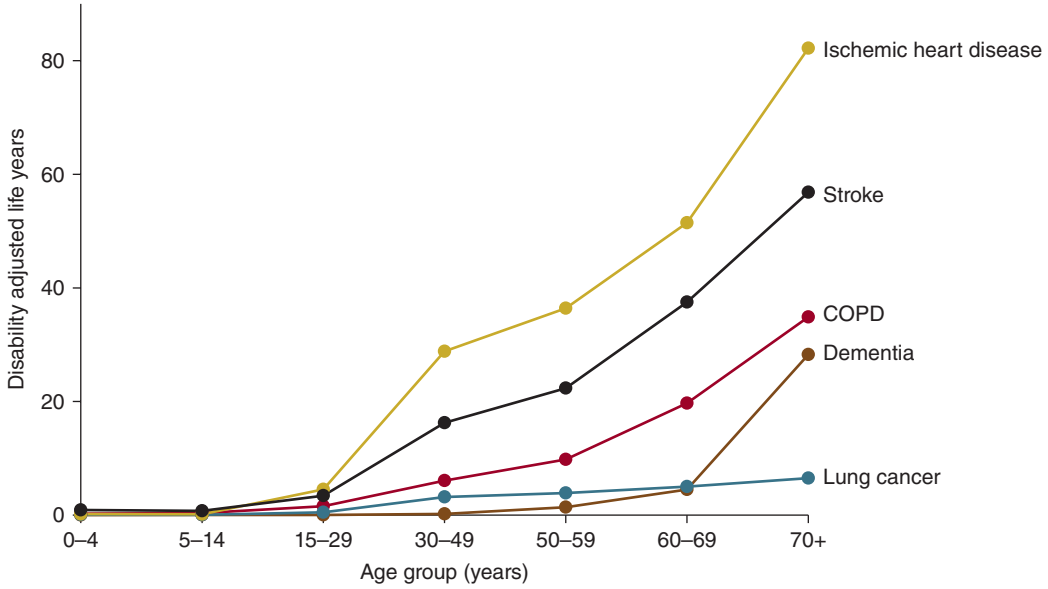

FIGURE 476-6 The relationship between age and disability adjusted life years for several common non-communicable diseases. COPD, chronic obstructive pulmonary disease.

strategies. Surprisingly, most of the effective aging interventions proposed to date converge on only a few molecular pathways: nutrient signaling, mitochondrial proteostasis, and the autophagic machinery.

Life span is inevitably accompanied by a gradual functional decline, steady increase of several chronic diseases, and ultimately death. For millennia, it has been a dream of mankind to prolong both life span and health span. Developed countries have profited from advances in medical care and technology, improvements in their public health care systems, and better living conditions derived from their socioeconomic power to achieve remarkable increases in life expectancy during the last century. In the United States, the percentage of the population aged ≥65 years is projected to increase from 13% in 2010 to 19.3% in 2030. However, old age remains the leading risk factor for major life-threatening disorders. The number of people suffering from age-related diseases is anticipated to almost double over the next two decades. The prevalence of age-related pathologies represents a major threat and an economic burden that urgently needs effective interventions.

Molecules, drugs, and other interventions that might decelerate aging processes continue to be a major focus among the general public and scientists of all biological and medical fields. Over the past two decades, this interest has taken root because many of the molecular mechanisms underlying aging are interconnected and linked with pathways that cause diseases, including cancer, cardiovascular disease, and neurodegenerative disorders. Unfortunately, results often lack reproducibility because of the unavoidable problem of the time needed to assess the effectiveness of antiaging interventions in mammals. Experiments lasting the lifetime of animal models are prone to develop artifacts, increasing the possibilities and time windows for experimental discrepancies. Some inconsistencies in the field arise from over-interpreting the results of animal models with shortened life span and scenarios of accelerated aging.

Molecules, drugs, and other interventions have been proposed to have antiaging properties throughout history and into the present. In the following sections, interventions will be restricted to those that meet the following highly selective criteria: (1) promotion of life span and/or health span, (2) validation in at least three model organisms, and (3) confirmation by at least three different laboratories. These include (1) caloric restriction (CR) and intermittent fasting regimens, (2) some pharmacotherapies (resveratrol, rapamycin, spermidine, and metformin), and (3) exercise.

Caloric Restriction One of the most important and robust interventions that delays aging is CR. This outcome has been recorded in rodents, dogs, worms, flies, yeasts, monkeys, and prokaryotes. CR is defined as a reduction in the total caloric intake, usually of ~30%, and without malnutrition. CR reduces the nutrient-mediated release of growth factors, such as growth hormone, insulin, and IGF-1, which have been shown to accelerate aging and enhance the probability for mortality in many organisms. Yet, the effects of CR on aging were first discovered by McCay in 1935, long before the discovery and signaling properties of these hormones and growth factors. Some of the pathways that mediate this remarkable response of CR have been elucidated in experimental models. These include the nutrient-sensing pathways (mTOR, AMPK, insulin/IGF-1, and sirtuins) and the family of FOXO transcription factors (orthologs are found in *D. melanogaster* and *C. elegans*). The transcription factor Nrf2 appears to confer most of the anticancer properties of CR in mice, even though it is dispensable for life span extension.

The effects of CR in monkeys have been assessed in two studies with different outcomes: one study observed prolonged life, while the other did not. In these monkey studies, key differences were noted in the onset of the intervention, diet composition, feeding protocols, and genetic background that may explain this discordance. However, both studies confirmed that CR increases health span by reducing the risk for diabetes, cardiovascular disease, and cancer. In humans, CR is associated with extended life span and increased health span. This is most convincingly demonstrated in Okinawa, Japan, where one of the most long-lived human populations resides. In comparison to the rest of the Japanese population, Okinawan people usually combine an above-average amount of daily exercise with a below-average food intake. However, when Okinawan families moved to Brazil, they adopted a Western lifestyle that affected both exercise and nutrition, causing a rise in weight and a reduction in life expectancy by nearly two decades. In the Biosphere II project, volunteers lived together for 24 months undergoing an unforeseen severe CR that led to improvements in insulin, blood sugar, glycated hemoglobin, cholesterol levels, and blood pressure—all outcomes that would be expected to benefit life span. CR changes many aspects of human aging that might influence life span such as the transcriptome, hormonal status (especially IGF-1 and thyroid hormones), oxidative stress, inflammation, mitochondrial function, glucose homeostasis, and cardiometabolic risk factors. Epigenetic modifications are also an emerging target for CR.

Periodic Fasting It must be noted that maintaining CR while avoiding malnutrition over a long period of time is not only arduous in humans but is also linked with substantial side effects. For instance, prolonged reduction of calorie intake may decrease fertility and libido, impair wound healing, reduce the potential to combat infections, and lead to amenorrhea and osteoporosis. How can CR be translated to humans in a socially and medically acceptable way? A whole series of periodic fasting regimens are asserting themselves as suitable strategies, among them (1) the alternate-day fasting diet, (2) the "5:2" intermittent fasting diet, (3) a 48-h fast once or twice each month, and (4) daily time-restricted feeding (TRF). Periodic fasting is psychologically more viable, lacks some of the negative side effects of CR, and is only accompanied by minimal weight loss. All these dietary interventions involve a substantial reduction of caloric intake for a defined period of time, leading to an elevation of circulating ketone bodies during those low-calorie intake periods, illustrating the metabolic switch from the utilization of glucose as a fuel source to the use of fatty acids and ketone bodies. This metabolic shift results in a reduction in the respiratory exchange ratio (the ratio of carbon dioxide produced to oxygen consumed), indicating greater metabolic flexibility and energy production efficiency from use of fatty acids and ketone bodies.

It is striking that many cultures implement periodic fasting rituals, including Buddhists, Christians, Hindus, Jews, Muslims, and some African animistic religions. It could be speculated that a selective advantage of fasting versus nonfasting populations is conferred by health-promoting attributes of religious routines that periodically limit caloric intake. Indeed, several lines of evidence indicate that intermittent fasting regimens exert antiaging effects. For example, improved morbidity and longevity were observed among Spanish nursing home residents who underwent alternate-day fasting. Rats subjected to alternate-day fasting live up to 83% longer than control animals fed *ad libitum*, and even one 24-h fasting period every 4 days is sufficient to generate life span extension.

Repeated fasting and eating cycles may circumvent the negative side effects of sustained CR. This strategy may even yield health benefits despite overeating behavior during the nonfasting periods. In a landmark experiment, mice fed a high-fat diet in a time-restricted manner, i.e., with regular fasting breaks, showed reduced inflammation markers, did not develop fatty liver, and were slim in comparison to mice fed *ad libitum* despite equivalent total calories consumed. From an evolutionary point of view, this kind of feeding pattern may reflect mammalian adaptation to food availability: overeating in times of nutrient availability (e.g., after a hunting success) and starvation in times of food scarcity. This is how some indigenous peoples who have avoided Western lifestyles live today; those who have been investigated show limited signs of age-induced diseases such as cancer, neurodegeneration, diabetes, cardiovascular disease, and hypertension.

Fasting exerts beneficial effects on health span by minimizing the risk of developing age-related diseases, including hypertension, neurodegeneration, cancer, and cardiovascular disease. The most effective and rapid repercussion of fasting is a reduction in hypertension. Two weeks of water-only fasting resulted in blood pressure <120/80 mmHg in 82% of subjects with borderline hypertension. Ten days of fasting cured all hypertensive patients who had been taking antihypertensive medication previously.

Periodic fasting dampens the consequences of many age-related neurodegenerative diseases in mouse models of Alzheimer's disease, Parkinson's disease, Huntington's disease, and frontotemporal dementia, but not amyotrophic lateral sclerosis. Fasting cycles are as effective as chemotherapy against certain tumors in mice. When combined with chemotherapy, fasting protects mice against the negative side effects of chemotherapeutic drugs, while enhancing efficacy against tumors. Combining fasting and chemotherapy rendered 20–60% of mice cancer-free when inoculated with highly aggressive tumors such as glioblastoma or pancreatic tumors, which have 100% mortality even with chemotherapy.

Pharmacologic Interventions to Delay Aging and Increase Life Span Virtually all obese people know that stable weight reduction will lower their risk of cardiometabolic disease and enhance their overall survival, and yet only 20% of overweight individuals are able to lose 10% of weight for a period of at least 1 year. Even in the most motivated people (such as the "Cronies" who deliberately attempt long-term CR in order to extend their lives), long-term CR is extremely difficult to adhere to. Thus, much focus has been directed at the possibility of developing medicines that replicate the beneficial effects of CR, but without the need for reducing food intake ("CR mimetics"; **Fig. 476-7**).

RESVERATROL Resveratrol, an agonist of SIRT1, is a polyphenol that is found in grapes and red wine. The potential of resveratrol to promote life span was first identified in yeast, and it has gathered fame since, at least in part, because it has been suggested to be responsible for the so-called French paradox whereby wine reduces some of the cardiometabolic risks of a high-fat diet. Resveratrol has been reported to increase life span in many lower order species such as yeast, fruit flies, worms, and fish, as well as mice on high-fat diets. In monkeys fed a diet high in sugar and fat, resveratrol had beneficial outcomes related to inflammation and cardiometabolic parameters. Some studies in humans have also shown improvements in cardiometabolic function, while others have not. Gene expression studies in animals and humans reveal that resveratrol mimics some of the metabolic and gene expression changes of CR. In most experimental models, resveratrol induces beneficial health effects by suppressing inflammation, oxidative damage, tumorigenesis, and immunomodulatory activities. Resveratrol also leads to improvements in mitochondrial function and protection against obesity, cancer, and cardiovascular dysfunction.

RAPAMYCIN Rapamycin, an inhibitor of mTOR, was originally discovered on Easter Island (Rapa Nui, hence its name) as a bacterial secretion with antibiotic properties. Before its emergence in the antiaging arena, rapamycin was known as an immunosuppressant and cancer chemotherapeutic agent in humans. Rapamycin extends life span in all organisms tested so far, including yeast, flies, worms, and mice. However, the potential utility of rapamycin in life span extension in humans is likely to be limited by adverse effects related to immunosuppression, impaired wound healing, proteinuria, and hypercholesterolemia, among others. An alternative strategy may be the implementation of intermittent rapamycin treatment, which was found to increase mouse life span.

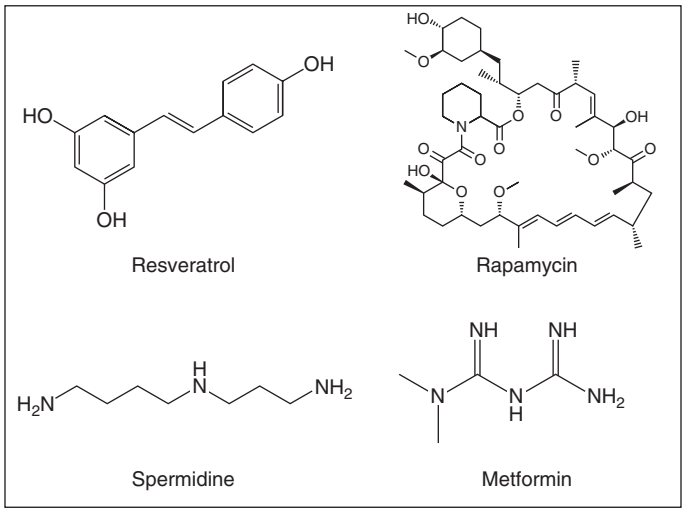

FIGURE 476-7 Chemical structure of four agents (resveratrol, rapamycin, spermidine, and metformin) that have been shown to delay aging in experimental animal models.

SPERMIDINE Spermidine is a physiologic polyamine that induces autophagy-mediated life span extension in yeast, flies, and worms. Endogenous spermidine levels decrease during life of virtually all organisms including humans, with the remarkable exception of centenarians. Oral administration of spermidine or upregulation of bacterial polyamine production in the gut leads to life span extension in short-lived mouse models. The life span effects of spermidine are mediated through the inhibition of histone acetylases and the activation of autophagy genes, such as *atg7*, *atg11*, and *atg15*. Spermidine has also been found to have beneficial effects on neurodegeneration and cardioprotection through activation of autophagy. Spermidine supplementation is safe in humans and has been associated with positive effects on cognitive function of older adults and on blood pressure maintenance.

METFORMIN Metformin, a biguanide first isolated from the French lilac, is widely used for the treatment of type 2 diabetes. Metformin decreases hepatic gluconeogenesis and increases insulin sensitivity. Other actions of metformin include AMPK activation, leading to mTOR inhibition and lower mitochondrial complex I activity, and activation of the transcription factor SKN-1/Nrf2. Metformin increases life span in different mouse strains including female mice predisposed to high incidence of mammary tumors. At a biochemical level, metformin supplementation is associated with reduced oxidative damage and inflammation and mimics some of the gene expression changes seen with CR. Based on experimental data on the positive outcomes in model organisms and the evidence emerging from epidemiologic studies, a clinical trial known as TAME (Targeting Aging with Metformin) has been initiated to assess whether metformin can delay the onset of age-related diseases beyond its effects on glucose metabolism. TAME is planning to enroll 3000 subjects, aged 65--79, in a multicenter trial in the United States.

Exercise and Physical Activity In humans and animals, regular exercise reduces the risk of morbidity and mortality. Given the marked increase in cardiovascular disease in the older people, the effects of exercise on human health may be even stronger than those seen in laboratory mice, as mice do not develop atherosclerosis and have a far lower incidence of age-related cardiovascular disease. An increase in aerobic exercise capacity, which declines during aging, is associated with favorable effects on blood pressure, lipids, glucose tolerance, bone density, and depression in older people. Likewise, exercise training protects against aging disorders such as cardiovascular disease, diabetes mellitus, and osteoporosis. Exercise is the only intervention that can prevent or even reverse sarcopenia (age-related muscle wasting). Even moderate or low levels of exercise (30 min of walking per day) have significant protective effects in obese subjects. In older people, regular physical activity has been found to increase the length of stay in independent living.

While clearly promoting health and quality of life, regular exercise does not extend life span. Furthermore, the combination of exercise with CR has no additive effect on maximal life span in rodents. On the other hand, alternate-day fasting with exercise is more beneficial for muscle mass than either treatment alone. In nonobese humans, exercise combined with CR has synergistic effects on insulin sensitivity and inflammation. From the evolutionary perspective, the responses to hunger and exercise are linked: when food is scarce, increased activity is required to hunt and gather.

Hormesis Paradoxically, the term hormesis describes the protective effects conferred by the exposure to low doses of stressors or toxins (or as Nietzsche stated, "What does not kill me makes me stronger"). Adaptive stress responses elicited by noxious agents (chemical, thermal, or radioactive) precondition an organism, rendering it resistant to subsequent higher and otherwise lethal doses of the same trigger.

Hormetic stressors have been found to influence aging and life span, presumably by increasing cellular resilience to factors that might contribute to aging such as oxidative stress.

Yeast cells that have been exposed to low doses oxidative stress exhibit a marked anti-stress-like response that inhibits death following exposure to lethal doses of oxidants. During ischemic preconditioning in humans, short periods of ischemia protect the brain and the heart against a more severe deprivation of oxygen and subsequent reperfusion-induced oxidative stress. Similarly, the lifelong and periodic exposure to various stressors can inhibit or retard the aging process. Consistent with this concept, heat or mild doses of oxidative stress can lead to life span extension in *C. elegans*. CR can also be considered as a type of hormetic stress that results in the activation of anti-stress transcription factors (e.g., Rim15, Gis1, and Msn2/Msn4 in yeast, NRF2 and FOXO in mammals) that enhance the expression of free radical–scavenging factors and heat shock proteins.

CONCLUSIONS

Clinicians need to understand aging biology in order to better manage and care for the older people. Moreover, there is an urgent need to develop strategies based on aging biology that delay aging, reduce the onset of age-related disorders, and increase health span for future generations. Dietary interventions and drugs that act on nutrient-sensing pathways are being developed and, in some cases, are already being tested in humans. Recently, well-controlled human clinical trials have started to recapitulate the preclinical evidence of intermittent fasting on obesity, diabetes mellitus, cardiovascular disease, cancers, and neurologic disorders. While most animal studies show that intermittent fasting improves health throughout the life span, most recent human studies are focused on relatively short-term interventions over a few days or months. While intriguing, it remains to be seen whether people will be willing to maintain strict intermittent fasting regimens over long periods of time or if there are short-term clinical benefits in combination with other therapeutic approaches.

477 Caring for the Geriatric Patient

Joseph G. Ouslander, Bernardo Reyes

AGING AND GERIATRIC CARE

DEMOGRAPHICS OF AGING AND ITS IMPLICATIONS FOR GERIATRIC CARE

The United States and other countries will continue to experience a rapid increase in the number of older adults who seek health care. The most rapidly growing segment of the population in the United States and many other developed countries is those older than 80 **(Fig. 477-1)**. According to the United Nations 2019 Aging Report, 1 in 6 people in the world will be 65 years old or older by the year 2050. Gender composition of the aging population around the world is also expected to change. Although females outlive males, an improvement in survival of the oldest-old males could result in more balanced gender distribution in the geriatric population in the future.

Based on the previously mentioned United Nations report, in high-income countries, consumption of health care resources will be most affected by the shift in the age distribution of the population over the next several decades. The World Health Organization continues to work actively to raise awareness of the changes necessary in current health care systems beyond increments in their budgets. Planning is increasingly being based on expected levels of disability and comorbidity. As life span increases, efforts should continue to focus on promoting healthy aging to reduce the burden of disability in health care systems all over the world.

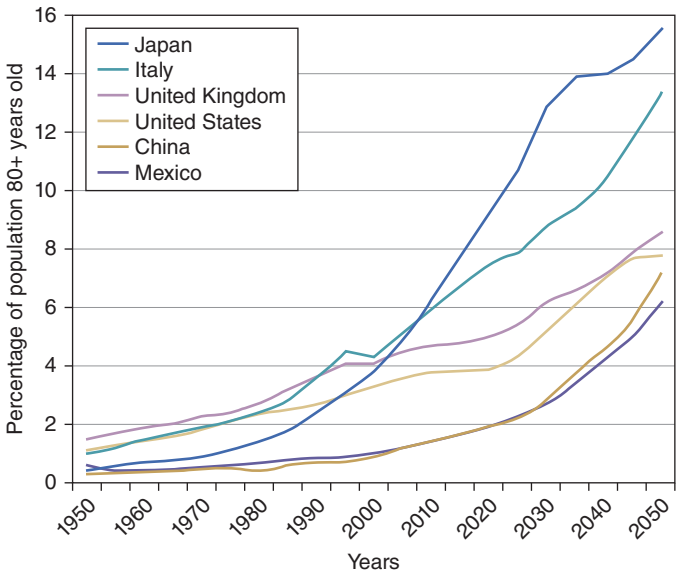

FIGURE 477-1 Percentage of the population age >80 years from 1950 to 2050 in representative nations. *(Updated data available at: https://esa.un.org/unpd/wpp/Graphs/DemographicProfiles/. Accessed December 30, 2016.)*

IMPLICATIONS OF THE AGING POPULATION FOR HEALTH CARE SYSTEMS AND SYSTEM-BASED PRACTICE

The geriatric population requires different approaches to care for several reasons. For any variable that can be measured in humans, the range of variation increases with age. The wide variations seen in aging make it difficult to develop age-related guidelines for diagnosis and treatment. For example, acute illnesses are most often not treated in isolation, but in the context of multiple comorbidities. Close to half of those older than 80 have three chronic conditions, and about one-third have four or more chronic conditions **(Fig. 477-2)**. Functional disabilities are prevalent **(Fig. 477-3)**, which require careful attention in the evaluation of the older patient, along with assessment of social supports available for assistance when needed for independent and safe living.

Effectively caring for the geriatric population requires consideration of several key principles:

1. Aging is not a disease; normal aging changes generally do not cause symptoms but do increase susceptibility to many diseases and conditions due to diminished physiologic reserve (which has been termed *homeostenosis*).
2. Medical conditions are commonly multiple ("multimorbidity") and multifactorial in origin, requiring a comprehensive approach to evaluation and management.
3. Many potentially reversible and treatable conditions are underdiagnosed and underevaluated in this population, such as fall risk, urinary incontinence, and elder abuse and neglect; simple screening tools can help detect them.
4. Similarly, cognitive and affective disorders (e.g., mild cognitive impairment, dementia, depression, anxiety) are common and may be undiagnosed in early stages; simple screening tools can help detect them.
5. Iatrogenic illnesses are common, especially related to adverse drug reactions and immobility and related deconditioning and other complications.

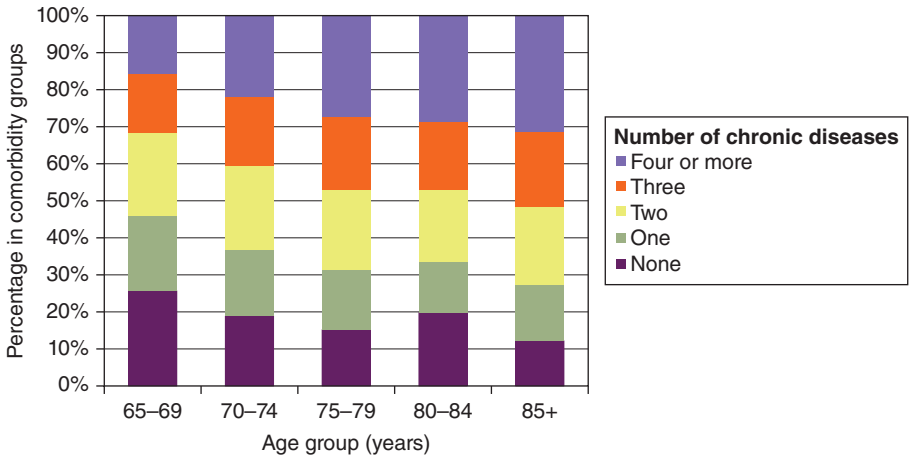

FIGURE 477-2 Prevalence of comorbidity by age group in persons ≥65 years old living in the United States and enrolled in Medicare Parts A and B in 1999. *(From JL Wolff et al: Arch Intern Med 162:2269, 2002.)*

6. Functional ability and quality of life, as opposed to cure, are key goals of care.
7. Social history, social support, and patient preferences are critical to treat older people in a safe and person-centered manner.
8. Effective geriatric care requires interprofessional collaboration among many different disciplines.
9. Geriatric care is provided largely outside the hospital (e.g., at home, in skilled nursing and assisted living settings), and attention to care transitions between settings is essential for effective care.
10. Ethical issues, palliative care, and end-of-life care are critical aspects of caring for the geriatric population.

Another way to summarize key concepts is using the "5M's of geriatrics" (mentation, medication, mobility, multicomplexity, and matters most) **(Fig. 477-4)**. This framework organizes care of older adults in a person-centered manner instead of disease-driven paradigm. The intention of the 5M's is to optimize utilization of existing resources during hospitalization of older adults, as well as to focus on key geriatric issues in all settings of care. At the core of the 5M's is what **matters** most to the patient when considering diagnostic tests and therapeutic interventions and planning for future care. **Mobility** is critical to individual function, quality of life, and fall risk, and ranges from the ability to move around the community to walking and transferring from a chair. Because mild cognitive impairment, dementia, delirium, and depression are all common in older adults, **mentation** is a core area for geriatric assessment. Polypharmacy and prescription of potentially inappropriate and harmful medications remain common; thus, careful **medication** reconciliation and consideration of deprescribing are core aspects of care for all older adults. Many older adults have complex clinical issues in more than one of the four M's just discussed, thus focusing attention on multiples comorbidities and **multicomplexity**.

In this chapter, these key principles serve as the background for the clinical recommendations for managing older adults. The reader is referred to textbooks of geriatric medicine for more details on each of the principles and the management of common diseases and conditions in this population.

MODELS OF GERIATRIC CARE

Several innovative models of care have been developed over the past three decades designed to provide high-quality and effective care for the burgeoning geriatric population with multimorbidity, functional and cognitive impairment, and challenges with social support. These include outpatient comprehensive geriatric assessment programs, inpatient acute care for the elderly (ACE) units and consultation services, and home-based programs. These models of care are assuming greater importance in the emerging era of value-based purchasing for health care services. While they may be challenging and inefficient to implement in fee-for-service–based systems, they may also result in improved care at a lower cost, as payers shift to other models of reimbursement, such as accountable care organizations, bundled payment programs, and managed care, in which an increasing number of older people are being enrolled.

Improving transitions of care between settings has become a major focus of governments, health systems, hospitals, postacute care (PAC) and long-term care (LTC) organizations and programs, physicians, and other health care professionals. Geriatric patients are especially vulnerable to complications at the time of discharge from an acute medical or psychiatric hospital, as well as at the time of discharge from a PAC facility (skilled nursing facility [SNF]; acute rehabilitation or long-term hospital) or home care program. With the increasing role of hospitalists and physicians and others who specialize in SNF care, medical care for geriatric patients has become fragmented at the time of transitions, creating opportunities for communication problems and medical errors. Changes in reimbursement and financial penalties for high rates of hospital readmissions have driven the development of many care transition interventions **(Table 477-1)**. These interventions involve interprofessional collaboration and a variety of strategies targeted at making care transitions safer, and reducing unnecessary return visits to the emergency department, hospital readmissions, and related complications and costs.

INTERPROFESSIONAL TEAMS AND CO-MANAGED CARE

The complexity of caring for the aging population is more evident during a hospitalization due to a new acute illness or exacerbation of preexisting chronic conditions. Interprofessional teams integrate different areas of expertise with the aim of providing patient-centered care. Physicians should understand and respect the roles of nurses; physical, occupational, and speech therapists; nutritionists; pharmacists; psychologists; social workers; clergy; and other direct care staff. The evolution of interprofessional teams has resulted in a comprehensive approach to care by opening channels of communication between these health professionals from different disciplines.

"Huddles" are an integrated mechanism of enhanced communication for interprofessional teams. The implementation of efficient huddles has been associated with improved safety and better utilization of resources by predicting patient needs and making appropriate changes in staffing and care plans. Huddles can also help identify potential threats to patient care, such as socioeconomic challenges that can make care plans ineffective of even harmful.

Another strategy for enhanced communication and collaboration in the care of complex geriatric patients is "co-managed medicine" of surgical patients. In this model, internists serve as part of a multispecialty team of physicians (including

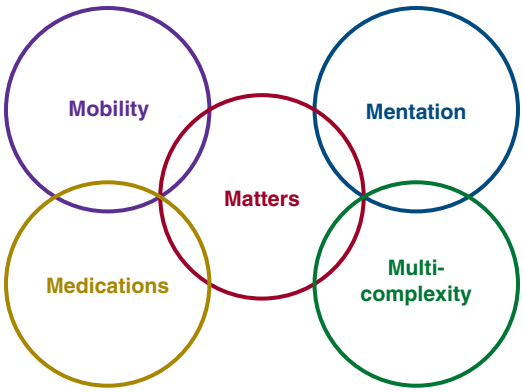

FIGURE 477-4 The 5M's of geriatrics.

TABLE 477-1 Examples Care Transitions Interventions

INTERVENTION	WEBSITE	CORE INTERVENTIONS
Re-Engineered Discharge (Project RED) (Jack et al: 2009)	*https://www.bu.edu/fammed/projectred/*	"Discharge advocate" performs the following: • Facilitates patient education and understanding • Performs medication reconciliation • Coordinates postdischarge appointments and communication with primary care provider (PCP) • Calls patient 2–3 days after discharge
Transitional Care Model (Naylor et al: 2004; Naylor et al: 1999)	*https://www.nursing.upenn.edu/ncth/transitional-care-model/*	Advanced practice nurse performs the following: • Coordinates patient care before and after discharge • Assesses each patient's needs; engages and activates the patient and family • Facilitates communication among patient, family, and health care providers • Conducts regular home visits and telephone support after discharge
Care Transitions Program® (Coleman et al: 2004)	*http://www.caretransitions.org*	"Transition coach" performs the following: • Facilitates improved self-management skills including medication management and how to respond to warning signs/symptoms • Makes postdischarge home visits and phone calls
Better Outcomes for Older Adults through Safe Transitions (BOOST) (Hansen et al: 2013)	*https://www.hospitalmedicine.org/clinical-topics/care-transitions/*	Includes toolkit facilitating the following: • Comprehensive identification and assessment of high-risk patients • Patient/caregiver education • Enhanced communication with posthospitalization care providers • Follow-up phone call with patient after discharge
Interventions to Reduce Acute Care Transfers (INTERACT) (Ouslander et al: 2013)	*http://www.interact-pathway.com*	Includes tools for skilled nursing, assisted living, and home health care, including: • Quality improvement • Communication • Decision support • Advance care planning

surgeons) that provides daily assessments, addresses medical comorbidities, and facilitates transitions of care, thereby enhancing the typical consultant model. Co-managed medicine is another example of how enhanced communication between different providers improves outcomes, avoids common complications, and saves resources. In the era of person-centered care and value-based medicine, effective co-managed medicine appears to deliver consistently high-quality care at a lower cost. Since the rise of hospitalist-based care, the use of co-managed care has increased significantly. Collaborations between internists and geriatricians are examples of this strategy. Hip fracture and trauma co-management programs have been developed in many academic and community hospitals and are demonstrating some success in reducing complications and length of stay in older trauma patients.

AGE-FRIENDLY HEALTH SYSTEMS

A new framework for providing comprehensive, integrated, and person-centered care across settings of care has been developed called "age-friendly health systems." Health systems participating in the development of age-friendly programs focus on the 5M's discussed above (Fig. 477-4) as a strategy to achieve high-quality care across the system. Strategies are implemented to educate and facilitate all system health care providers to focus on the 5M's of geriatrics under the leadership and mentorship of specially trained geriatrics health professionals.

FUNDAMENTALS OF GERIATRIC CARE

PERSON-CENTERED CARE

Person-centered care is a critical concept in caring for older people because of the complexity of their medical, functional, and psychosocial problems and, in many instances, the lack of rigorous data on the most effective strategies for caring for specific conditions in patients with multimorbidity. Thus, decision-making on goals and approaches to care must account for patient and family preferences and goals, values, perception of risk, prognosis, financial resources, and other individual factors. For almost any condition, from common disorders such as hypertension and diabetes, to geriatric syndromes such as fall risk and urinary incontinence, the answer to how best to treat medical conditions in an older patient with multimorbidity does not only depend on evidence-based medicine—it also depends on careful weighing of the factors listed above. In everyday practice with complex older patients, a focus on improving or maintaining function and independence, quality of life, comfort, and dignity will be consistent with patient and family goals.

The American Geriatrics Society (AGS) identifies the following elements as key to person-centered care: (1) an individualized, goal-oriented care plan based on the person's preferences; (2) ongoing review of the person's goals and care plan; (3) continual information sharing and integrated communication; (4) education and training for providers and, when appropriate, the person and those important to the person; and (5) performance measurement and quality improvement using feedback from the person and caregivers. Several tools are available to assist in implementing person-centered care, including estimation of prognosis (e.g., "ePrognosis") and "Choosing Wisely" recommendations from the AGS and AMDA—The Society for Post-Acute and Long-Term Care Medicine. Examples of these recommendations that are relevant to internal medicine practice are illustrated in Table 477-2.

EVALUATION OF THE GERIATRIC PATIENT

Geriatric Assessment A series of screening questions can be useful as a "geriatric review of systems" in clinical practice with older patients because of the importance and high prevalence of functional impairments and disabilities, limited social support to assist with functional limitations, cognitive and affective disorders, and geriatric conditions that may go undetected and cause patient safety issues and complications (Table 477-3). Positive responses to one or more of the

TABLE 477-2 Examples of Choosing Wisely Recommendations Helpful in Implementing Person-Centered Care in Complex Geriatric Patients

- Don't recommend percutaneous feeding tubes in patients with advanced dementia; instead, offer oral assisted feeding.
- Don't use antipsychotics as the first choice to treat behavioral and psychological symptoms of dementia.
- Avoid using medications other than metformin to achieve hemoglobin A_{1C} <7.5% in most older adults; moderate control is generally better.
- Don't use benzodiazepines or other sedative-hypnotics in older adults as first choice for insomnia, agitation, or delirium.
- Don't use antimicrobials to treat bacteriuria in older adults unless specific urinary tract symptoms are present.
- Don't prescribe cholinesterase inhibitors for dementia without periodic assessment for perceived cognitive benefits and adverse gastrointestinal effects.
- Don't recommend screening for breast, colorectal, prostate, or lung cancer without considering life expectancy and the risks of testing, overdiagnosis, and overtreatment.
- Don't routinely prescribe lipid-lowering medications in individuals with a limited life expectancy.
- Don't obtain a *Clostridioides difficile* toxin test to confirm "cure" if symptoms have resolved.
- Don't recommend aggressive or hospital-level care for a frail elder without a clear understanding of the individual's goals of care and the possible benefits and burdens.

screening questions for each item should prompt consideration of further assessments, many of which can be accomplished using standard and validated tools available on the Internet, such as activities of daily living scales, depression scales, sleep questionnaires, and mental status examinations.

Evaluation of Medical Decision-Making Capacity Key aspects of decision-making in older adults are illustrated in **Fig. 477-5**. Including the patient in the consent process for any treatment is the foundation of patient autonomy and person-centered care. Because aging is associated with an increasing potential to develop cognitive impairment, determination of decision-making capacity is important not only to protect the patients against potential abuse, but also to preserve autonomy when possible and, when it is not, to ensure an appropriate surrogate decision-making process is followed. Assessing for capacity is usually triggered by specific circumstances (e.g., the need for invasive diagnostic testing or surgery). Determination of decision-making capacity limited to medical circumstances should be differentiated from declaring a patient "incompetent" to make all decisions. Declaring someone incompetent is a legal definition and usually is reserved for court settings. Another caveat about evaluating decision-making capacity is distinguishing lack of capacity from poorly presented information, sensory impairment, language barriers, and/or low level of literacy. The clinician should corroborate that the patient has received all the necessary information, comprehends the information provided, and has no major auditory or visual impairments. For geriatric patients, it is important to determine if the patient uses hearing aids of prescription glasses and ensure they are available for their use.

Standard tests of cognitive function correlate poorly with capacity to consent for specific interventions. Several standardized tools have been validated to determine decision-making capacity. The MacArthur Competence Assessment Tool-Treatment (MacCAT-T) is a structured tool that has been validated, but it is lengthy and can be difficult to administer in some patients. The Capacity to Consent to Treatment Instrument (CCTI) is another tool that has been validated in patients with mild to moderate Alzheimer's disease. It is structured in two different vignettes, and the patient is asked to answer a series of questions. The test has high interrater reliability validity.

Evaluation of the Older Driver For many older adults in the United States, driving is essential for maintaining independence and driving cessation is associated with negative outcomes including social isolation and depression. On the other hand, older adults are at higher risk of being involved in fatal crashes than younger counterparts, with up to a ninefold higher risk for those ≥85 years old. Older people should be routinely assessed for their driving status and whether they have been in any car crashes, in addition to assessment for sensory, functional, and cognitive impairments that can make driving unsafe (Table 477-3). In addition to common geriatric conditions, several different types of drugs can impair various aspects of driving performance and should be carefully considered in older people who continue to drive, including antianxiety agents, narcotic analgesics, antipsychotics, anticonvulsants, and drugs with strong anticholinergic properties.

Suspected driving impairment can be a source of conflict between the patient (who wants to maintain independence), the family (who may want their relative to continue driving due to lack of other transportation, or may be concerned about their safety, or both), and the physician (who is concerned about the patient's, passengers', and other drivers' safety). These decisions involve liability, since local governments might not require driving retesting for all older drivers, but in some states, physicians are required to report older people who they believe are unsafe drivers. Evaluation of driving should be interprofessional and aimed to first try to correct any reversible causes of losing driving skills, such as vision and hearing impairment. Although tests of executive function such as the Trails B have been associated with poor driving performance, no single screening test predicts unsafe driving. A combination of neuropsychological testing by a psychologist and on-road testing by a trained occupational therapist can provide the physician with essential input in making the difficult decision on driving cessation. The AGS and the U.S. Department of Transportation's National Highway Traffic Safety Administration have updated the "Physician's Guide to Assessing and Counseling Older Drivers," which can be helpful to practicing clinicians and is available on the AGS website.

Interpretation of Diagnostic Tests Atypical presentations of medical conditions are a common feature of geriatric medicine. Physiologic changes associated with aging can affect the results of common diagnostic tests as well. The large variation of many physiologic measures that is associated with normal aging makes establishing what is "normal" for many tests challenging. For this reason, the results of several diagnostic tests must be interpreted with caution. Ambulatory cardiac monitoring may identify a variety of arrhythmias in older adults. Such arrhythmias must be linked to symptoms or adverse outcomes if left untreated before considering the use of potentially toxic medications or invasive procedures. Advanced imaging also could demonstrate incidental abnormalities. Although a significant portion of these findings are benign, the rate of malignancy among incidental findings in the colon and extracolonic structures, as well as ovarian and thyroid gland, is ~20%. Musculoskeletal imaging, such as an MRI of the spine, may reveal multiple abnormalities that may or may not be related to symptoms.

For the most part, abnormal diagnostic tests require further evaluation in older patients, unless further evaluation would not lead to a change in the goals of care and treatment plan. Examples include low hemoglobin levels, abnormal thyroid function tests, age-/sex-/weight-adjusted creatinine clearance, and elevated liver function tests. None of these result from normal aging and generally indicate a physiologic abnormality resulting from a disease or disorder that may or may not be reversible.

PREVENTION IN OLDER ADULTS

Age-Appropriate Screening Screening tests for specific diseases, as opposed to screening for geriatric conditions, require a careful person-centered approach. The focus of preventive medicine depends heavily on the ability to identify those who are at risk for specific conditions **(Chap. 6)**. Several professional societies have provided guidance regarding specific tests in older adults **(Table 477-4)**. An

TABLE 477-3 Examples of Screening Questions and Tools and Strategies for Further Evaluation of Social Support, Functional Status, Geriatric Syndromes, and Cognition and Affect

GERIATRIC ASSESSMENT DOMAINS		RECOMMENDED SCREENS	FURTHER ASSESSMENT FOR POSITIVE SCREEN
SOCIAL	**Social Support**	Do you live alone? Do you have a caregiver? Are you a caregiver?	• Consider referral to a social worker • Refer to Area Agency on Aging
	Elder Neglect/Abuse	Do you ever feel unsafe where you live? Has anyone ever threatened or hurt you? Has anyone been taking your money without your permission?	• Consider referral to a social worker and/or Adult Protective Services
	Advance Directives	Would you like information or forms for a power of attorney for health care? Would you like information on a living will?	• Discussion on advance directives • Physician Orders for Life-Sustaining Treatment (POLST) (or MOLST or POST)
FUNCTIONAL	**Functional Status**	Do you need assistance with shopping or finances? Do you need assistance with bathing or taking a shower?	• Instrumental Activities of Daily Living (ADL) Scale • Basic ADL Scale
	Driving	Do you still drive? If yes: While driving, have you had an accident in the past 6 months? Driving concerns by family member?	• Vision testing • Consider occupational therapy and/or formal driving evaluation
	Vision	Do you have trouble seeing, reading, or watching TV? (with glasses, if used)	• Vision testing • Consider referral for eye exam
	Hearing	Do you have difficulty hearing conversation in a quiet room? Unable to hear whisper test 6 inches away?	• Check for cerumen in ear canals and remove if impacted • Hearing Handicap Inventory • Consider audiology referral
GERIATRIC SYNDROMES	**Medications**	Do you take 5 or more routine medications? Do you understand the reason for each of your medications?	• Match medications with diagnoses • Consider reducing doses, stopping drugs, adherence aides, and/or consultation with a pharmacist
	Fall Risk	Have you fallen in the past year? Are you afraid of falling? Do you have trouble climbing stairs or rising from chairs?	• "Get Up and Go" test • Consider full fall assessment • Consider physical therapy evaluation • Consider home safety assessment
	Continence	Do you have any trouble with your bladder? Do you lose urine or stool when you do not want to? Do you wear pads or adult diapers?	• Consider full continence assessment • 3IQ Questionnaire (women) • AUA 7 symptom inventory (men)
	Weight Loss	Weight <100 pounds or Unintentional weight loss ≥10 pounds over 6 months?	• Assess for common risk factors for malnutrition • Consider referral to dietician for nutritional evaluation
	Sleep	Do you often feel sleepy during the day? Do you have difficulty falling asleep at night?	• Epworth Sleepiness Scale or Pittsburgh Sleep Index • Consider referral for sleep evaluation
	Pain	Are you experiencing pain or discomfort?	• Pain assessment
	Alcohol Abuse	Do you drink >2 drinks/day?	• AUDIT-C
COGNITION AND AFFECT	**Depression**	Do you often feel sad or depressed? Have you lost pleasure in doing things over the past few months?	• PHQ-9 or Geriatric Depression Scale • Screen for suicide risk
	Cognition	Self-reported memory loss? Cognitive screen positive? (3-item recall and Clock Draw test "Mini-Cog") Confusion Assessment (CAM) for delirium	• Montreal Cognitive Assessment or Mini Mental State Examination • If diagnosis is unclear, consider neuropsychological testing

Abbreviations: 3IQ, Three Incontinence Questions; AUA, American Urological Association; AUDIT-C, Alcohol Use Disorders Identification Test; MOLST, Medical Orders for Life-Sustaining Treatment; PHQ, Patient Health Questionnaire; POST, Physician Orders for Scope of Treatment.

important caveat about screening to prevent disease in older patients (e.g., colonoscopy for colon cancer, Pap smears, prostate-specific antigen testing) is that abnormal results may lead to subsequent testing and treatment among individuals who will not suffer morbidity or mortality from the disease because of limited life expectancy. Thus, geriatric patients pose a significant challenge for deciding what screening tests could offer a reasonable ratio of benefit and risk as well as being cost-effective. As an example, the U.S. Preventive Services Task Force recommends colorectal cancer screening up to the age of 75 years. For those between 76 and 85 years old, the recommendation is to only consider screening colonoscopy if they have never been screened and they are healthy enough to undergo treatment if colon cancer is detected.

Vaccinations The use of vaccines in older adults is aimed at creating immunity against common infections that could lead to serious complications and rebuilding previously obtained immunity. The U.S. Centers for Disease Control and Prevention recommends routine vaccination against influenza, pneumococcus, and shingles as they are prevalent in this age group. Other countries in Europe and Asia have similar trends on vaccinations with small variances.

Sexually Transmitted Diseases Although most sexually transmitted diseases (STDs) occur in younger people (Chap. 136), a portion of older adults have high-risk sexual behavior. Most Americans remain sexually active in their 60s and 70s, and up to a quarter of individuals

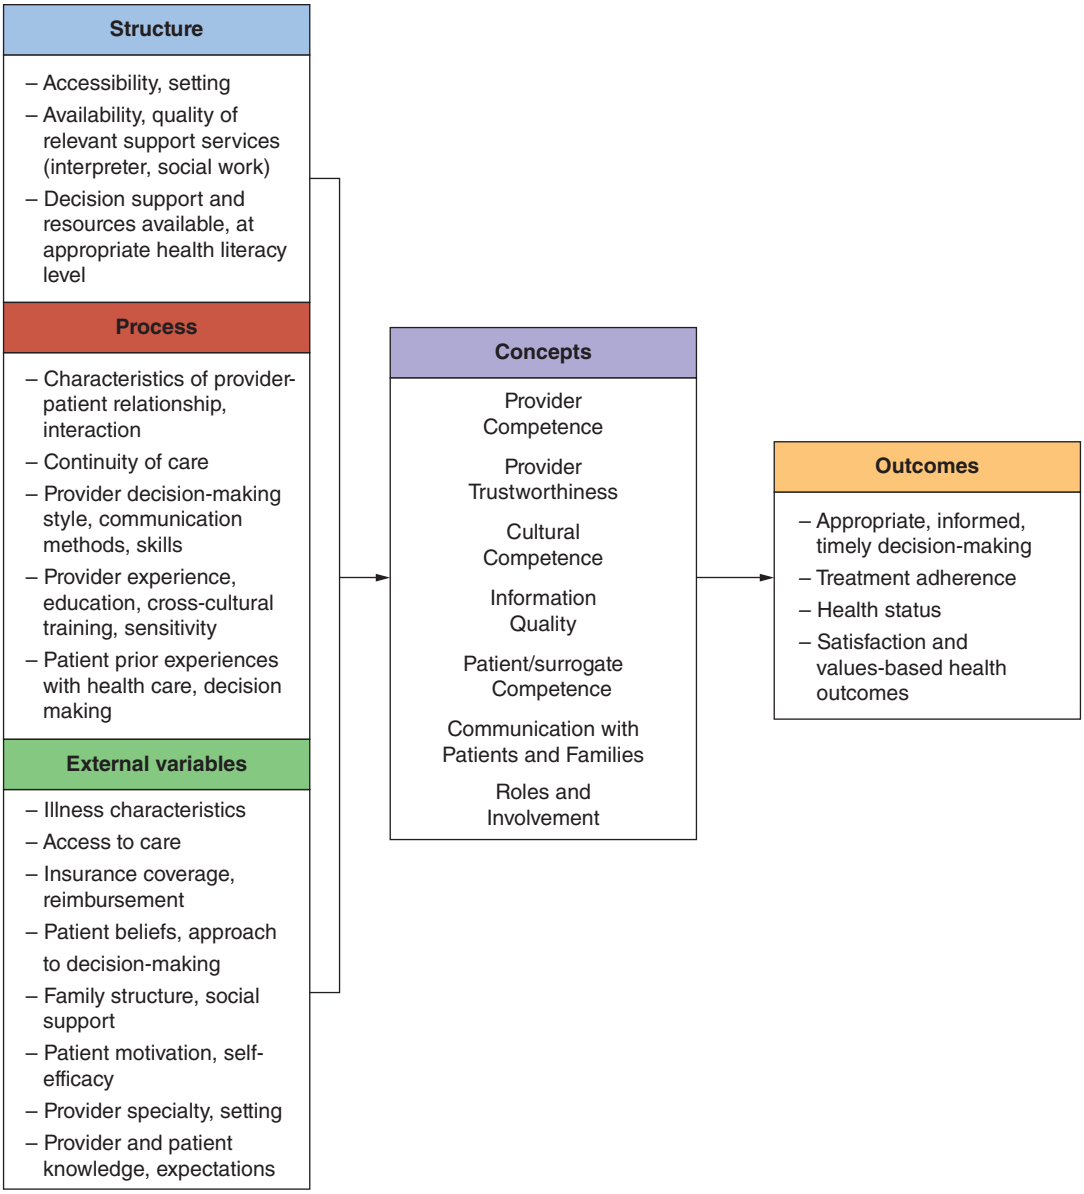

FIGURE 477-5 Key aspects of decision-making in older adults. *(Reproduced with permission from SM Dy, TS Purnell: Key concepts relevant to quality of complex and shared decision-making in health care: A literature review. Soc Sci Med 74:582, 2012.)*

in their 80s considers themselves sexually active. Sexually active older adults may have a lower awareness of the need for safe sexual practices, such as the risks of multiple sexual partners and condom use. The incidence of STDs in older people is still relatively low. Individuals born in the United States between 1945 and 1965 are at higher risk of having hepatitis C due to lack of awareness of the disease and lack of institutions of universal precautions before the 1980s for blood transfusions. Other factors that could affect such risk are use of intravenous drugs and unprotected sex with multiple partners. The prevalence of tertiary syphilis is higher than newly contracted syphilis in older adults. The incidence of gonococcal infection decreases with age. Nonetheless, patients presenting with symptoms compatible with syphilis or gonococcal infection (cervicitis, urethritis, proctitis, epididymitis) should be screened for high-risk sexual behavior and educated if necessary. Clinical symptoms of herpes simplex infection and the possibility of becoming contagious also decrease with age. As ulcerative lesions are less frequent, herpes simplex virus-2–specific serologic testing should be considered for patients with recurrent nonspecific genital symptoms. Therapy should not be started unless the patients are symptomatic.

In the United States alone, 2600 per 100,000 persons above the age of 50 are infected with HIV. Since the introduction of highly active antiretroviral therapy, life expectancy of patients with HIV has increased, resulting in a significant increase in the number of older adults living with the disease. De novo infections have also contributed to the rising number of HIV cases in older adults. The low rate of condom use and lack of knowledge of the disease play a key role in the transmission rate. Age is an independent predictor of HIV progression and associated mortality. There are no age-specific guidelines for treating HIV. Like all other conditions, a higher incidence of medication-related side effects is seen in older patients, especially those with other comorbidities and on multiple other medications, and this should be considered in treatment decisions.

TREATMENT OF COMMON DISEASES IN THE GERIATRIC POPULATION

HYPERTENSION

In the United States, 70% of older adults have hypertension. Several clinical trials have demonstrated the benefits of hypertension treatment on risk reduction of cardiovascular events in older people. Nonetheless, blood pressure targets remain controversial. The balance between the cardiovascular protective benefits versus the risk of treatment-related adverse events must be considered in individual patients based on their comorbidities and level of function. For example, hypotension and

TABLE 477-4 Recommendations for Primary Prevention Screening for Specific Diseases in Older Adults from Different Professional Societies

TYPE OF SCREENING	TEST	FREQUENCY	PROFESSIONAL SOCIETY ISSUING RECOMMENDATIONS		
			USPSTF[a]	ACS[b]	ACP[c]
Colorectal	Fecal occult blood test or fecal immunochemical test (FIT) or Sigmoidoscopy or Colonoscopy	Annual Every 5 y Every 10 y	Screen all adults age 50–75; prognosis may support screening individuals of age 76–85 if never screened; not recommended for adults over age 85	Screen all adults age >50; discontinuing screening is reasonable in people with severe comorbidity that would preclude treatment	Screen all adults age 50–75 People with life expectancy <10 y should not be screened
Breast	Mammography	Every 1–2 y	Biennial screening of all women age 50–74; evidence of benefits and harms is insufficient for women age >75	Annual screening starting at age 40; continue while in good health	ECOG[d] Annual screening starting at age 40 y
Cervical	Pap smear HPV test	Pap only, every 3 y HPV + Pap, every 5 y	Screen women age 21–65; discontinue at age 65 if adequate prior screening	Screen women age 21–65; discontinue at age 65; discontinue at age 65 if regular screening normal	Screening should stop at age 65 if evidence of negative adequate prior screening.
Lung	Low-dose CT scan	Annual	Screen age 55–80 current and former smokers with a 30+ pack-year smoking history; discontinue screening once a person has not smoked for 15 years or develops a health problem that limits their ability or willingness to have curative surgery	Screen 55–74-y-old current and former smokers in good health with a 30+ pack-year smoking history	ACCP[e] In settings that can deliver the comprehensive care provided to National Lung Screening Trial participants, offer screening to people age 55–74 who are current and former smokers with 30+ pack-year smoking history
Prostate	Prostate-specific antigen (PSA)	1–2 y	Do not screen men for prostate cancer with PSA if age 70 y or older	Screen men age 50 and over with a life expectancy >10 y after discussion about the risks, benefits, and uncertainties of PSA screening Follow-up screening should occur annually if PSA >2.5 ng/mL or biennially if PSA <2.5 ng/mL	AUA[f] Biennial PSA screening in men age 55–69 y with life expectancy >10–15 y, after shared decision-making discussions accounting for values and preferences
Osteoporosis	Dual-energy x-ray absorptiometry (DEXA) Measure height, preferably with a wall-mounted stadiometer	Perform bone mineral density testing 1–2 y after initiating medical therapy for osteoporosis and every 2 y annually thereafter	USPSTF[a] Screen women age 65; the current evidence is insufficient to assess the balance of benefits and harms of screening for osteoporosis to prevent osteoporotic fractures in men	NOF[g] Screen women age 65 and older and men age 70 and older; postmenopausal women and men age 50–69, based on risk factor profile; postmenopausal women and men age 50 and older who have had an adult-age fracture	
Carotid Disease	Carotid ultrasound	Once	Society of Vascular Surgery Age over 65, coronary artery disease, need for coronary bypass, symptomatic lower extremity arterial occlusive disease, history of tobacco use, and high cholesterol would be appropriate risk factors to prompt ultrasound in patients with a bruit		
Coronary Artery Disease (CAD)	Coronary Calcium Score (CCS)	Once	SCCT[h] Do not use CCS for patients with known CAD	AHA/ACC[i] CCS of 0 may have a strong negative predictive value for coronary events in older adults	
Abdominal Aortic Aneurysm	Abdominal ultrasound	Once	USPSTF[a] The USPSTF recommends one-time screening for abdominal aortic aneurysm with ultrasonography in men aged 65–75 y who have ever smoked; there is insufficient evidence to recommend screening for women even if they have ever smoked	AAFP[j] Recommended for men aged 65–75 y who have ever smoked	
Diabetes	Fasting blood glucose, glucose tolerance test, or hemoglobin A_{1C}	Annually	USPSTF[a] No evidence to screen for diabetes after the age of 70; recommendation being reviewed at the time of this publication	ADA[k] Screen people 45 y and older

postural hypotension related to antihypertensive therapy are common causes of near-syncope and falls and related injuries in the geriatric population, especially those with multimorbidity. In addition to cardiovascular disease prevention, control of systolic blood pressure (SBP) may reduce the burden of white matter changes in the brain, which are associated with gait abnormalities and cognitive decline. To date, no studies in older patients with multimorbidity have documented any beneficial effects of tight control of hypertension on the incidence of falls and cognitive decline. The European Society of Cardiology/European Society of Hypertension guidelines recommend pharmacologic treatment for individuals 80 years old or older if SBP is 160 mmHg or higher. In contrast, the American College of Physicians recommends starting treatment if SBP is 150 mmHg or higher.

Two large studies (HYVET and SPRINT) have shed some light on these issues. HYVET was a multicenter study conducted in several countries involving ~3800 patients ≥80 years old. The study demonstrated that active treatment of hypertension with a target of ≤150 mmHg significantly reduced not only the risk of stroke and heart failure but also the mortality risk. As with other large hypertension studies like ALLHAT, a linear association was noted between blood pressure and stroke reduction. Nonetheless, in the HYVET study, this association was less prominent as age increased. SPRINT was another large randomized trial targeting lowering SBP to targets of <140 versus 120 mmHg (measured with an automated device) with a subgroup analysis in those aged 75 and older. Significant reductions were documented in the primary endpoint, which was a composite of cardiovascular disease events (including myocardial infarction, acute coronary syndrome, heart failure, stroke, or death from cardiovascular causes). However, it is critical to recognize that patients with diabetes, history of stroke or heart failure, and SBP <110 mmHg after 1 min of standing, as well as people with several other comorbidities, were excluded from the SPRINT trial, and aggressive treatment in the setting of these comorbidities may incur more risk of adverse effects.

Overall, these data strongly suggest a person-centered approach to hypertension in the heterogeneous older population. For older patients with minimal comorbidity, no postural hypotension, and low risk of falls and volume depletion, the benefit-risk ratio favors lower targets for SBP (<130 mmHg measured by a hand sphygmomanometer). Aggressive targets also may be more beneficial for patients with concomitant nonvalvular atrial fibrillation or coronary artery disease. However, for those with diabetes, heart failure, or postural hypotension, careful treatment of blood pressure with higher SBP targets (<150 mmHg) is probably a safer approach.

DIABETES

The prevalence of diabetes in the older adult population is now >25% and expected to increase due to adverse lifestyle changes and an increased incidence of obesity. Those between the ages of 65 and 74 have the highest rates of complications associated with diabetes. Nonetheless, due to a lack of data on patients with multimorbidity and those age 80 and older, as well as the high incidence of hypoglycemia in this population when treated with multiple hypoglycemic agents, the approach to managing diabetes requires a person-centered approach like that described for hypertension. Older diabetic patients are at significant risk of hypoglycemia because of potential medication errors, progressive renal insufficiency, and inconsistent oral intake, among other reasons. Diabetic patients age 75 or older are in fact at twice the risk of visiting the emergency department due to hypoglycemia. Hypoglycemic episodes are associated with progressive cognitive decline in older adults, especially those with existing cognitive impairment. On the other hand, uncontrolled diabetes is associated with an increased risk of all-cause dementia.

Data from randomized clinical trials suggest that intensive glycemic control does not reduce major macrovascular events in older adults for at least 10 years or result in improved microvascular outcomes for at least 8 years and, at the same time, increases the risk of severe hypoglycemia by 1.5 to 3 folds. Thus, the AGS guideline on diabetes in older adults (see **"Further Readings"**) and the Choosing Wisely recommendations (Table 477-2) suggest that, in most older adults, the harms associated with a hemoglobin A_{1C} (HbA_{1C}) target <7.5% are likely to outweigh the benefits. These recommendations are consistent with the American Diabetes Association guidelines from 2020 that recommends an HbA_{1C} target of <7.5% among older adults with intact cognitive function and functional capacity and few comorbidities. The goals of treating diabetes in the geriatric population should be tailored to the patient's functional status, coexisting geriatric syndromes, social support, personal goals, perception of risk, and life expectancy. For specifics of treatment options, see **Table 477-5**. Regardless of the therapeutic goals for HbA_{1C}, older diabetic patients should be regularly examined for neuropathy, which can lead to the development of lesions on the feet that could become infected, as well as for retinopathy and vision loss that may require ophthalmologic intervention. In addition, lifestyle management is an important component of the plan of care. If possible, diabetic older adults should exercise regularly and should have an adequate protein intake to try maintaining muscle mass. For

TABLE 477-5 Recommendations and Considerations for Pharmacologic Therapy of Diabetes in Older Adults

MEDICATION	RECOMMENDATIONS AND CONSIDERATIONS
Metformin	• Metformin is the first-line agent for older adults with type 2 diabetes • Low risk of hypoglycemia • Recent studies suggest it may be used safely in patients with estimated glomerular filtration rate ≥30 mL/min/1.73 m^2 • Contraindicated in patients with advanced renal insufficiency or significant heart failure • Can cause gastrointestinal symptoms with lower appetite
Sodium-Glucose Cotransporter 2 (SGLT-2) Inhibitors	• Offer an oral route, which may be convenient for older adults • Low risk of hypoglycemia • Strong evidence for renal protection and improved cardiovascular outcomes • Caution when combined with other therapies such as diuretics
Thiazolidinediones	• If used at all, should be used very cautiously in those with, or at risk for, congestive heart failure and those at risk for falls or fractures
Sulfonylureas	• Associated with hypoglycemia and should be used with caution • Shorter-duration sulfonylureas such as glipizide are preferred • Glyburide is longer duration and contraindicated in older adults
Dipeptidyl Peptidase 4 (DPP-4) Inhibitors	• Few side effects and minimal hypoglycemia, but costs may be a barrier • No evidence of increase in major adverse cardiovascular events
Glucagon-Like Peptide 1 (GLP-1) Agonist	• GLP-1 receptor agonists are injectable, which requires visual, motor, and cognitive skills • Associated with nausea, vomiting, diarrhea, and weight loss, which may not be desirable in some older patients, particularly those with cachexia
Insulin Therapy	• Requires that patients or their caregivers have good visual and motor skills and cognitive ability • Insulin doses should be titrated to meet individualized glycemic targets and to avoid hypoglycemia • Once-daily basal insulin injection therapy is associated with minimal side effects and may be a reasonable option in many older patients • Multiple daily injections of insulin may be too complex for the older patient with advanced diabetes complications, life-limiting comorbid illnesses, or limited functional status

Source: Based on recommendations from the American Diabetes Association 2020 and JS Custódio Jr et al: Drugs Aging 37:399, 2020.

patients living in LTC facilities, diabetes education of staff and periodic revision of individual glucose targets could reduce unnecessary complications associated with diabetes treatment.

HYPERLIPIDEMIA

While good evidence exists regarding the benefits of statins on primary cardiovascular risk prevention in patients ≤75 years old, for those older than 75, the data are very limited. The use of statins in those older than 75 or 80 for prevention of cardiovascular events and mortality is the subject of ongoing debate in the geriatric literature. The Prospective Study of Pravastatin in the Elderly at Risk (PROSPER) demonstrated a significant reduction in cardiovascular events over a 3.2-year follow-up among older adults taking statins when compared with those not taking them. Nonetheless, the study failed to demonstrate a mortality benefit. For secondary prevention, a large observational study in Europe demonstrated that after excluding patients who die within the first year of a myocardial infarction, those taking statins may have a 37% reduction in cardiovascular mortality. In contrast, a review published in 2014 concluded that no evidence from randomized controlled trials exists to guide statin initiation after age 80 years and that treatment of hypercholesterolemia for patients at risk of atherosclerotic cardiovascular disease should start before they turn 80 years old. Two other factors make the use of statins in older adults controversial. First, the major benefits have been demonstrated over long-term use; thus, life expectancy is a limiting factor to observe any meaningful change in outcomes. A substantial proportion of patients are maintained on statins at the end of life, even though such agents can be safely discontinued. Thus, continuing statins in older patients with end-stage illnesses does not make any clinical sense. On the other hand, statins are safe to use in older adults, especially at moderate to low doses. Although many older adults on statins complain of muscle pain, the risk of myositis and rhabdomyolysis is increased mostly with the coexistence of other risk factors such as sarcopenia, polypharmacy, and use of high doses of statins. Adverse effects of statins on cognitive function appear to be uncommon. Thus, some relatively healthy adults older than 75 with life expectancy of >10 years may benefit from statin use, and the approach to hyperlipidemia should be person-centered in this population, as discussed for both hypertension and diabetes.

OSTEOARTHRITIS

The approach to the management of symptomatic osteoarthritis (OA) in the geriatric population differs from the approach in younger patients **(Chaps. 370 and 371)** because of the substantial toxicity of nonsteroidal anti-inflammatory drugs (NSAIDs) in older patients. Nonpharmacologic interventions, briefly discussed below, should be the first line of treatment. While some patients older than 65 can tolerate NSAID use with concomitant protection from gastrointestinal (GI) bleeding with a proton pump inhibitor (PPI), this regimen exposes patients to two drugs with numerous potential adverse drug effects. NSAIDs are well known to be associated not only with GI bleeding but also with worsening renal function based on multiple potential mechanisms and with sodium and fluid retention and exacerbation of hypertension and congestive heart failure. In addition, a substantial number of older patients are on anticoagulants or platelet aggregation inhibitors, which could further increase the risk of bleeding from NSAIDs. PPIs are associated with a higher incidence of pneumonia, osteoporosis, and *Clostridioides difficile*–associated diarrhea, and they may be associated with a higher risk of dementia.

Thus, in older patients with multimorbidity who have painful OA, the risks of NSAIDs most often outweigh the benefits, and older patients should be discouraged from taking nonprescription NSAIDs without consulting their primary care clinician. Topical NSAIDs are better tolerated, and lidocaine patches and other nonprescription analgesic creams may also be effective. The AGS guideline on the management of chronic pain recommends that routine acetaminophen in doses up to 1 g four times daily should be the basis of pharmacologic treatment. Failure to respond could be followed up with careful trials of tramadol or a narcotic agent (started in a short-acting preparation) with appropriate attention to avoiding narcotic-induced constipation. Although prescription of narcotics is getting increasingly cumbersome because of high rates of abuse, this should not deter prescription of these agents to relieve pain and disability in older patients. Despite recent guidelines from governmental agencies, professional societies endorse the use of opioids for chronic pain, especially among older adults in LTC facilities.

Many older patients respond well to a variety of nonpharmacologic interventions, including stretching, strengthening, timely and appropriate use of heat and ice, massage, swimming and whirlpool therapy, bracing, acupuncture, and therapeutic electrical stimulation. These interventions are best carried out under the supervision of physical therapists or other professionals with appropriate expertise to avoid injury. Surgical interventions, including replacement of major joints, has improved over the past several years, and even older patients with multimorbidity may benefit in terms of function and quality of life. Total knee replacement, for example, has been shown to be effective in generally healthy older patients and should be considered in selected higher risk patients. "Pre-habilitation," with targeted strengthening and endurance exercises, and willingness to go through several weeks of postoperative physical therapy should be prerequisites for referring older patients for joint replacement.

CANCER

More than half of new cases of cancer and mortality associated with it occur after the age of 65. Data regarding older adults with multiple comorbid conditions and their response to cancer treatment are limited. While only ~10% of clinical trials have had age-stratification analyses, the available evidence suggests that age alone is not a predictor of harm. Nonetheless, making treatment decisions is challenging due to both shorter life expectancy in older adults and the cumulative effect of multiple comorbidities. Thus, a person-centered approach is essential.

Older adults generally experience decreases in functional status after receiving chemotherapy. Most of this negative effect appears to be related to comorbidity and baseline functional status, rather than due to age alone. For this reason, specialists in geriatric oncology have proposed using comprehensive geriatric assessment, including many of the issues addressed in Table 477-3, as a strategy to better predict which older adults will tolerate and benefit most from cancer treatment. Other considerations before making decisions about treatment plans should include socioeconomic factors. Lack of social support has been associated with poor outcomes after radiation and chemotherapy, especially in older women. Other important issues in cancer treatment planning include availability of transportation for treatments, economic and insurance status, the patient's ability to follow treatment plans, and family and social support available during therapy, when adverse effects and functional decline may occur.

ANEMIA

A low hemoglobin or hematocrit is not a normal age-related change in older adults. All anemic older adults should have a basic evaluation to determine the etiology including a complete blood count, examination of a peripheral red blood cell smear, reticulocyte count, and measurement of iron, iron binding capacity, and transferrin saturation. A serum ferritin level can help distinguish iron deficiency from anemia of chronic disease; the two types of anemia occur commonly in older adults. The prevalence of anemia in older adults varies between 7% and 47%, with the highest prevalence among nursing home residents. Even mild anemia is associated with worse overall outcomes in older adults, including functional and cognitive decline, falls, hospitalization, frailty, and mortality. Microcytic indices suggest occult blood loss. Iron deficiency is the most common cause, with other nutritional anemias (e.g., B_{12} deficiency) and myelodysplasia each accounting for a small percentage. Anemia of chronic disease is common in older people who have several chronic illnesses. The etiology of the anemia in older adults cannot be specifically explained in more than a third of the cases, and this unexplained anemia is generally normocytic, mild in degree, with a low reticulocyte count, and associated with normal or low erythropoietin levels in the face of inadequate production of new red cells. Red cell life span is not decreased, but the production

of erythropoietin is compromised even in the absence of overt renal disease. Anemia is frequently asymptomatic, but severe cases could present with symptoms such as generalized weakness and functional decline, shortness of breath, chest pain, or syncope. The unexplained anemia of aging appears to be responsive to erythropoietin, but it is unclear whether correction of the anemia improves outcomes. Thresholds for transfusion of packed red cells among older adults should be based on symptoms and associated conditions. For example, for geriatric patients suffering acute blood loss anemia after an orthopedic procedure, the trigger for transfusion should be a hemoglobin <8 mg/dL instead of 7 mg/dL for patients with anemia associated with chronic disease or a myelodysplastic syndrome. Similarly, older patients with active cardiovascular disease, such as angina or heart failure, may need to be transfused a levels <8 or 9 mg/dL. **For details of the general evaluation and management of anemia, please refer to the Chap. 63 on anemia.**

GERIATRIC SYNDROMES AND CONDITIONS

In this section, selected geriatric syndromes and conditions likely to be encountered by internists in hospital, clinic, office, PAC, and LTC settings are discussed. For a more thorough discussion of these and other syndromes and conditions, the reader is referred to textbooks that focus specifically on geriatrics and gerontology (see **"Further Reading"**).

FALLS

Epidemiology and Impact Among all geriatric syndromes, falls are probably the most common that internists will encounter. Falls are responsible for potentially devastating consequences for function and quality of life, as well as mortality. About one in three older community-dwelling and one in two older LTC facility residents fall annually, with many more at risk for falls. The consequences of falls include fear of falling with adverse effects on quality of life, painful injures including hip and wrist fractures, subdural hematomas, and death. Falls are associated with loss of function and death within the year after a fall. For these reasons, internists should regularly screen older people for falling using questions such as, "Have you fallen in the past year?" "Are you afraid of falling?" "Do you have trouble climbing stairs or rising from chairs?" (Table 477-3).

Evaluation The risks and causes of falls are multifactorial. Most older people at risk for a fall or who have suffered a fall have more than one potential underlying risk factor or cause. Many falls are labeled as "mechanical" and attributed to simply tripping or slipping. It is essential to recognize, however, that older people who trip or slip may have a variety of underlying reversible conditions that could have contributed to the event. Thus, a thorough evaluation of all falls is warranted. In addition to evaluating the patient who has fallen for injury, it is critical to determine, to the extent possible, whether the patient had a syncopal episode or a seizure, which dictates a very different approach to evaluation and management. As many as half of "unexplained falls" in older people with dementia (e.g., found on the floor) may be due to near-syncope or syncope related to postural hypotension.

Figure 477-6 illustrates an overview of the approach to an older person who reports a history of one or more falls in the past 6 months,

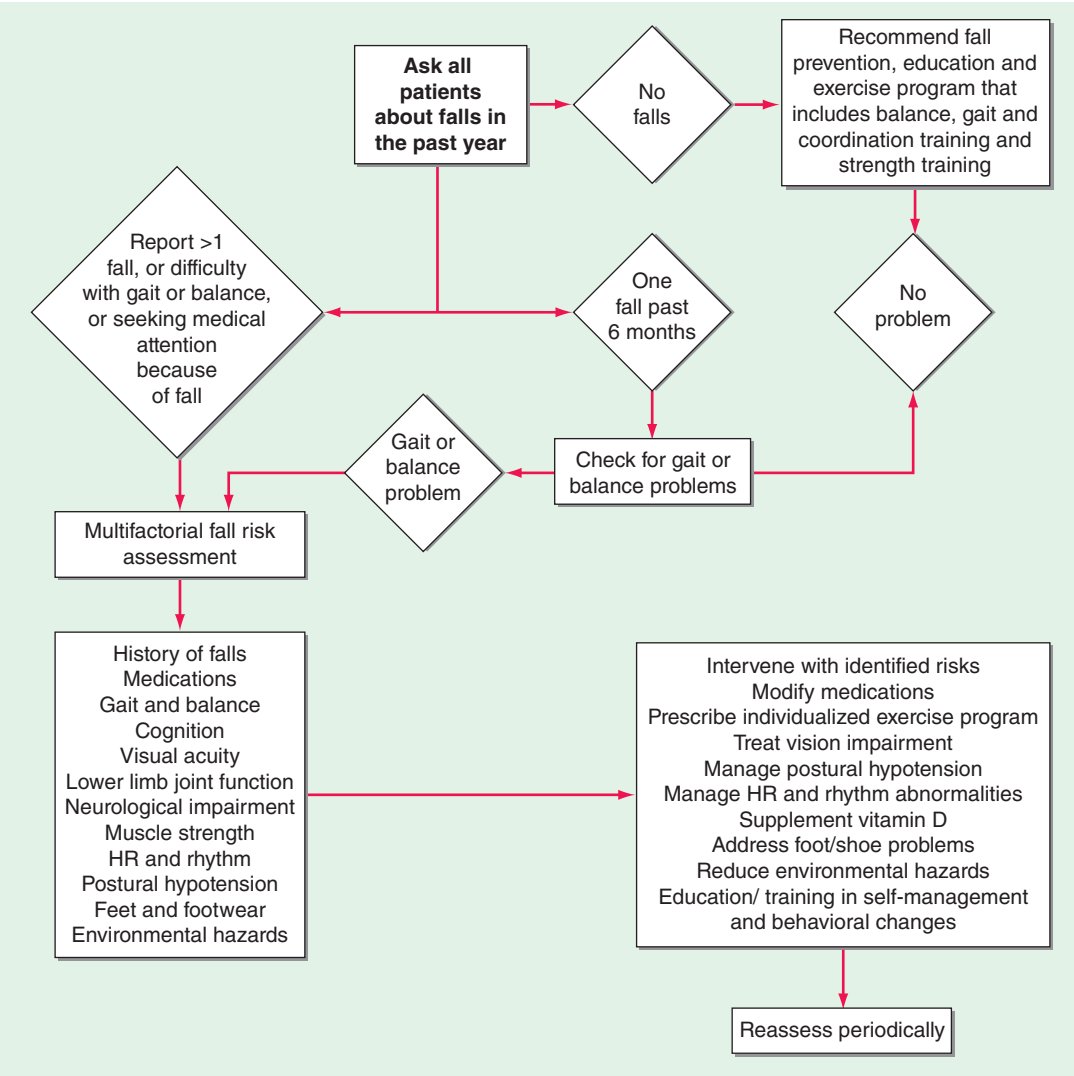

FIGURE 477-6 Algorithm depicting assessment and management of falls in older patients. HR, heart rate. *(Reproduced with permission of American Geriatrics Society. American Geriatrics Society and British Geriatrics Society: Clinical Practice Guideline for the Prevention of Falls in Older Persons. New York, American Geriatrics Society, 2010.)*

TABLE 477-6 Evaluating the Older Person Who Falls—Immediate Post-Fall Evaluation

History

- Circumstances surrounding the fall
  - Relationship to changes in posture, turning of head, after a meal or medication intake, rushing to the toilet, nocturia, straining to urinate or defecate
  - Accidental trip or slip (note that many correctable factors can contribute to a reported "mechanical" fall—see text)
  - Hazards in the living environment (loose rugs, cords, unsafe steps, slippery floors, etc.)
- Premonitory or associated symptoms
  - Dizziness (lightheadedness vs vertigo); cardiovascular (postural lightheadedness, palpitations, chest pain, shortness of breath); focal neurologic symptoms suggestive of stroke or transient ischemic attack (weakness, sensory disturbance, dysarthria, ataxia, aphasia); symptoms of a seizure (witnessed clinic movements, incontinence of urine or stool, tongue biting)
  - Symptoms over the previous few days that may have led to volume depletion (poor food/fluid intake, nausea/vomiting, diarrhea, urinary frequency/polyuria)
- Exclude loss of consciousness or seizure (may be difficult without a witness)
- Medications—chronic and within the few hours before the fall
  - Diuretics and other antihypertensive drugs
  - Nitrates
  - Drugs that cause bradycardia—beta blockers; cholinesterase inhibitors
  - Psychotropics—antipsychotics, hypnotics, sedatives, antidepressants
  - Antiparkinsonian drugs
  - Hypoglycemic drugs
- Excessive alcohol intake

Physical Examination

- Exclude physical injury
  - Head trauma, hip range of motion, pubic bone tenderness, wrist pain, other signs of trauma
  - Bruising in patients on anticoagulants/platelet inhibitors
- Exclude acute illness
  - Vital signs
  - Postural vital signs (if feasible/safe)
  - Fingerstick glucose in diabetics
  - Poor skin turgor suggesting volume depletion (over chest; other areas unreliable)
  - Signs of an acute respiratory, cardiovascular, or abdominal condition
  - Focal neurologic signs suggestive of stroke
- Signs of conditions that increase risk for falls
  - Poor visual acuity; use of bifocals
  - Limited range of motion of neck (to detect possible cervical arthritis/disk disease)
  - Cardiovascular—arrhythmias, carotid bruits, aortic stenosis, mitral insufficiency, heart failure
  - Degenerative joint disease in lower extremities causing pain, limited range of motion, and/or deformity
  - Podiatric conditions (calluses; bunions; ulcerations; poorly fitted, inappropriate, or unsafe shoes)
  - Neurologic signs—lower extremity muscle weakness; peripheral neuropathy; tremor, rigidity, and/or bradykinesia suggestive of undiagnosed Parkinson's disease; cerebellar signs (abnormal heel to shin or heel tapping); abnormal reflexes that could reflect upper motor neuron disorder such as spinal cord compression or subdural hematoma; cognitive deficits that can result in poor judgement
  - Observation of gait and balance—simple Get Up and Go test (see text) with observation for short steps, poor foot elevation, wide-based gait, multiple steps to turn 180 degrees; other abnormalities that might suggest normal pressure hydrocephalus (especially in combination with symptoms of incontinence and/or cognitive impairment)

Laboratory and/or Imaging Studies

- Should be guided by history and physical examination—common examples include:
  - Complete blood count, basic metabolic panel to exclude/verify acute illness
  - Urinalysis (only when additional symptoms of urinary tract infection present)
  - Electrocardiogram (in patients suspected of acute coronary syndrome or with significant known cardiovascular disease)
  - X-rays to exclude fractures
  - Brain imaging if signs present to exclude subdural hematoma, stroke
  - Cardiac monitoring in patients with history suggestive of syncope or near-syncope
  - Electroencephalography in patients with history suggestive of seizure

and Table 477-6 provides more detail on the immediate evaluation of an older person who has fallen. **Chap. 26 provides more detail on the evaluation of gait and balance disorders.**

Management Table 477-7 illustrates approaches to the management of falls. Immediately after a fall, injuries and underlying acute illnesses should be identified and treated. It is common practice for older patients who come to an emergency department with a history of a fall to have a brain imaging study. While this is understandable from a potential liability standpoint, it is also reasonable to avoid such studies if no history or signs of head trauma, neurologic symptoms or signs, or anticoagulation is noted and to monitor the patient carefully over the next 48–72 h for the development of specific indications for a brain imaging study.

Because the causes of and risk factors for falls are often multifactorial, management commonly requires multiple interventions in the same patient. Among the most common and effective interventions are physical therapy for strengthening and balance; Tai Chi has also been shown to be effective in multiple trials. Although many older people who fall are vitamin D deficient, the role of vitamin D replacement in

TABLE 477-7 Examples of Management for Underlying Causes of Falls in Older Patients

CAUSES	EXAMPLES OF TREATMENT
Cardiovascular	
Arrhythmias	Antiarrhythmic medication, ablation, pacemaker (depending on nature of arrhythmia)
Aortic stenosis with syncope or near syncope	Valve surgery (transcatheter procedure if appropriate)
Postural hypotension	Reduce or eliminate hypotensive drugs Hydration, support stockings Medication (Proamatine [midodrine], fludrocortisone, droxidopa) Adaptive behaviors (e.g., pausing and getting up slowly)
Hypertension	Manage carefully to avoid hypotension and near syncope; control may be important in patients with periventricular white matter changes in preventing further gait disturbance
Neurologic	
Autonomic dysfunction with postural hypotension	As above
Cervical spondylosis (with spinal cord compression)	Neck brace; physical therapy; consider surgery
Parkinson's disease	Antiparkinsonian drugs
Visual impairment	Ophthalmologic/optometric evaluation and specific treatment
Seizure disorder	Anticonvulsants
Normal-pressure hydrocephalus	Surgery (ventricular-peritoneal shunt)
Dementia	Supervised activities Hazard-free environment
Benign positional vertigo	Habituation exercises Anti-vertiginous medication
Others	
Foot disorders	Podiatric evaluation and treatment
Gait and balance disorders	Properly fitted shoes Physical therapy Exercise with balance training (including Tai Chi where available)
Muscle weakness, deconditioning	Lower extremity strength training
Drug adverse effects (e.g., sedatives, alcohol, other psychotropic drugs, antihypertensive)	Elimination of drug(s) when feasible
Vitamin D deficiency	Vitamin D supplementation
Recurrent falls	Fall alert system for those who live alone; hip protectors in selected patients

preventing falls or preventing injuries from falls when combined with interventions such as strength and balance training is not clear. The risk/benefit ratio probably favors vitamin D replacement with at least 800 IU per day, but high-dose vitamin D (60,000 IU in one oral dose monthly) has been associated with an increase in risk of falls. Patients who suffer a fracture after a fall should be investigated and treated for osteoporosis. Patients at high risk for recurrent falls and injuries should be encouraged to use a fall alert system; selected patients may benefit from hip protectors.

POLYPHARMACY

Epidemiology and Impact Polypharmacy is defined as the prescription of multiple medications using various thresholds (generally ranging from five up to nine simultaneous drugs) and has been identified as a major challenge in the geriatric population for decades. About 40% of the U.S. population age 65 and older take five to nine medications, and close to 20% take 10 or more. Polypharmacy is an increasingly complex challenge because of the rising prevalence of multimorbidity, a plethora of clinical practice guidelines, proliferation of medications that can effectively treat common geriatric conditions, and rising patient and family demand for medications due in part to television advertising and information available on the Internet. For example, based on several condition-specific clinical practice guidelines (which do not account for multimorbidity), an 80-year-old person with multimorbidity including diabetes, chronic obstructive lung disease, hypertension, osteoporosis, and degenerative joint disease might be prescribed an extremely complicated nonpharmacologic regimen and over a dozen medications with the potential for multiple drug-drug and drug-disease interactions.

Polypharmacy increases the risks associated with age-related changes in the pharmacology of many drugs and the risk of adverse drug events. Such events cause >100,000 hospitalizations per year; the main culprits are warfarin and other antiplatelet agents and insulin and other hypoglycemic agents. Other categories of drugs are also involved, including cardiovascular drugs that can cause electrolyte and volume disturbances and hypotension, falls, and syncope; central nervous system drugs associated with altered mental status and falls; and antimicrobials, which cause allergic reactions, diarrhea, and other adverse drug effects.

Evaluation All older patients should have careful medication reconciliation at each office or clinic visit and especially at the time of care transitions, including acute hospitalization, hospital discharge, admission to a PAC facility or home health program, and discharge from a PAC facility to home. At each transition, all medications should be considered in terms of unclear diagnosis or indication, uncertain dose or route of administration, stop date, hold parameters, lab tests needed for monitoring, dosages different than the last care setting, medication duplication, medications that should be restarted, and the potential for drug-drug and drug-disease interactions. At each clinic or office visit for community-dwelling older people, possible adverse drug effects, effectiveness of drug therapy, and adherence should be evaluated.

Management Table 477-8 lists several general recommendations for geriatric prescribing that should help make drug therapy more effective and safer in older patients, especially those with multimorbidity. **Chapter 67 also provides information on general principles of clinical pharmacology.** Because these patients often see multiple specialists, the internist should serve as the "quarterback" for all prescribing to help ensure adherence and minimize the potential for adverse drug effects. In hospital, PAC, and LTC settings, clinical pharmacists can be extremely helpful in achieving these recommendations and goals.

While undertreatment of certain conditions may occur in older people (such as osteoporosis, depression, and overactive bladder), more attention is now being paid to "deprescribing." Deprescribing must be done carefully, especially at the time of care transitions, when indications for specific drugs and patient preferences may not be clear. The AGS's updated Beers criteria includes a comprehensive list of drugs that may be inappropriate in older people and the rationale for this rating. The Screening Tool of Older Persons' Prescriptions (STOPP) criteria are also useful in identifying drugs that should be reconsidered on older people.

Several commonly prescribed drugs should be considered for deprescribing efforts, including (1) diuretics and hypotensive agents when patients have systolic hypotension or postural hypotension that can precipitate near-syncope and falls; (2) overreliance on antianxiety and hypnotic medications, especially benzodiazepines; (3) psychotropic and other drugs with anticholinergic activity that can cause dry mouth and constipation and increase the long-term risk of cognitive impairment; (4) PPIs with unclear indications because of numerous reported potential adverse drug effects, including increased risk of

TABLE 477-8 General Recommendations for Geriatric Prescribing

1. Evaluate geriatric patients thoroughly to identify all conditions that could (a) benefit from drug treatment; (b) be adversely affected by drug treatment; and (c) influence the efficacy of drug treatment.
2. Manage medical conditions without drugs as often as possible.
3. Know the pharmacology of the drug(s) being prescribed.
4. Consider how the clinical status (e.g., renal function, hydration) of each patient could influence the pharmacology of the drug(s).
5. Avoid potentially serious adverse drug-drug interactions.
6. For drugs or their active metabolites eliminated predominantly by the kidney, use a formula to approximate age-related changes in renal function and adjust dosages accordingly; the Cockcroft-Gault formula (below) is probably safer as it tends to underestimate creatinine clearance.

$$\text{Creatinine clearance} = \frac{(140 - \text{age}) \times \text{body weight (kg)}}{72 \times \text{serum creatinine level}} (\times 0.85 \text{ for women})$$

7. If there is a question about drug dosage, start with smaller doses and increase gradually until the drug is effective or intolerable side effects are observed.
8. Drug blood concentrations can be helpful in monitoring several potentially toxic drugs used in the geriatric population.
9. Help to ensure adherence by:
   a. Making drug regimens and instructions as simple as possible
   b. Using the same dosage schedule for all drugs whenever feasible (e.g., once or twice per day)
   c. Timing the doses in conjunction with a daily routine
   d. Paying attention to impaired cognitive function, diminished hearing, and poor vision when instructing patients and labeling prescriptions
   e. Instructing relatives and caregivers on the drug regimen
   f. Enlisting other health professionals (e.g., home health aides, pharmacists) to help ensure compliance
   g. Making sure the older patient can get to a pharmacist (or vice versa), can afford the prescriptions, and can open the container
   h. Using aids (e.g., special pillboxes and drug calendars) whenever appropriate
   i. Performing careful medication adjudication and patient/family education at the time of every hospital discharge
   j. Keeping updated medication records and review them at each visit
   k. Reviewing knowledge of and adherence with drug regimens regularly
10. Monitor older patients frequently for adherence, drug effectiveness, and adverse effects, and adjust drug therapy accordingly.

pneumonia, osteoporosis, and dementia; (5) cholinesterase inhibitors and memantine in patients with severe cognitive impairment who have been on them for years; (6) hypoglycemic agents in patients with multimorbidity who should not have tightly controlled blood sugar with increased risk of hypoglycemia; and (7) statins and prophylactic aspirin in patients with severe chronic illness who are near the end of life.

Careful deprescribing is a critical aspect of person-centered care in the geriatric population. Several general principles, including some in Table 477-8, may assist with deprescribing efforts, including the following: (1) ascertain all drugs the patient is currently taking and the reasons for each one; (2) consider overall risk of drug-induced harm in individual patients in determining the required intensity of deprescribing intervention; (3) assess each drug as to its current or future benefit potential compared with current or future harm or burden potential; (4) prioritize drugs for discontinuation that have the lowest benefit-harm ratio and lowest likelihood of adverse withdrawal reactions or disease rebound syndromes; and (5) implement a discontinuation regimen based on the pharmacology of the drug being discontinued and monitor patients closely for improvement in outcomes or onset of adverse effects.

COGNITIVE IMPAIRMENT: DELIRIUM AND DEMENTIA

The reader is referred to other chapters in this text (Chaps. 431–434) on cognitive impairment. Because these conditions are so prevalent in the older population, selected aspects highly relevant to geriatrics are briefly discussed here.

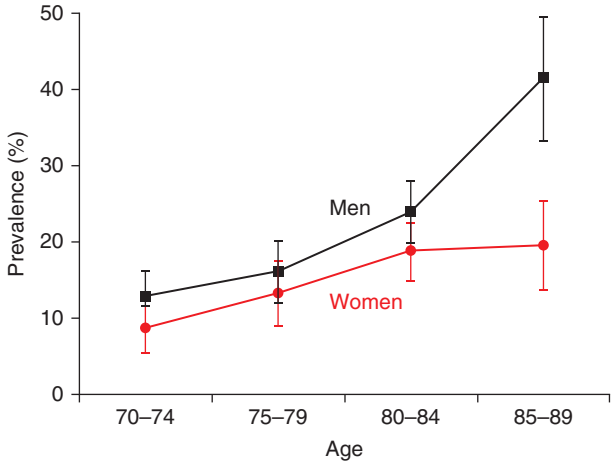

FIGURE 477-7 Prevalence of mild cognitive impairment by age and sex in Olmstead County, MN. *(Reproduced with permission from RC Petersen et al: Prevalence of mild cognitive impairment is higher in men. The Mayo Clinic Study of Aging. Neurology 75:889, 2010.)*

Epidemiology and Impact Delirium occurs in up to 40% of hospitalized older patients and is associated with increased morbidity, length of hospital stays, need for institutional care, health care utilization, and mortality in this population. While most episodes of delirium clear within a few days if the underlying cause(s) is identified and treated, delirium may persist for weeks or, in a few cases, for months after an acute hospitalization.

Normal aging does not cause impairment of cognitive function of sufficient severity to render an individual dysfunctional, which is the hallmark of a dementia syndrome. Slowed thinking and reaction time, mild recent memory loss, and impaired executive function can occur with increasing age and may or may not progress to dementia. Figure 477-7 illustrates the prevalence of memory impairment with increasing age. Just over 20% of people over age 70 in the United States have cognitive impairment without dementia, generally referred to as mild cognitive impairment (MCI). Up to 15–20% of those diagnosed with MCI will progress to dementia over the course of a year; thus, most people with MCI will progress to dementia within 5 years. Therapeutic implications of MCI are subjects of intensive research. No nonpharmacologic or pharmacologic intervention has been shown to prevent progression to dementia.
